TRANSACTIONS

OF THE

AMERICAN INSTITUTE

OF

ELECTRICAL ENGINEERS

JANUARY TO DECEMBER 1925.

VOL. XLIV

PUBLISHED BY THE
AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS
33 WEST THIRTY-NINTH STREET
NEW YORK, N. Y., U. S. A.
1925

Press of McIlroy & Smith, Inc., 22 Thames Street, New York

Preface

The publication of this book marks the completion of the forty-fourth volume of the TRANSACTIONS of the American Institute of Electrical Engineers. There are contained herein papers and discussions presented at six Institute conventions and regional meetings, and printed in the JOURNAL during the year 1925. For several years it has been found impossible to include in the TRANSACTIONS all of the large amount of material presented annually before the Institute. This year a departure from custom has been made in that the papers which were reproduced in the JOURNAL but not in the TRANSACTIONS have been indexed with the TRANSACTIONS contents rather than on a separate page. The improved system of indexing which was introduced last year has been continued in this volume; the subjects are classified under general headings chosen with regard to the information contained in the papers and in many instances the subjects are also cross-referenced. The report of the Board of Directors for the fiscal year ending April 30, 1925 and lists of the officers and committeemen for the current year are also included.

Power-Factor Correction

By L. W. W. MORROW*
Member A.I.E.E.

Synopsis.—Power-factor correction has become a commercial problem of major importance, and technical knowledge and corrective equipment are available to make correction a part of the activities of the electrical industry. Field studies on several properties show power-factor correction can be obtained without difficulty.

Conditions can be improved by requiring all new business to be installed for high power-factor operation and a cooperative movement should be made to bring about this condition. The situation on existing systems can be improved in either a wholesale or retail manner depending upon conditions.

Cost analyses should be made to determine the type of correction to use and to decide upon the location of corrective equipment. But they should not be used for rate making purposes. A study of the types of systems in existence shows that in general correction is most economically and most effectively instituted at the loads. Also experience indicates the greatest effect of correction is to improve voltage regulation and service quality.

Different types of rates and billing methods have been used, but a study of the art shows the kv-a. demand charge and the kw. energy charge can be used most successfully to secure power-factor correction.

THE effects of low power factor on the operations of the electrical industry have been discussed for many years and much experience in the institution of corrective measures has been had. Yet on an industry-wide scale the evils associated with low-power-factor conditions become greater each year, even though the incentives for the institution of corrective measures increase. Low power factor has come to be recognized as the major handicap to better and more efficient electric service, and men of the industry are striving actively for a commercial and engineering method for its correction.

An analysis of the data and experiences of those properties which have instituted power-factor correction leads to the conclusion that operation under high-power-factor conditions improves both the quality and the efficiency of the service rendered by the utilities and used by their customers. Correction of power factor has its greatest influence in improving the voltage regulation and through this action enables the utility to give better service and the customers to secure better use of the service. Secondary gains resulting from power-factor correction consist of the release of system capacity with a consequent reduction in investment and a reduction in system losses with a resultant reduction in operating charges. Thus correction tunes the system and makes it cheaper and easier to give service of the quality desired in modern industry.

Actual experience shows that power-factor correction can be instituted successfully as a part of the business activities of light and power companies and as a part of the normal operating activities of industrial users of electricity. It does not require an elaborate or costly departure from customary business activities, and it secures returns to the producer and the user whose value is tangible and worth while. Yet little actual progress in power-factor correction can be seen because of many obstacles, mostly imaginary, set up in the minds of executives, engineers and customers. Some of these are: the inertia encountered when proposing any changes in a going business which is prosperous and follows time-tried methods; difficulties met in attempting to evaluate the costs of either low or high power-factor operation; fears introduced by the necessity for instituting new or changed rates and billing methods; difficulties encountered in attempts to make people understand the meaning of power factor; obstacles encountered in attempts to devise a correction scheme for universal application, and technical difficulties met in connection with the selection and location of corrective equipment. The literature of the industry is filled with objections to power-factor corrective measures and with elaborate technical and cost analysis, and very few data or opinions of a constructive character have been obtained to show that most of the obstacles to correction result from misconceptions and lack of actual experience with it in commercial practise.

The fact is that many properties have instituted correction successfully and made it a profitable part of their business. They have done this without any difficulty and did not find any great complexity or major changes introduced in their operating routine. Thus the time is ripe and the methods are available for eliminating low-power-factor conditions in the electrical industry. The rewards are ample, and the necessity for this move becomes greater with the growth of electrical systems.

Correction is a business problem and not a technical problem. The technical features of power-factor discussions begin nowhere and end at the same place, and they have little if anything to do with the business-like application of corrective measures. No one can define electricity or power factor, yet definite laws enable engineers to use resistance, inductance and capacity in circuits or in machines to secure any desired power factor at any definite place. Also, engineers understand fully the influence of lagging and leading current on system regulation and machine

Presented at Regional Meeting of District No. 2. Washington, D. C., January 23-24, 1925.

stability. Technical mastery of power factor prevails, and what is needed is commercial mastery.

In order to obtain commercial mastery two suggestions are offered which will apply to every electrical system:

1. Require high-power-factor operation of all new business served.

2. Correct low-power-factor conditions on existing systems either: (a) promptly and in a wholesale manner, or (b) slowly and by steps.

Make New Business Good Business

Any consideration of the first suggestion, in the light of the growth of the electrical industry and the increasing importance of service quality, shows its logic, and there remains then the use of definite methods to secure the desired results.

A light and power company is a public utility and cannot enforce any rule requiring customers to install high-power-factor equipment before it will give service, so this direct and self-evident method must be replaced by methods which are cooperative and educational in character. The job requires the cooperation of utility men, electrical manufacturers and customers and must be done for each new business prospect on each property, and in addition work must be done on a national basis. It is not a difficult task, for both means and methods are available for doing the work quickly and efficiently.

The cooperative element in the work calls for:

1. Closer contact between central-station power salesmen and prospective customers whereby guidance and expert knowledge are made available to customers.

2. Closer contact between central-station executives and electrical manufacturers so the manufacturers may be encouraged to build high-power-factor equipment and to sell this equipment on a quality rather than a price basis and with greater consideration for the engineering requirements of the purchaser.

These two cooperative suggestions are already in operation in large degree, but conscious executive attention should be given to their application in order to secure complete commercial results rapidly. The job requires that each new customer install available electrical equipment from the standpoint of his own economic production requirements. Both power factor and quality apparatus will inevitably follow every real economic analysis of an industrial electrical application, and central-station men and manufacturers' representatives must give up the slogan that any new business is good business and do more to help their customers secure quality service and cooperate more closely to sell quality equipment. It would seem easy to organize a local cooperative committee for each utility to secure the desired results. This would be composed of power salesmen, electrical manufacturers' representatives, electrical contractors, and perhaps consulting engineers, and might well be part of the activities of the local electrical leagues already instituted in so many cities. National agencies are already available in the N. E. L. A., Power Club and other associations, but their attention must be given to this problem.

There is no handicap to the manufacture and sale of electrical equipment and service on a quality rather than a price basis in an industry whose product is popular, is necessary to industry and is the cheapest and best element ever introduced into industrial processes. When the cost of power is such a small fraction of the cost of manufacture of most industrial products, it is false economy to talk first cost of service or of equipment to purchasers.

Thus very little organized effort should institute as industry-wide practise the custom of obtaining only high-power-factor business in each new load added to existing systems. The principle to apply is that service to customers should be given before they install equipment and ask for electrical energy from a utility.

The Correction of Existing Conditions

The second suggestion for power-factor correction is that existing conditions be bettered either by making corrections quickly on a wholesale basis or by improving conditions slowly and in steps. In many respects the slow and detailed method is best for those systems inexperienced in correction, but past experiences show that it is not difficult to do the whole job quickly on the entire system provided proper analyses are made and workable methods are adopted before correction is actually instituted. Whatever decision is made has little influence upon the methods used or the results obtained and predominantly influences only the time required to secure improvements in conditions. The situation on each system will determine the best procedure to use, for operating and financial requirements must be met by individual properties.

Three things only are needed to institute correction on an existing system:

1. Decisions as to the location of corrective equipment.

2. Decisions as to the corrective equipment to be used.

3. The establishment of a rate system which takes power factor directly or indirectly into account.

The first two requirements largely involve engineering and economic data and decisions to be secured within a utility organization, but the third requirement must take into consideration the utility, the customers and the regulatory commissions and involves public relations, economics and education.

Locations for Corrective Equipment

A study to determine the locations in which to install corrective equipment on existing systems

shows that the decision is somewhat influenced by the type of system and by local conditions. Usually corrective equipment should be located at all low-power-factor loads, in some cases at substations at a distance from generating stations, particularly if voltage regulation is desirable, and in very few instances in generating stations. The source of low power factor is at the load, and analyses will show that corrective equipment is best and most economically used in this location.

Some of the types of systems encountered in this country and some of the elements faced in locating corrective equipment are enumerated below:

1. A hydroelectric system containing long high-voltage transmission lines with one or more distribution systems located at the ends of the lines.
2. A combination system having both steam and hydro stations, many high-tension lines and widely distributed load centers.
3. A hydroelectric system with standby steam stations containing capacity idle a great part of the time and made up of networks of high-tension lines supplying a scattered territory.
4. A metropolitan system containing several large steam stations and made up of both overhead and underground transmission circuits.
5. A system already operating and designed for a power factor of 80 to 85 per cent.
6. A system designed to operate at a power factor of 90 to 95 per cent.
7. Systems which are growing rapidly in magnitude of load and extent of territory covered and those which have reserve capacity through interconnections.

It is seen that each system is a specific study for power-factor correction at other places than at the load sources of low power factor, and the choice of location of corrective equipment at other locations must be made after economic and operating studies. The making of cost evaluations for a particular system should be decided upon only after careful study, for they are difficult and are useful only in serving as guides for the location of corrective equipment. They serve no purpose in rate making as cost-of-service rates are now obsolete in the utility industry. However, if cost analysis are desired in some cases, the usual approach to determining fixed and operating charges is to evaluate the cost of capacity and of losses in generating stations, transmission lines, substations, transformers and distribution systems.

Generating Station Correction

The evaluation of the reduction of the reactive-kv-a. load on a generating station due to power-factor correction is difficult because so many conditions must be considered. There is much more to the problem than raising a station power factor from 70 per cent to 90 per cent in order to make available approximately 20 per cent increase in station capacity

In hydroelectric plants it is usually desirable to have reactive kv-a. available for line regulation, and in addition it is usual to find an excess of capacity installed in order to meet stream-flow conditions. Therefore, generally, no value can be placed on power-factor correction for such stations. Also, in large systems using steam and hydro stations in combination with interconnected high-tension lines, lagging current is often an operating asset, and in this case also correction is seldom or ever desirable for generating stations.

In the large steam stations feeding a power system concentrated in a comparatively small area power-factor correction may improve regulation and operation, but here again the savings in station costs are sometimes very small and must be evaluated for the conditions encountered. These plants are usually designed for 85 to 90 per cent power-factor operation at the stations, and a little study will show that cost decreases are difficult to secure. Offhand it may be said that every kv-a. of station capacity means the release of fixed charges on at least $6.00 of investment and every reduction of a per cent in losses from the normal 2 per cent of output kw-hr. can be credited in dollars and cents of operating charge. But there are some other factors that must be considered before these sums mean anything or will stand the examination of a court or commission; for example, in connection with stations in modern systems:

(a) Most systems increase their installed station capacity in units of large size and seldom permit their peak to approach a value equal to installed capacity. For example, station additions are made in units of 30,000 kw. up to 200,000 kw. and ample reserve is held at all times.

(b) Every metropolitan system often introduces large losses into its normal operations in order to insure reliability of service; for example:

(1) A station having several large units is likely to continue all of them in operation even at very light load in order to reduce the starting hazard and the time element involved in warming up a large unit and synchronizing it with the system.

(2) In order to control voltage and load division, it is common practise on systems having multiple stations to operate generating units with large lagging or leading currents.

(c) It is a difficult, if not impossible, task to determine actual station power-factor conditions during a twenty-four-hour period for the different stations in a large metropolitan network. Any method of determining power factor and of determining the value of losses is subject to criticism as to its technical accuracy, and the values obtained cannot be divided easily between power factor, load division and regulation requirements. In fact, for a given load power factor as defined and as measured by different methods will vary 10 to 30 per cent in value.

The actual capacity cost of the reactive load on a generating station not loaded to capacity is usually very little even though the cost of the increased capacity of alternators, exciters, switch gear, busses and building is determined. Seldom would this cost exceed $6.00 per reactive kv-a., and any added operating expense due to low power factor is very debatable. For some specific installations, however, where the peak load is equal to the station capacity or where the load power factor is lower than that for which the station equipment was designed, it may be well to institute power-factor correction as a temporary economical expedient for securing capacity to carry the load. Load factors, future system growth and other elements, however, must be considered.

In most other cases, however, it is cheaper and easier to buy, install and operate alternators, busses and exciters with a higher rating than it is to buy, install and operate corrective equipment and its control. For example, the increment cost of a 35,000-kv-a. alternator over a 30,000-kv-a. unit as compared to the cost of a 5000-kv-a. synchronous condenser and its control equipment is in favor of the alternator. In most stations generating capacity can usually be obtained more cheaply than by the use of corrective equipment.

Very few operating costs are affected by low power factor because the copper losses inside a station amount to an inappreciable sum. At light load the usually lowest power-factor condition increases the losses in proportion to the kw. output. This indicates the advisability of fixing a power-factor charge that varies with output. This charge should be greatest at minimum-load conditions in some cases and at peak-load conditions in other cases. A very small increment in energy charges seems the only businesslike way to cover these station losses due to low power factor as at a maximum they comprise only 2 or 3 per cent of the system losses.

The practical possibility and the dollar value of regulation by power-factor correction inside large steam stations is very dubious. The unit type of installation with the unit bus and a group of feeders for each unit has become popular, and it is difficult to conceive of this type of station operating with all busses in parallel at one voltage or to devise a switching and bus arrangement for throwing the synchronous condenser on any feeder requiring regulation. In addition, the cost of the corrective equipment used for regulation exceeds that of voltage regulators, which have the added advantages of being automatic in their operation and of having a greater voltage range.

In the general case, therefore, seldom will it be found economical to institute power-factor correction in generating stations.

Substation Correction

The installation of corrective equipment at substations reduces the kv-a. load on transmission lines and transformers between the substations and the generating stations and improves the voltage regulation. This would seem desirable in all cases, but a little study shows it is often very uneconomical and usually not the best way to secure complete correction.

In modern systems reliability of service, provision for future growth and maintenance practises dictate the use of multiple feeders to substations and multiple transformer installations. Also, modern practise tends to the use of standardized ratings for lines and transformers on the transmission system. These requirements call for the installation of a greater number and a excess of line and transformer capacity, which makes it very difficult to show the economic value of substation corrective equipment.

Moreover, it must be borne in mind that future load requirements, structural needs and legal limitations have a direct bearing on both overhead and underground line installations. The overhead line must have a certain size of pole, a conductor sufficiently large to be strong mechanically, a large number of poles per mile and very often a legal voltage limitation. These elements often must be weighed carefully when discussing the release of line capacity by the use of substation corrective equipment. In underground cable installations it has become customary to install reserve ducts and cables and to standardize greatly, so the number and the capacity of installed cables at a given time is very often determined by other things than the magnitude of the kv-a. loads. It must be considered, however, that the overload capacity of an overhead line is very great as compared with that of cables and transformers.

Thus any cable or transformer that has reached its limit in capacity while operating at a low power factor is capable of carrying an increased load and consequently earning more revenue if correction is applied at substations. The cost of the corrective equipment may be less than the installation of another line and more transformers, and regulation is improved, so that more load may be carried on a given circuit. In other words, correction will, for the same line loss, increase either the economic distance of transmission or the amount of load possible to transmit. In such cases the substation correction may be economical, but it is an expense which must be paid for in fixed charges, while a new line provides a revenue-producing and useful element for the present and future system. A system using a ring high-tension network and having multiple generating stations and several large substations on the ring may use corrective equipment in distant substations to advantage to reduce losses, release capacity and control regulation, but the economic value of this practise must be ascertained for each particular case.

Thus in very few cases will the release of system capacity justify substation correction; therefore, either decreased losses or improved regulation must be evalu-

ated to make a case. The reduction in line and transformer losses by the use of corrective equipment increases the load at which the investment cost per kv-a. transmitted is a minimum and reduces the direct operating cost of energy losses. On an average system the line energy losses will be around 10 per cent of the total output while the transformer losses should not exceed 5 per cent. These losses therefore represent a direct money loss, which, if reduced, results in an appreciable saving. Assuming that correction decreases these losses even 20 per cent, it often becomes profitable to install corrective equipment.

For example: Assume an energy cost of 1 cent per kw-hr. and a system output of 100,000,000 kw-hr. with total losses of 15 per cent in lines and transformers. If it is assumed correction will reduce the losses 20 per cent, the yearly value of correction is: $100,000,000 \times 0.15 \times 0.20 \times 0.01 = \$30,000$, or a return of 15 per cent on an investment of $200,000.

Losses in corrective equipment must be considered in a financial analysis of this character and their cost determined. If synchronous condensers should be used, this value would be changed, since the condenser has losses which must be charged against the saving produced in lines and transformers. If static condensers are used, the value of the losses in the corrective equipment is very small. In either case, particularly if the voltage at the substation is high, the losses in the transformer bank supplying the corrective equipment should be evaluated and charged against the cost of correction.

The general conclusion is that substation correction, considering the value of losses, capacity and regulation, is usually warranted for those substations located at a distance from generating stations, at least as a temporary move, until full consumer correction has been established.

Consumer Correction

The analysis for determining the proper location of corrective equipment leads inevitably to the conclusion that most of it should be placed on the premises of consumers and that consumers using high-power-factor equipment are operating most economically from their own standpoint and from that of the central station. From the angle of the central-station consumer correction relieves the system of the necessity for correction at other locations, releases the transformer and cable capacity where it is most valuable from income and load-factor standpoints, reduces losses where they are greatest and improves regulation where it is most desirable to have good regulation.

From the angle of the consumer correction of his equipment or the replacement of low-power-factor equipment with high-power-factor equipment will secure several tangible and intangible results. It will reduce the losses inside his premises, for which he pays a high rate; it will improve his voltage regulation and reduce his voltage drop, so that his machinery will operate faster and more smoothly; it will give him better-quality production, better lighting, fewer rejections of manufactured product, faster machine-starting conditions and secure for him a direct decrease in his power bill if he buys under a proper rate system.

Experience shows that operating complexity is not increased and that the industrial plant corrected for bad power-factor conditions reaps very decided tangible and intangible benefits. Needless to say, it is useless to attempt an itemized cost evaluation for correction at load locations, because the complexity of modern distribution systems, the variety of loads and services and the many assumptions necessarily made all combine to give inaccurate results. In a broad way, however, based on the actual cost of the distribution system, the cost of voltage regulation and the cost of losses, an analysis in dollars will show very decided inducements for investing power-factor correction at the source.

Kinds of Corrective Equipment

The corrective equipment to install at locations decided upon is determined largely by each local situation, but there are applications for all available types at low-power-factor loads, *i. e.:*

(a) The synchronous motor

(b) The synchronous condenser

(c) The high-power-factor commutating motor of the Fynn-Weichsel type

(d) The static condenser

Investment charges on existing installations, production requirements, fixed and operating charges on corrective equipment and the skill required to operate the equipment influence the decision to be made for each load considered.

For substation correction the same types of corrective equipment are available, but the synchronous condenser and group static condensers predominate. The decision as to which type to use at substations is influenced by cost analyses and by load and voltage regulation requirements.

Experiences on properties give evidence that the choice of equipment for correction is quite readily made for a particular location. Each system should be studied as a whole and each power customer considered if good results are desired. The utility engineers can readily determine the substation correction to use, but greater difficulty is encountered in the correction of power customers. The installation of each customer must be studied in detail if a real engineering job is to be done, and this requires time, skilled engineering and an expenditure of money. Production processes, motorization, wiring and testing are elements in the study, and a great deal of education and cooperation must be had. For these reasons a slow process of customer correction is usually advisable. Utility power salesmen, consulting engineers, factory engineers and electrical manufacturers' salesmen and engineers should cooperate in these customer studies. In actual practise no great difficulty or high costs have

been encountered in attempts to institute customer corrections, because the great majority of them can be made adequately by an over-all factory test or by competent engineering inspection. Very frequently zone studies or piecemeal areas are corrected with very little trouble.

POWER-FACTOR RATES

Electric service is a business and as such must institute power-factor correction as a part of business activity. Thus, a rate of some form must be used to secure power-factor correction, and it also follows that metering and billing accompany the institution of a rate. Experience with energy and power-factor rates over many years shows that commercial rates cannot be made upon the basis of cost of service. Experience also shows that financial inducements are the best stimuli to industrial accomplishments. Rates, billing systems and metering methods are largely matters of tradition and commercial application, but should be simple, understandable and easy to use in business.

When alternating current was first used the wonderful Thomson-Houston meter was invented and installed. This meter measured watt-hours and eliminated the necessity of measuring ampere-hours and multiplying by the normal voltage of the service as had hitherto been practised. It was an ideal instrument for measuring lighting loads, and no thought was taken on its ultimate effects on the utility business. Rates were made on a watt-hour basis and the cheap, accurate watt-hour meter became the standard measuring device for electric service. Then came the induction motor and it was early noticed that the product of current and voltage did not equal the registration of the meter. Thus power factor was discovered, and until recently the utilities decided that it was better to suffer its effects than to attempt to improve conditions or to charge for service by methods involving the use of other units than watt-hours. Power factor was difficult to define accurately, difficult to measure and still more difficult to explain to customers and executives.

However, there is a tendency today actually to measure power factor or to meter customers by methods which will take power factor into account. The first trend is indicated by the development of kv-a. meters, the use of reactive and active watt-hour meters and the use of power-factor meters. Any of these meters or metering methods are subject to objections from an economic, a technical and an operating standpoint. The cost, the complexity of the billing and the difficulty of obtaining and maintaining reliable and accurate measurements by any of these means have so far prohibited their use except for large power customers having a technical staff or sufficient consumption to warrant the cost and the trouble. Nothing very promising is on the horizon in the way of directly measuring either kv-a. or power factor on a universal commercial basis.

One metering authority has recently suggested that it would be advisable to meter customers on the old ampere-hour basis since all service is at practically constant voltage and the ampere-hour meter, besides being cheap and accurate, is a true and readily understood measure of both energy and capacity use. Multiplying ampere-hours by the voltage of the supply would permit of billing on a kv-a.-hour basis very readily. Thus a system could be developed which would use an ampere demand meter and an ampere-hour meter only for direct measurement on any three-phase or single-phase circuit. It is argued that this method is sufficiently accurate, is easy to institute, is logical and that its results compare well in accuracy with those from any existing method of measurement.

The ultimate approach to power-factor correction for customers is by means of rate making. This has generally taken the form of:

(a) The use of power-factor clauses
(b) The use of kv-a. demand clauses
(c) The use of kv-a.-hour clauses
(d) A combination of two of the foregoing

All these methods have been used and all have worked more or less successfully, but all are subject to very definite criticisms. Years of effort proved the impossibility of developing utility rate on a cost-of-service basis, and, however reluctantly, rate makers have admitted its impossibility and impracticability for modern conditions of utility service. No cost-of-service basis can be found, therefore, for the making of any type of power-factor rate, and each property must evolve a rate which can be instituted and operated to suit conditions encountered. A fundamental in power-factor rate making would be to secure a simple rate, one that could be applied to all customers, one that needed little maintenance or supervision and one that offered a financial inducement to customers to maintain and correct power-factor conditions.

Viewing the art in its technical and commercial aspects and basing opinions on practical experiences, the best form of power rate today should use a kv-a. demand charge to cover capacity costs and an energy charge to cover production costs. Power factor, as such, should not appear in the costomer rates, but should be accounted for in the kv-a. demand charge. This rate can be used to secure power-factor correction on any system very satisfactorily and does not necessarily involve the use of a kv-a. demand meter. Power customers can be tested under normal operating conditions, and the power contract can then be written for a period of time with a kw-hr. meter and a kw. demand meter to serve as checks and for energy billing. In other cases the installation of a power-factor meter normally out of circuit, in combination with ordinary watt-hour meters can be used to check customer conditions and to meet billing requirements.

However, every type of power-factor rate has been used and used successfully, so the necessity of a rate to secure power-factor correction is not a real obstacle to the institution of correction. It must be remembered that grand average results only are to be expected and that precision methods and analyses must be modified by commercial considerations.

A New Alternating-Current General-Purpose Motor

BY H. WEICHSEL[1]
Fellow, A. I. E. E.

FROM the first days of the successful commercial introduction of the a-c. system of distribution down to a comparatively recent date, all forms of general purpose a-c. motors have in one way or another been subject to serious objection from the standpoint of approaching the engineer's ideal of satisfactory design and performance.

Speaking in general terms, the types of a-c. motors available for general purpose use have been as follows:

1. The well-known squirrel-cage motor.
2. The induction motor with wound secondary.
3. The conventional form of synchronous motor.

The squirrel-cage motor, while very simple in construction, has relatively poor starting performance, and its design characteristics are frequently subordinated to the starting-load requirements rather than to best performance under normal running conditions.

The wound-secondary-induction motor is free from the defect of inadequate starting torque, but shares with the squirrel-cage motor the very serious defect of drawing from the line, under all operating conditions, a very heavy magnetizing current. This, as is well known, results in the operation of both forms of motor with a lagging power factor. When built for high or moderate speeds, the power factor at full load is reasonably satisfactory, but decreases rapidly with decreasing load. For slow-speed motors of both types, the power factor, even at full load, is very unsatisfactory, and is correspondingly lower at fractional loads.

The power factor of the circuit supplying energy to an installation of induction motors is usually considerably below unity due to the following:

The installation contains a number of slow-speed motors. Occasionally no high-speed motors are used at all. The majority of motors installed operate below full load and consequently with poor power factor. This is particularly true in cases where squirrel-cage motors are used. The size of these motors as mentioned above, is frequently larger than really required for the actual running load for the sole purpose of obtaining satisfactory starting conditions. Consequently these motors operate at low power factor, because they are only partly loaded.

The serious operating difficulties and the excess investment and operating costs resulting from poor power factor are fully understood and will not be discussed in this paper.

While the pronounced pole-synchronous motors are free of the shortcoming of poor power factor, they have unfortunately a number of other deficiencies which have prevented them from being used as general purpose motors. The main objections to this type of motor for general purpose are:

1. The starting performance is poor.
2. A separate d-c. excitation is required, which must be obtained from either a separate exciter or from an independent d-c. supply.
3. The machines are not well suited to loads which fluctuate very materially and often exceed considerably the normal rating of the machine.

The electrical industry has long appreciated the importance of the development of a new form of motor which would preserve the satisfactory features of the well-known conventional types, and, at the same time, be free from their very obvious disadvantages. In recent years the demand for such a new motor has been growing much more insistent, and the time is now at hand when the central-station section of the industry is urgently demanding such a motor.

The company with which the author is identified has, after many years of research work, developed a new type of motor which approaches to a remarkable degree, an ideal design, preserving the good characteristics of both the induction and the synchronous motor, yet free from their most serious shortcomings. This new machine, which is known under the name of the Fynn-Weichsel motor, is the subject of this paper.

The outstanding characteristics of this new motor may be stated as follows:

1. It operates over the whole normal working range with leading or unity power factor.
2. When operated in parallel with induction motors, the leading power factor of this new motor counteracts the lagging power factor of the induction motors.

1. Chief Designing Engr., Wagner Electric Corp., St. Louis, Mo.

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 9-12, 1925.

3. The starting characteristics are as excellent as those of an induction motor with wound secondary.

4. It is able to operate at very heavy temporary overloads.

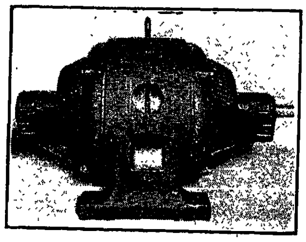

FIG. 1—100-H. P., EIGHT-POLE, 60-CYCLE, THREE-PHASE MOTOR

5. From no load to about 150 to 200 per cent load, the machine operates as a synchronous motor. When the load increases beyond these values, it operates as an induction motor, and if the load is again decreased

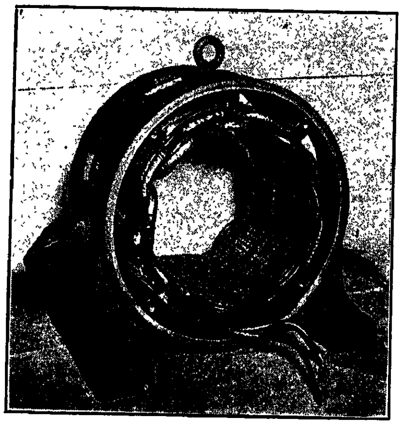

FIG. 2—STATOR OF 100-H. P., EIGHT-POLE, 60-CYCLE, THREE-PHASE MOTOR

to values in the neighborhood of 150 to 200 per cent of normal, it automatically returns to synchronous operation.

Fig. 1 presents a view of a 100 h. p., 900 rev. per min. machine of this new type.

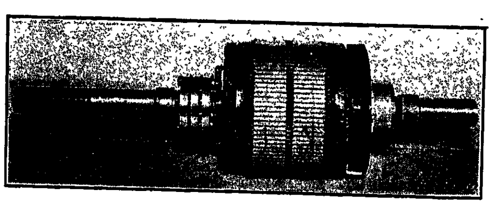

FIG. 3—ROTOR OF 100 H. P., EIGHT-POLE, 60-CYCLE, THREE-PHASE MOTOR

Fig. 2 exhibits a view of the stator.

Fig. 3 shows the rotor construction.

The rotor is provided with slip-rings and a relatively small commutator. The rotor laminations are provided with slots on the circumference and carry two windings. In the bottom of the slots, is located a small d-c winding which is connected to the commutator; and in the top of the same slots is a standard polyphrase winding which is connected to the slip-rings.

In the larger units the slip-rings and commutators are arranged on opposite ends of the armature; and in the smaller units, both of these members are located on the same side. In either case, the a-c. rotor winding is connected through the slip-rings to the a-c. supply line.

The stator is built of laminated iron with slots in the inner circumference which gives a general appearance similar to that of a standard induction motor, *i. e.*, no pronounced poles are used.

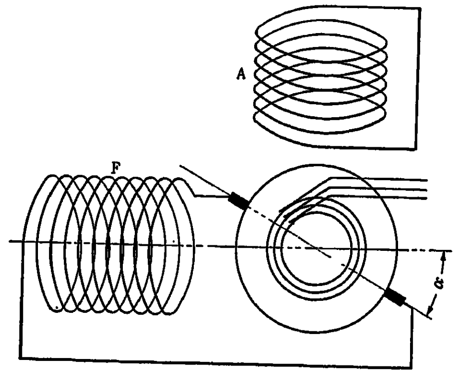

FIG. 4—RUNNING CONNECTION OF FYNN-WEICHSEL MOTORS

The stator carries two windings—the field winding, *F*, and the auxiliary winding, *A*, which are 90 electrical degrees displaced from each other. These windings are of the simplest kind possible. They are wound concentric, as is clearly depicted in Fig. 2.

The normal running connection between the individual windings is diagrammatically given in Fig. 4. It will be observed that the secondary winding *F*,

Starting Connections

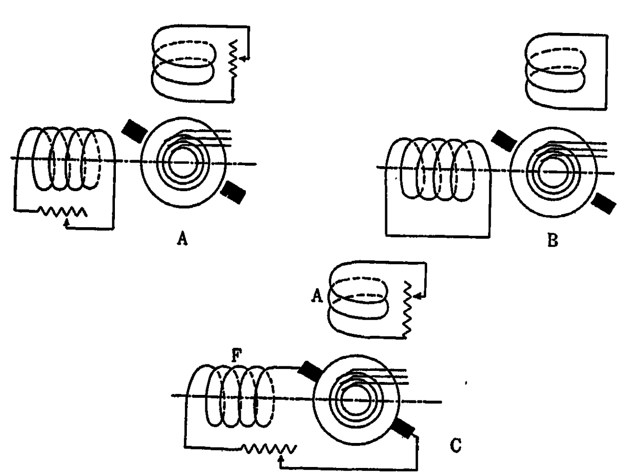

FIG. 5

located on the stator, is connected in series with the brushes riding on the commutator, and that the axis of the brushes forms an angle less than 90 deg. with the axis of the field-winding *F*. The secondary winding *A*, also located on the stator, is short-circuited. The slip-rings are connected to the line.

The machine is started by inserting ohmic resistance

in the circuits of the windings F and A. Fig. 5A illustrates a starting connection which in every respect gives the same starting performance as that inherent to a slip-ring induction motor. When this machine has reached the highest speed possible, and after all resistance in the secondary has been cut out, the windings are so reorganized as to agree with Fig. 4, which illustrates the running connection.

It is possible to start the machine in the running connection by introducing resistance in the A and F circuits and leaving the commuted winding in series with the F winding. This arrangement is extremely simple, and for this reason is used in all medium and small size machines. See Fig. 5C.

Generally speaking, this latter arrangement gives starting characteristics very similar to those of a slip-ring induction motor, but due to the commuted winding being in series with the F winding, the torque, for a given resistance in the secondary circuit, is favorably influenced.

This increase in torque grows rapidly with decreasing resistance in the rotor circuit. This is caused by the voltage, appearing across the commutator brushes, which is connected in series with the voltage induced in the winding F.

It will be proved later that the voltage appearing across the brushes has the same frequency as the voltage induced in the F winding. Therefore, by injecting this voltage in the F winding, we increase the total voltage acting on the F circuit and thereby increase the current in the circuit over the value which would exist at the same speed when the machine is operating as an induction motor. This increase in current naturally must be followed by an increase in torque, or what means the same, for a given useful torque the Fynn-Weichsel motor will operate at a higher speed than an induction motor when operating under otherwise equal conditions.

This is, roughly speaking, the explanation for the Fynn-Weichsel motor's ability to synchronize automatically.[2]

The synchronizing ability of this motor is excellent and, therefore, the machine can be used with advantage in cases where heavy mechanical torque or inertia loads have to be accelerated to synchronous speed.

The phenomena which take place during the starting and synchronizing periods will be discussed somewhat more in detail in the following:

With the armature at rest, a polyphrase voltage is impressed on the slip-rings and a rotating magnetic field is set up by the armature windings. The speed of this field, in respect to a given armature conductor, is given by the well-known formula:

$$n_0 = \frac{120 \times f_0}{p}$$

2. See paper presented before the Association of Iron and Steel Electrical Engineers, Feb. 16, 1924, "The Motor that Corrects Power-Factor." by H. Weichsel.

n_0 = speed of the field in rev. per min.
f_0 = frequency of supply circuit.
p = number of poles.

As the commuted and a-c windings are located in the same slots, the rotating field also cuts the commuted winding and consequently sets up a voltage in it. With the armature at rest, the voltage which appears across the commutator brushes has the same frequency as the line voltage. The phase of the voltage appearing across the brushes depends, however, on the relative location of the brush axis in respect to a fixed point in space.

Furthermore, the rotating field cuts the stator windings, F and A, and thereby produces a voltage in these windings which also has a frequency equal to that of the line so long as the motor is at rest.

If the axis of the commutator brushes coincides with that of the F winding, then the voltage induced in the F winding and the voltage appearing across the brushes not only have the same frequency but are also in phase. This can be seen from Fig. 6, where the com-

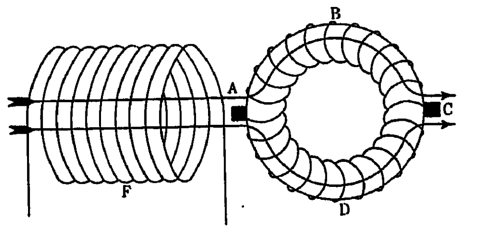

FIG. 6

muted winding is represented in form of a Gramme ring.

From this figure it will be seen that if a rotating field intersects the ring and the F winding the maximum lines are embraced by the winding A-B-C and A-D-C at the same moment when the maximum lines are embraced by the winding F, provided the brush axis coincides with F axis.

Therefore, the voltages appearing across the brushes and the induced voltage in the F winding must be in phase.

If the secondary windings F and A are closed over a resistance, a torque is set up, acting on the armature in the well-known manner. This torque, due to the fundamental induction laws, has such a direction as to rotate the armature in the direction opposite to that of the rotating field. Therefore, if the rotating field has the velocity of n_0 in respect to the armature conductors, and these latter operate with a speed n_x in direction opposite to n_0, due to the armature torque, then the rotating field has a velocity of $n_0 - n_x$ in respect to a fixed point, in space. Therefore, the speed with which the secondary windings F and A are cut by the magnetic field decreases with increasing armature speed, and the frequency of the voltage produced in the windings F and A is given by the equation:

$$f_2 = \frac{n_0 - n_x}{n_0} \times f_0$$

f_2 = frequency induced in windings A and F.
f_0 = line frequency.
n_0 = speed of rotating field in respect to armature, expressed in rev. per min.
n_x = speed of armature, expressed in rev. per min.

The voltage induced in the secondary is given by the equation:

$$E_0 \frac{n_0 - n_x}{n_0} = E_x$$

E_0 = voltage induced in the secondary when armature is at standstill.

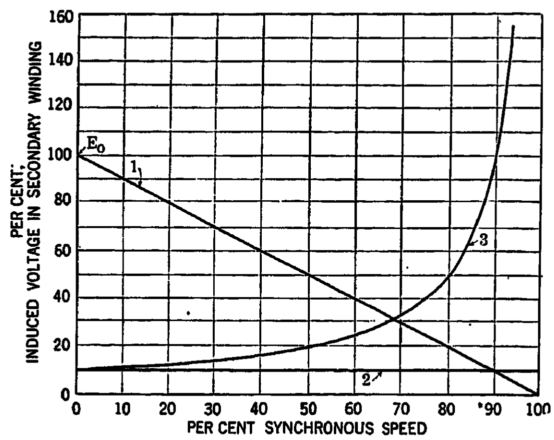

FIG. 7—OPEN CIRCUIT VOLTAGE IN SECONDARY WINDING AND ACROSS COMMUTATOR

E_0 = Induced Voltage in Field at Standstill
1 = Induced Voltage in Secondary E
2 = Volts Across Commutator in percentage of Induced Secondary Volts at Standstill
3 = Volts across Commutator in percentage of Induced Volts

E_x = voltage induced in the secondary when armature rotates with speed n_x.

This means that the voltage and frequency in the windings F and A decrease with increasing rotor speed and become zero when the armature rotates at synchronous speed. This is the same simple law which governs the voltages in the secondary of an induction motor.

However, the conditions are somewhat different if we consider the voltage appearing across the commutator brushes. The voltage appearing across the brushes has a frequency which is determined by the velocity of the rotating field in respect to the brushes, or what means the same thing, in respect to a fixed point in space. Therefore, the frequency across the brushes is, for any armature speed, equal to the frequency induced in the secondary windings, F and A.

On the other hand, the magnitude of the voltage appearing across the brushes, is determined by the velocity with which the rotating field cuts the conductors of the commuted winding. This velocity is, at any armature speed, equal to the synchronous speed of the field. Therefore, the voltage appearing across the brushes is independent of the armature speed.

These relations are graphically represented in Fig. 7. The induced voltage in the secondary falls from the value O-E_0 at standstill of the armature to the value of zero when armature operates at synchronous speed. The voltage across the commutator brushes remains fixed, as represented by the horizontal line marked No. 2. If the voltage of the F winding is connected in series with the voltage across the commutator brushes, the total voltage will differ by only a small amount from the induced voltage in F when the armature is at standstill. However, the influence of the injected voltage becomes very marked when the armature rotates near synchronous speed. The expression voltage of the commutator winding, divided by the voltage across the F winding, is given by the curve No. 3 which shows a very rapid percentage increase when the armature approaches synchronous speed. Therefore, the influence of this commutator voltage on the torque characteristics of the machine must increase very rapidly with increasing speed of the armature, or in other words, with decreasing slip of the armature.

In a standard induction motor the torque produced by a phase of the secondary winding is, at any time, proportional to the product of the current in this winding and a voltage of the same frequency as the current,

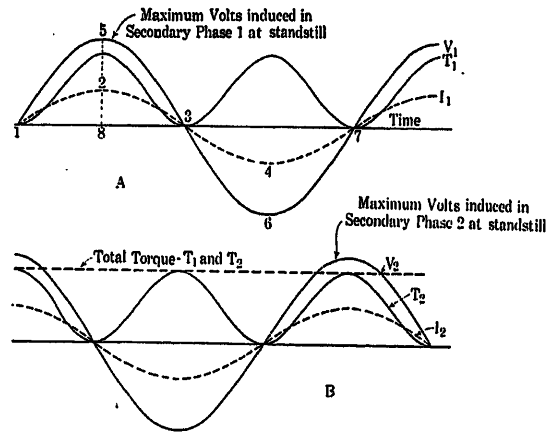

FIG. 8

A. V_1 = Volts Induced in Secondary phase 1 at Standstill
T_1 = Torque of Secondary phase 1
I_1 = Current in Secondary phase 1

B. T_2 = Torque of Secondary phase 2
I_2 = Current in Secondary phase 2

the maximum value of the voltage being equal to that of the induced voltage at standstill. The phase relation between the secondary current and this imaginary voltage must be selected equal to that of the current in respect to the actual voltage induced in the secondary at the speed under discussion.

This law is proved in Appendix No. 1.

Assuming that the secondary winding is of the two-phase type, the torque condition in a standard induction motor can be represented by the Figs. 8A and 8B. The line 1-2-3-4 gives the current flowing at any moment in the winding of the secondary phase, No. 1.

The curve 1-5-3-6-7 represents the imaginary voltage with the same frequency as the induced current I_1. The maximum value of this voltage is 5-8, and is equal to the maximum value of the induced voltage in this winding with rotor at standstill.

For the sake of simplicity, we assumed that the current I_1 and the voltage E are in phase, a condition which is always satisfied in an ideal motor without leakage reactance and is very nearly satisfied in a machine with leakage when the currents do not materially exceed the full-load currents.

The torque at any moment produced by the phase No. 1 of the secondary is, according to the above law, proportional to the product of the current I_2 and the voltage V_1 at the same moment. Making this product, the curve marked T_1, which is a sine square curve is formed.

Fig. 8B represents the same conditions as Fig. 8A, but refers to the torque produced by phase No. 2 of the secondary of the induction motor. As the secondary was assumed to be wound two-phase, it follows that the current in the second phase is 90 electrical degrees displaced from the voltage induced in the secondary phase No. 1.

Fig. 8B is identical to Fig. 8A, except that Fig. 8B is 90 electrical degrees shifted against Fig. 8A. The

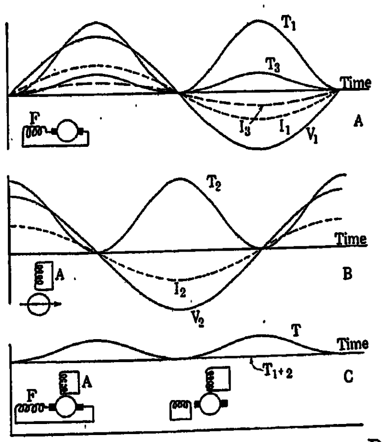

Fig. 9 —A. Torques Produced by Secondary Winding F

C. Torque Produced by Windings A and F
T_{1+2} – Resultant Torque $T_1 + T_2$
T – Final Torque Acting to Produce Rotation $T_1 + T_2 + T_3$

torque T_2 obtained from Fig. 8B is absolutely identical in its magnitude to the torque T_1 of phase No. 1, but when the torque due to phase No. 1 is a maximum, the torque T_2 due to phase No. 2 is a minimum. The total torque acting on the machine will be the sum of the torque T_1 and T_2. It is readily seen that the sum of these torque is a constant value at any time.

This reasoning assumes that the secondary windings have the same resistances, resistances being reduced to the same induced voltages. If this assumption is not fulfilled, then the maximum torque of phase No. 2 does not equal the maximum torque of phase No. 1. However, the respective phase relations of the torque curves T_1 and T_2 remain as given in Figs. 8A and 8B. The total motor torque, *i. e.*, the sum of torque T_1 and

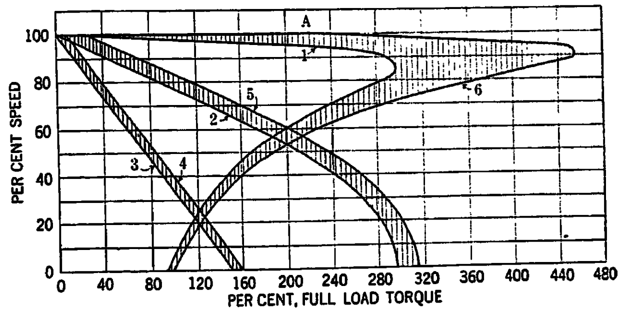

Fig. 10—Speed Torque Curves of Fynn-Weichsel Motor
1—Operating as Induction Motor—no External Resistance in Circuit
2—Sufficient Resistance to Give Maximum Starting Torque
3—Resistance Necessary to Start 150 per cent. Torque

T_2, in this case, is equal to a constant torque over which is superposed a fluctuating torque. The fluctuation is of the same frequency as that of torque T_1 and T_2. Let us assume that an additional e. m. f. is injected into phase 1 and that this injected e. m. f. has the same frequency and the same phase relation as the voltage 1-5-3-6-7 in Fig. 8A, which is redrawn in Fig. 9A. A current I_3 then flows in this circuit, caused by the injected e. m. f., in addition to current I_1 which flows due to the induced e. m. f. This injected current I_3 produces at any moment a torque equal to the product of the instantaneous value of the current I_3 and the voltage V_1. Therefore, the torque due to the injected e. m. f. is given by curve T_3 in Fig. 9A. This condition exists when the winding F and the commuted winding are connected in series, as diagrammatically indicated in Fig. 9A.

The conditions in the winding A cannot, in any manner, be altered by injecting a current in the winding F and therefore the torque produced by the winding A remains unaltered and is represented in Fig. 9B. The total torque on the armature must be the sum of the three torques discussed; Torque T_1, due to the induced current in winding F, torque T_2 due to the induced current in winding A, and torque T_3 due to the injected current in winding F.

By forming this addition from moment to moment, we obtain curve marked T in Fig. 9C, which is nothing more or less than the constant induction motor torque T_1 plus T_2, upon which is superposed a pulsating torque T_3, due to the injected current I_3 in the winding F.

Knowing the torque relations in the machine at any speed, it is possible to derive the speed-torque curves of this type of machine during the starting period, as

shown in Fig. 10. Let it be assumed that the commutator voltage e_c is 6 per cent of the induced voltage in winding F at standstill. Let the curve No. 3, represent the speed-torque curve of the machine when operating as straight induction motor with sufficient resistance in the secondary to give 150 per cent starting torque. If a voltage of 6 per cent is injected in this circuit at standstill, the torque, due to winding F, increases 6 per cent, *i. e.*, from 150 per cent to 159 per cent. For any other speed, n_x, the induced voltage

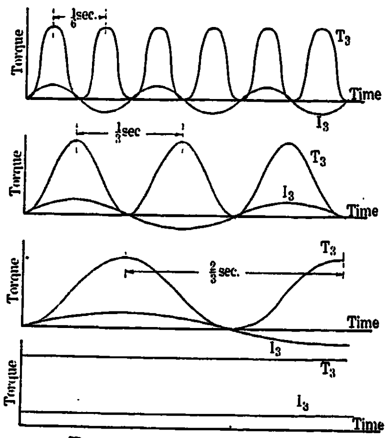

FIG. 11—TORQUE DUE TO INJECTED CURRENT AS A FUNCTION OF SLIP

a. Five per cent. Slip –three ~ per Second in Secondary
b. 2½ per cent. Slip –1½ ~ per sec. in Secondary
c. 1¼ per cent. Slip –0.75 ~ per sec. in Secondary
d. 0 Slip –0 ~ per sec. in Secondary

in the winding F is proportional to the slip speed, s_x, which equals $n_o - n_x$. If the constant voltage, e_c, is injected into the F winding, then the current flowing in the winding will be $\dfrac{e_0 \, s_x + e_c}{e_0 \times s_x}$ as great as it was originally, and the torque will be increased in the same ratio. For a slip of 20 per cent with an injected voltage of 6 per cent, the torque due to winding F will have become greater in the ratio $\dfrac{0.2 + .06}{0.2}$ which equals 1.3 times its original value.

When the resistance in the secondary circuit is reduced, the speed torque curve of the machine, as an induction motor, assumes the shape of No. 2. By performing the above calculation for a number of points, curve No. 5 is obtained.

It will be noticed that the torque of the curve No. 2 is increased more materially by the injected voltage than the torques corresponding to curve No. 3. This is simply due to the fact that the curve No. 2 is obtained with a smaller resistance in the F circuit than the resistance corresponding to the curve No. 3. Considering curve No. 1, which represents the speed torque curve of the motor when no external resistance is in the secondary, and again increasing the torque for each given slip in the ratio of injected voltage plus induced voltage over induced voltage, curve No. 6 is found. This curve is of special interest, as it shows the large increase in the maximum torque of the machine.

In other words, the remarkable condition exists that the machine with the injected voltage has a larger maximum torque than the same machine operating as a straight induction motor. This condition can readily be observed on actual tests.

Furthermore, curve No. 6 intersects the horizontal line representing the synchronous speed at the point A, corresponding to 230 per cent torque, meaning that after synchronous speed has been reached and torque T_1 and T_2 has disappeared, T_3 still exists and is equal to 230 per cent of normal full-load torque, which is the maximum torque of the motor as synchronous machine. The increase in torque, due to the injected voltage, is given in the diagram by shaded areas.

From what has been said in the beginning regarding these torques, it is known that the induction motor torque at any speed has a constant value and is independent of time. However, the torque due to the injected current, pulsates between zero and a maximum value if the injected voltage is in phase with the induced voltage. The frequency of pulsation of this torque decreases with decreasing slip. For instance, at standstill, the time between two adjacent maximums is 1/120 of a second if a 60-cycle supply is used. At 10 per cent slip, however, the time between two maximums of the pulsating torque is 1/12 of a second and at 5 per cent slip the time has increased to $^1/_6$ of a second. This has been graphically represented in Fig. 11 for 5, 2½, 1¼, and 0 per cent slip. This figure shows the torque due to the injected current when the external resistance in the secondary windings is zero, corresponding to the difference between the speed torque curves No. 6 and No. 1 in Fig. 10.

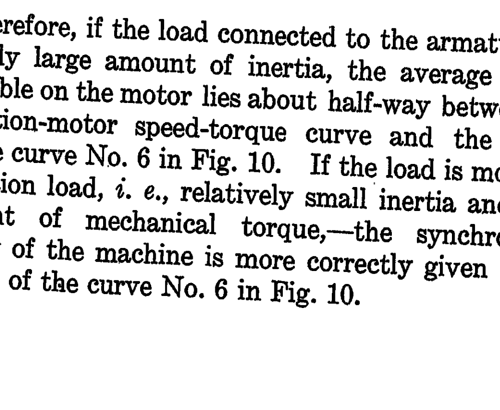

FIG. 12

Therefore, if the load connected to the armature has a fairly large amount of inertia, the average torque available on the motor lies about half-way between the induction-motor speed-torque curve and the speed-torque curve No. 6 in Fig. 10. If the load is more like a friction load, *i. e.*, relatively small inertia and large amount of mechanical torque,—the synchronizing ability of the machine is more correctly given by the torque of the curve No. 6 in Fig. 10.

The above discussion has been carried on under the assumption that the injected e. m. f. is in phase with the e. m. f. induced in winding F. As shown above, this condition exists, when the brush axis coincides with the axis of the F winding. However, if these two axes are displaced by the angle α, then the injected e. m. f. will be α degrees displaced from the induced e. m. f., and the torque curve takes the shape given in Fig. 12.

As the torque curve is formed by the product of instantaneous values of current and voltage, it must

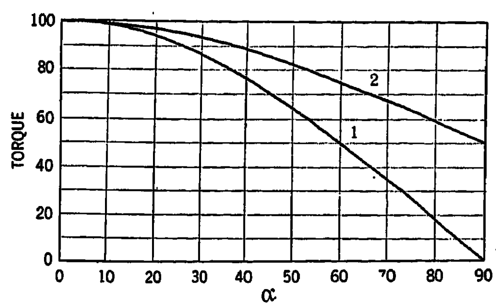

FIG. 13—1. COSINE CURVE
2. SINE² (90 DEG. − $\alpha/2$)

have the same shape as a watt curve for any circuit where the voltage and current are α degrees displaced from each other. The average watt draw of such a circuit is given by the equation:

$$\bar{E} \times \bar{I} \ \frac{\cos \alpha}{2}$$

where $\bar{E}$ and $\bar{I}$ represent peak values as distinguished from $\sqrt{\text{mean}^2}$ values. Therefore, the average torque is given by the same equation.

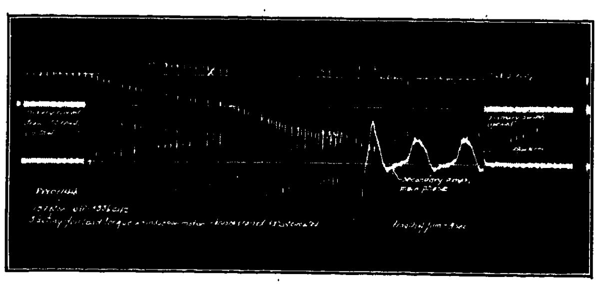

FIG. 14—10-H. P., FOUR-POLE, 60-CYCLE, THREE-PHASE MOTOR STARTING FULL-LOAD TORQUE AS SLIP-RING INDUCTION MOTOR USING REMOTE CONTROL STARTER

From this figure, it follows that the *maximum* torque is proportional to the relation:

$$\bar{E}\,\bar{I}\,\sin^2\left(90 - \frac{\alpha}{2}\right)$$

If the average torque due to the injected current is plotted as function of the brush displacement, curve No. 1 in Fig. 13 is obtained; and, if the maximum available torque is plotted as function of the brush position, curve No. 2 is obtained. In either case, the maximum value has been called 100 per cent. These curves clearly show that small brush displacements, say zero to 30 deg. do not appreciably influence the synchronizing ability for either friction or inertia load. For a larger brush displacement, however, the synchronizing ability of the machine for an inertia load decreases quite rapidly and becomes zero at 90 deg. brush displacement, while for friction load under these conditions, a synchronous torque of about 50 per cent of the maximum available torque exists.

The foregoing discussion gives in general the phenomena as they take place during starting and synchronizing periods of this new machine. Oscillograms taken on actual machines during the starting and synchronizing periods will be of interest.

Fig. 14 gives the currents in the primary and secondary circuits of the machine when connected as a straight induction motor with resistance in the secondary; *i. e.*, the commuted winding is not in circuit.

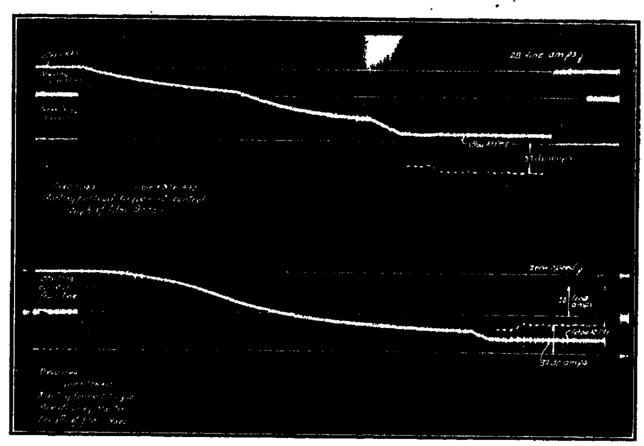

FIG. 15—10-H. P., FOUR-POLE, 60-CYCLE, THREE-PHASE MOTOR STARTING FULL-LOAD TORQUE USING CARBON-PILE STARTER

Upper Oscillogram, 15 A
Lower Oscillogram, 15 B

The machine, therefore, operated as a standard induction motor, and the current curves given in the oscillogram represented the starting conditions of a slip-ring induction motor.

Fig. 15B gives the oscillogram of the current draw in the primary and in the secondary of the same machine, as shown in Fig. 14, but with the commuted winding connected in series with the winding F.

During the starting and running periods in the tests illustrated in Figs. 14 and 15B, the same starting resistances have been used. A comparison of these two oscillograms shows that the new machine starts as a synchronous motor with a current draw not very materially different from the current draw of a motor operating as a straight induction machine.

The secondary current curve on Fig. 15B is of special interest: The frequency is high at first, then gradually decreases and finally changes into direct current when the machine has reached synchronism. In this figure, the starting resistance of the machine was purposely

selected of such a value that the machine could not run faster than 25 per cent slip when operating as an induction machine. On short-circuiting this resistance and leaving the commuted winding in series with the F winding, the machine immediately went into synchronous operation without abnormal current draw.

Fig. 15A shows the starting performance of this type of synchronous motor with a carbon-pile starter. The very low current inrushes in this diagram are of particular interest.

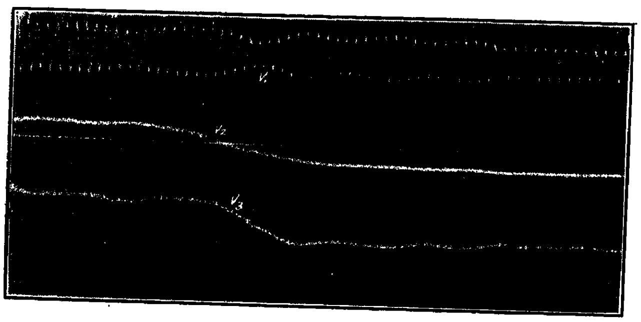

FIG. 16—V1. SHOWS CURRENT ON MOTOR CIRCUIT WHEN THE MOTOR RETURNS TO SYNCHRONOUS OPERATION WHEN LOAD IS REDUCED TO 150 PER CENT

V_2. Current in the a-c.-Field, which becomes Zero as soon as the Motor Pulls into Step and Operates as a Synchronous Motor

V_3. Current in the d-c.-Field, Which Does not become Uniform until the Motor Pulls into Step.

Fig. 17 gives the oscillogram of the same machine, but starting idle. During this test, the starter was in circuit, but was thrown very quickly into running position in order to be within the time limit of the film.

Summing up the main conclusion of the above discussion, the following laws are obtained:

1. The brush displacement from the field axis should be made zero or as small as possible in order to obtain good synchronizing characteristics.

2. The inherent slip of the motor as an induction machine should be made as small as is consistent with the general design of the motor.

3. The injected current should be as large as possible. If it is about two times the full-load secondary current as induction motor, good commercial relations will be obtained on the machine when operating as a synchronous motor.

If these rules are followed, the machine will be found to synchronize very smoothly, and when pulled out of step, will continue to operate very satisfactorily as an induction motor.

Tests on actual machines have shown that under normal operating conditions, the synchronizing torque is from 90 per cent to 95 per cent of the pull-out torque of the machine, when operating as a synchronous motor.

The vector diagram for a synchronous motor with separate excitation and without pronounced poles, *i. e.*, with an iron circuit similar to that of an induction motor, is given in Fig. 18.

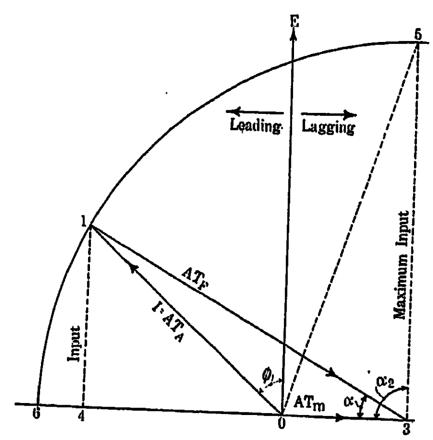

FIG. 18—VECTOR DIAGRAM OF A SEPARATELY EXCITED IDEAL SYNCHRONOUS MOTOR

For purposes of simplification, the assumption has been made that the machine is free of all ohmic resistance and leakage reactance. The machine is assumed to be built with the primary member on the rotor and the secondary member on the stator.

The resultant field in the machine is produced by the ampere-turns $A\ T_m$. These are of the same magnitude as the no-load ampere-turns of the machine when operating as an induction motor.

The armature ampere-turns in this diagram are $A\ T_a$, and the d-c. field ampere-turns are $A\ T_f$.

The resultant motor field, produced by the ampere-turns $A\ T_m$ while rotating in respect to the rotor winding, is stationary in space, as has been shown in the previous discussion on synchronizing torque. The magnitude of this field is constant if leakage reactance and ohmic resistance are zero.

If (besides the polyphase winding) the armature of this machine carries a commuted winding, then a d-c.

voltage appears across the commutator brushes due to the rotation of the commuted winding in this stationary field.

In the Fynn-Weichsel motor, the commutator brushes are connected to the field winding F (see Fig. 4) and the motor is thereby made self-exciting.

In a previous part of this paper it was shown that the angular displacement between brush and field axis materially influences the speed torque curve during the

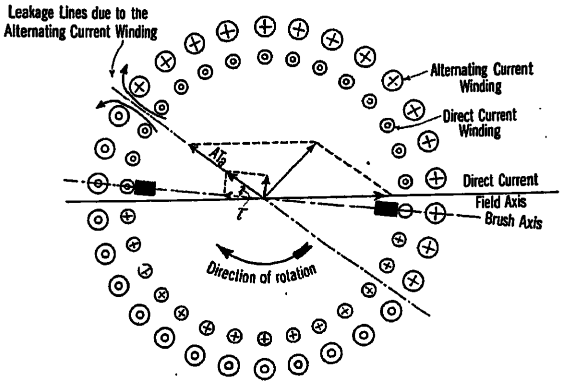

Fig. 19—Influence of Armature Leakage Flux on the Direct-Current Voltage

starting period as well as the self-synchronizing ability of the machine.

From the vector diagram Fig. 18 of the separately-excited synchronous motor, it follows that the space position of resultant motor field changes with load. Therefore, it is readily seen that the operating characteristics of a self-excited motor must be a function of the angular displacement between brush axis and field axis.

The influence of the brush displacement on the operating performance of a motor of this type will not be discussed in this paper, as the subject has been fully treated in a paper by Mr. V. A. Fynn, previously presented before the Spring Convention of the Institute, April 7-10, 1924, Birmingham, Alabama.

In the above, it was assumed that the rotor leakage reactance and ohmic resistance were zero. In reality the ohmic resistance of the a-c. winding produces a voltage drop in phase with the current and the a-c. leakage reactance produces a drop of 90 deg. displacement from the current. Under different load conditions, both of these factors tend to change the magnitude of the stationary field referred to above. These are well-known facts and can be readily considered in the calculations if desired.

The a-c. leakage reactance flux not only causes the stationary field to change its magnitude with different loads but also produces an additional voltage across the commutator brushes.

This, as well as some other phenomena, especially the interactions caused by the d-c. armature winding, will be discussed in the following.

Influence of the Leakage Flux on the D-C. Voltage

The a-c. winding of the armature produces some magnetic lines which are not interlinked with the stator winding but which are still interlinked with the d-c.-armature winding. These lines are usually called the a-c. leakage lines.

Fig. 19 shows the current distributions in the a-c.- and d-c.-armature windings, and also the general direction of the leakage flux, which is coaxial with the vector $A\ T_a$. The d-c. winding cutting this leakage flux, produces a voltage across the d-c. brushes which is given by the relation:

$$l_L = K \text{ sine } \tau$$

This value is positive when the angle, with respect to the vector $A\ T_a$ lies in a direction opposite to the direction of the armature rotation.

This additional d-c. voltage is negative when the angle τ is located in the same direction as the direction of rotation with respect to the vector $A\ T_a$.

In one case, the voltage due to leakage flux adds to the main d-c. voltage and in the other case, it subtracts from it.

Besides these leakage lines produced by the a-c. winding, there exists a group of leakage lines produced by the d-c. winding. These latter lines cut the a-c. winding and generate a reactance voltage in the a-c. winding, which is approximately in opposition phase to the reactance voltage produced in this winding by its own leakage flux.

The distribution of the leakage flux produced by the d-c. winding is given in Fig. 20.

The influence of the d-c. winding leakage flux on the operation of the machine is very small, because the armature d-c. ampere-turns are approximately 5 per cent of the armature a-c. ampere-turns.

Fig. 20

Therefore, the leakage flux produced by the armature d-c. ampere-turns is of the order of 10 per cent of the leakage lines produced by the armature a-c. ampere-turns, on account of the different field shapes. (See Fig. 20.)

In other words, the voltage produced by the d-c. leakage flux in the a-c. winding will be 10 per cent or less of the voltage induced in the a-c. winding by its own leakage flux. Therefore, the effect of the d-c.-leakage flux on the operation of the machine must be very small. It is evident that the d-c. leakage flux

cannot in any manner influence the d-c. voltage across the brushes, because the axis of the d-c. leakage flux is in line with the axis of the d-c. brushes.

Armature Reaction of the D-C. Armature Winding

The d-c.-armature winding produces ampere-turns in the direction of the brush axis, which remains fixed in space for all load conditions. Furthermore, these d-c. ampere-turns are connected in series with the stator d-c. ampere-turns. Both will increase and de-

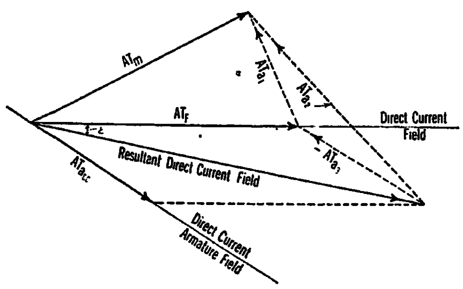

Fig. 21—Influence of d-c.-Armature Currents on the Operation of the Motors

A-c.-ampere-turns $A\ T_{a3}$ are Set up, neutralizing the armature d-c.-ampere-Turns

crease at the same rate. Therefore, the stator d-c. ampere-turns and the rotor d-c. ampere-turns add vectorially. The effect of this is that a resultant d-c. field is obtained which forms a somewhat smaller angle with the brush axis than the original angle between brush axis and field axis.

This is shown in Fig. 21. This diagram is drawn under the assumption that the magnitude of the magnetizing ampere-turns, $A\ T_m$, and their vectorial relation to the field axis F is kept constant. The total ampere-turns on the armature are represented by the vector $A\ T_{a2}$. This vector can be considered as being composed of a vector $A\ T_{a1}$ and a vector $A\ T_{a3}$, the latter being equal and opposed to the vector $A\ T_{adc}$, representing the armature reaction of the d-c. winding. This establishes the very important fact that *under all conditions, the d-c.-armature reaction ampere-turns are, at any time, counterbalanced by equivalent armature a-c.-ampere-turns*, a condition very similar to that existing in a rotary converter.

Stator Leakage Lines

As in any induction motor, there are also leakage lines around the secondary member of the machine which in this case, is the stator. As the stator is excited with direct-current, the stator leakage lines can in no manner react on the stator windings. According to their definition, these lines are not interlinked with the rotor windings, and it follows that the stator leakage lines cannot, in any manner, influence the synchronous operation of the machine. The only effect which these lines have is a slight change in the core-and-teeth induction of the stator member, but this can readily be cared for in the original dimensioning of the iron circuit when designing the machine.

Commutation

Two problems have to be considered under this heading:

1. The commutation so far as sparking is concerned.
2. The influence on the operation of the machine of the currents flowing in the short-circuited coils undergoing commutation.

The second point will first be considered. For a d-c. machine with a straight line commutation, the relations are represented by Fig. 22A. The ampere-turns, during the time of commutation zero to two, are equal and opposed to the ampere-turns during the time of commutation two to four. In other words, the coil undergoing commutation produces a very rapidly alternating magnetic flux and the average magnetic effect of this high-frequency alternating flux on the action of the machine, will be zero, as shown by sketches, 0, 1, 2, 3, representing the positions of commutation 0, 1, 2, 3 of Fig. 22A.

However, the conditions are quite different if the commutating current does not follow a symmetrical curve. Curves as given in Fig. 22B and Fig. 22C, are quite feasible. From these figures, it is seen that during the first part of commutation the positive wave of the current contains a much larger area than the negative wave representing the second part of the commutating period. The result is that the field produced by the currents flowing in the short-circuited coils undergoing commutation is of a pulsating character and in which the field in one direction predominates.

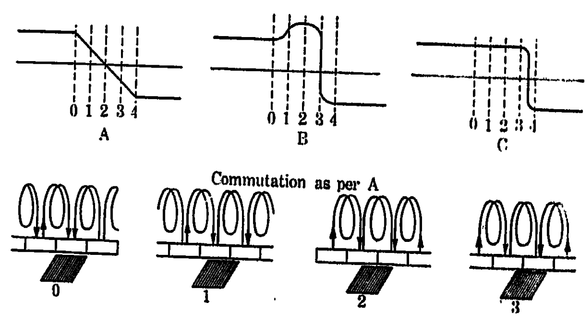

Fig. 22

Position	0	1	2	3
Time	0	1	2	3
Ampere-Turns in Short Circuit Coil	0	+ ½	0	− ½

The average ampere-turns produced by the short-circuited coil undergoing commutation must lie in a direction vertical to the axis of the brushes $A\ T_c$. (See Fig. 23). The resultant magnetizing ampere-turns in the machine $A\ T_m$, must remain constant. The vector, $A\ T_m$ can be decomposed into one vector parallel to the brush axis and one vector vertical to the brush axis.

The ampere-turns produced by the commutating current have the tendency to change the magnitude of the component $A\ T_{m1}$, and as this is not permissible,

it follows that the a-c.-armature winding must set up ampere-turns $A\ T_2$ equal and opposed to the ampere-turns $A\ T_c$ produced by the currents undergoing commutation. This has been diagrammatically shown in the vector diagram Fig. 23. From this it follows that the currents undergoing commutation have the effect of bringing the power factor nearer to unity.

Besides this magnetic effect, the currents flowing in the short-circuited coils undergoing commutation produce a certain amount of loss. This loss decreases with increasing load and is a maximum at no load. But

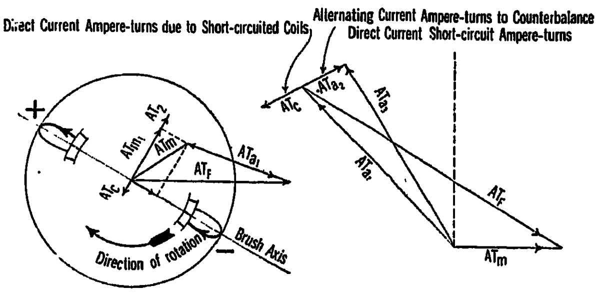

Fig. 23—Effect of Current in Coils Undergoing Commutation

even under no load, it is a very small percentage of the normal motor output, provided the commutating conditions are properly selected in the design of the machine.

It has been shown that at no load the resultant field in the machine is nearly in line with the axis of the d-c.-field excitation and at the maximum load; *i. e.*, near the breakdown point of the machine as a synchronous motor, the axis of the resultant field is nearly at right-angles to the axis of the d-c. exciting field. As the d-c.-brush axis is only slightly displaced from the d-c.-field winding axis, it follows that at no load the coils which undergo commutation stand nearly in line with the resultant field, and at maximum load are approximately 90 deg. displaced against the resultant field.

Therefore, the voltage generated in the short-circuited coil undergoing commutation is a maximum at no load and a minimum at maximum load, so that the losses due to the current in the short-circuited coils undergoing commutation decrease with increasing load.

Sparking

Under the heading "Armature Reaction of d-c.-Armature Winding," it was proved that under all conditions the d-c.-armature reaction ampere-turns are counterbalanced by equivalent a-c.-armature ampere-turns. No voltage, therefore, can be generated in the short-circuited coils undergoing commutation due to an armature reactance flux. In this respect the machine operates very much the same as a d-c. machine in which armature reaction is perfectly neutralized.

However, there remain two voltages in the short-circuited coils—No. 1. A voltage which is due to the leakage reactance flux surrounding the conductor undergoing commutation and No. 2, a voltage generated in the short-circuited coil by its movement in the main field of the machine.

This latter voltage, as has been pointed out above, is a maximum at no load and is practically zero when the machine has reached its maximum load as a synchronous machine. By properly designing the d-c. winding, it is possible to hold this voltage at such a low value that it cannot produce commutation trouble, even under no load conditions.

The leakage reactance voltage referred to under No. 1 is in every respect similar to the leakage reactance voltage in a standard d-c. machine.

Considering the three different voltages just discussed, and comparing their actions with those which occur in a neutralized d-c. machine, it will be found that this new motor from the commutating point of view operates in a manner similar to a neutralized d-c. machine in which the neutralizing winding is somewhat weaker than the d-c. armature reaction.

Due to the fact that in this new type of machine the total voltage across the brushes is in all cases considerably below 100 volts, it is evident that the commutation must be perfect.

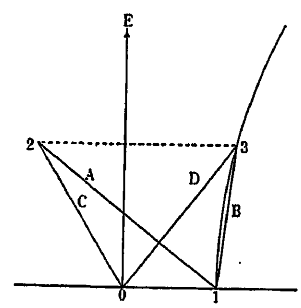

Fig. 24—Comparison of Ampere-Turn Relations in Fynn-Weichsel and Induction Motors

Losses in Fynn-Weichsel Motor

The losses can be subdivided in the following manner:

1. Primary copper losses.
2. Iron losses in the primary member.
3. Secondary copper losses.
4. Copper losses in the d-c. armature winding.
5. Friction losses.
6. Commutating losses, including brush losses.
7. Stray losses.

In order to compare these individual losses with those occurring in a standard induction motor, it is essential to compare the vector diagrams of these two types of machines:

Fig. 24 shows the vector diagram of a Fynn-Weichsel motor and a vector diagram of the same motor when running as straight induction machine.

Vectors 0-1-2 represent the operation of the machine

as synchronous motor, and the vectors 0-3-1 represent the operation of the machine as straight induction motor.

For operation as an induction motor, the vector 0-3 represents the ampere-turns on the primary member, and for operation as a synchronous motor the vector 0-2 represents the ampere-turns on the primary member.

PRIMARY COPPER LOSSES

The ratio of the length of these two vectors, D and C, gives a measure of the change in primary ampere-turns from induction motor operation to synchronous motor operation.

The primary copper loss of the machine operating as a synchronous motor, is, therefore, equal to $\left(\frac{C}{D}\right)^2 \times$ the primary copper loss of the machine when running as induction motor.

The relation of $\left(\frac{C}{D}\right)$ depends, to a large extent, on the power factor of the machine when operating as an induction motor or as a synchronous motor. Generally speaking it will be found that the primary ampere-turns are less in the Fynn-Weichsel motor than in the induction motor. Therefore, the primary copper losses in the Fynn-Weichsel motor will be smaller for a given output than the corresponding primary copper loss in a standard induction motor.

In addition to this, the mean-turn length of the primary winding in the Fynn-Weichsel motor is usually somewhat less than the mean-turn length of the primary winding of an equivalent standard induction motor, because in the latter case the winding is on the stator and in the former case the winding is on the rotor, thereby decreasing the mean-turn length.

SECONDARY COPPER LOSSES

In a similar manner, the losses in the secondary member, when running as a synchronous motor, are $\left(\frac{A}{B}\right)^2 \times$ secondary copper losses as an induction motor.

The secondary ampere-turns A of the Fynn-Weichsel motor are usually larger than the secondary ampere-turns B in a standard induction motor. This does not mean, however, that the secondary copper losses in the Fynn-Weichsel motor are materially larger than the slip loss in an induction motor, for the following reasons.

The secondary winding used in the Fynn-Weichsel motor is of the concentric type, which has a considerably shorter mean-turn length than the diamond winding usually employed in induction motors. Furthermore, the space factor for a concentric winding is somewhat better than that of an equivalent diamond winding. Both of these factors tend to decrease the secondary loss in the Fynn-Weichsel motors below the value expected by the ratio of vector length.

The above train of reasoning assumes that the d-c.-ampere-turns, 1-2, produce under otherwise equal conditions the same losses as equivalent polyphase ampere-turns of the magnitude 1-2. The correctness of this assumption is proved in the appendix, No. 2.

IRON LOSSES

For an equal number of magnetic lines, the Fynn-Weichsel motor has, as a rule, less iron losses than the equivalent standard induction motor, because in the Fynn-Weichsel motor the iron losses are located in the rotating member, while in the induction motor they are mainly located in the stationary member. But the rotating member contains less iron and therefore, for otherwise equal conditions the iron losses will be smaller than in an induction motor.

COPPER LOSSES IN THE D-C. ARMATURE WINDING

The necessary voltage for excitation generated in the d-c.-armature winding is the result of a relatively high cutting velocity between this winding and a field stationary in space. Therefore, the number of turns on this winding can be made very small. From this it follows that the resistance of this d-c.-armature winding must be very small and the loss in this winding will be found to be practically negligible.

FRICTION AND WINDAGE LOSSES

These losses are made up of:

1. Bearing losses.
2. Windage losses.
3. Slip-ring friction losses.
4. Commutator friction losses.

Items 1, 2, and 3 are in every respect identical to those in a standard induction motor.

The loss due to commutator friction, however, is inherent to this type of machine, but its value is small, as the commutator has relatively small dimensions and can be built with a small number of segments. Therefore, the friction loss due to the commutator may be considered as being counterbalanced by the decreased iron losses in this type of machine over those of a standard induction machine.

COMMUTATING LOSSES

These losses have been discussed in a previous chapter and were found to be small.

STRAY LOSSES

As a distribution of the magnetic fluxes and of the ampere-turns in this type of machine are absolutely identical to those in a standard induction motor, it follows that the stray losses are identical to those in an equivalent induction motor.

The above has shown that, generally speaking, the losses under full load on a Fynn-Weichsel motor and a standard induction motor must be very nearly the same.

From this it follows that both machines can be built in practically the same frame sizes for equal outputs and that, furthermore, the efficiencies of these new machines cannot differ materially from those of a standard induction motor. A further study of the relations shows that there is a tendency for the losses in a Fynn-Weichsel motor to be slightly heavier at fractional loads and slightly lighter at overloads than in a standard induc-

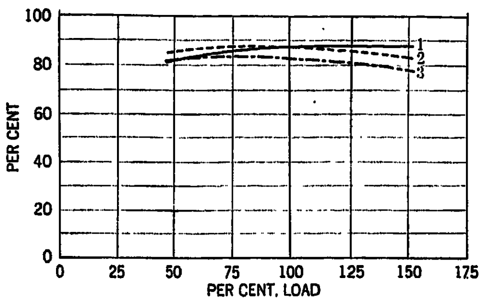

FIG. 25.—EFFICIENCIES OF 15-H. P., FOUR-POLE, 60-CYCLE, THREE-PHASE MOTORS

1. Fynn Weichsel 2. Squirrel-Cage 3. Slip Ring

tion motor. This difference in losses is the result of the difference in power factor under which these machines operate in comparison with induction motors for these extreme load conditions.

Having now discussed in general the theoretical behavior of this new type of machine, the actual behavior of the machine as found from tests will be of interest.

Fig. 25, Fig. 26, and Fig. 27 show the efficiencies of actual machines compared with those of standard in-

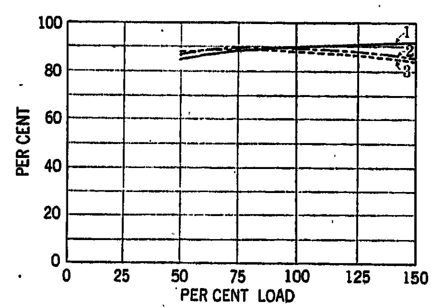

FIG. 26—EFFICIENCIES OF 30-H. P., EIGHT-POLE, 60-CYCLE, THREE-PHASE MOTORS

1. Fynn-Weichsel 2. Squirrel-Cage 3. Slip Ring

duction motors. It will be seen that these performances compare quite favorably.

Fig. 28 gives the performance of a 75-h. p. 1200 rev. per min. motor and also the performance of a 15-h. p. four-pole motor. These curves show that, similar to induction motors, the efficiencies increase with increasing h. p. capacities. They further show the general characteristic of the power-factor curve of this type of machine, which is somewhat leading at full load and becomes more leading at fractional loads. When the breakdown as a synchronous motor occurs, the power factor is near unity. After the machine has stopped operating as synchronous motor and continues to operate as induction motor, the power factor becomes lagging and reaches values similar to those of a standard induction motor. The efficiency curve of this part of the operation is also similar to that of a standard induction motor.

The change in operating characteristics of these machines under abnormal line and voltage conditions, such as high and low frequencies, follows very similar laws to those which are known to exist for standard induction motors. A detailed discussion on this sub-

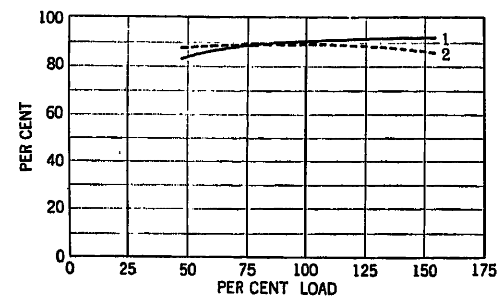

FIG. 27—EFFICIENCIES OF 75-H. P., SIX-POLE, 60-CYCLE, THREE-PHASE MOTORS

1. Fynn-Weichsel 2. Squirrel-Cage and Slip Ring

ject will be found in a paper read before the Franklin Institute, October 30, 1924, and also in the *Iron and Steel Engineer* of April, 1924.

As this new machine operates with leading power factor over its normal working range, it follows that it draws leading magnetizing current which will subtract

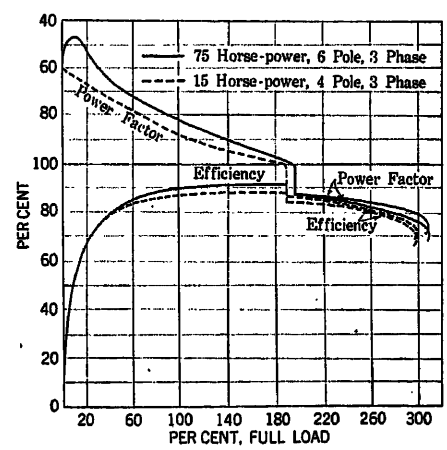

FIG. 28—COMPARISON OF POWER FACTOR AND EFFICIENCY OF FYNN-WEICHSEL MOTORS

from the lagging magnetizing current taken by induction motors, and if an installation consists of induction motors and motors of this new type, it is evident that the resultant magnetizing current of this installation can be greatly reduced. By properly selecting the relations of the Fynn-Weichsel motors and the induction motors, it is possible to obtain unity power factor

or any other desired power factor over the whole load range of the installation.

As the variation of the wattless leading current of a Fynn-Weichsel motor and of the wattless lagging current of an induction motor as a function of load follows similar laws, the power factor of the whole installation consisting of Fynn-Weichsel and induction motors will not alter materially with change in load. Tests have shown that, for instance, a 15-h. p. four-pole in-

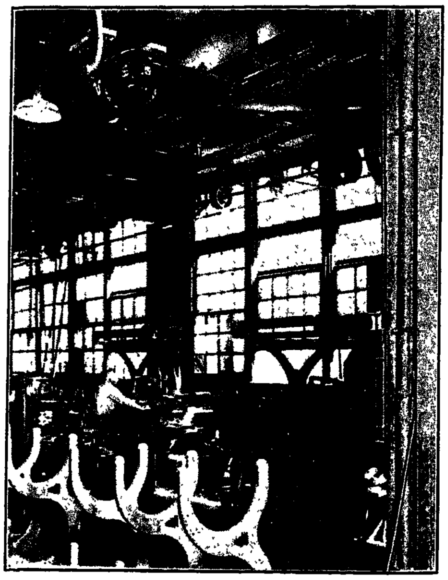

FIG. 29—15-H.P. MOTOR OPERATING WET GRINDERS

duction motor operating in parallel with a four-pole, 15-h. p. Fynn-Weichsel motor produces unity power factor over the whole load range when both motors are equally loaded as well as when both motors are loaded differently. Detail information on this subject will also be found in the above mentioned *Iron and Steel Electrical Engineer*.

APPLICATION OF THE MOTOR

From what has been said in the preceding paragraph, it follows that the most desirable manner of using these machines in an installation consists in the combination of these motors with standard induction motors and in selecting the ratios of the Fynn-Weichsel motor capacity to the remaining induction motor capacity in such a manner as to obtain the desired power factor in the installation. In laying out a new installation, it is quite simple to select this ratio in the desired manner.

In an existing installation, it is advisable to remove some of the induction motors, especially those which produce the largest magnetizing current, and to replace them by motors of the Fynn-Weichsel type.

In cases where old installations must be enlarged, it is possible to install, in the new section, Fynn-Weichsel motors, and in this manner to obtain the desired power-factor correction.

It will be found that an installation whose power factor is corrected in this manner as a rule requires less energy draw from the line than when the power factor correction is obtained by simply adding to the installation some idle-running corrective devices.

In Appendix No. 3 a calculation is given showing how much the efficiency of the Fynn-Weichsel motors can be below that of the replaced squirrel-cage motors and still give the same overall efficiency of the installation which would exist when the same installation has its power factor corrected by idle-running corrective devices.

These tables show clearly that the allowable decrease in the Fynn-Weichsel motor efficiency over the squirrel-cage motor efficiency is very large. But in a previous chapter, it has been shown that the efficiency of this new type of machine compares very favorably with the efficiencies of standard induction motors. Therefore, the overall efficiencies of an installation consisting of a combination of induction and Fynn-Weichsel motors, will be in most cases better than the overall efficiency of an induction motor installation corrected by idle-running corrective devices.

In closing, a description of a few actual installations will be given.

Fig. 29 shows a Fynn-Weichsel motor driving a set of grinders. This installation is particularly interesting, as the load on the grinders is such that very frequently the motor is greatly overloaded and thereby

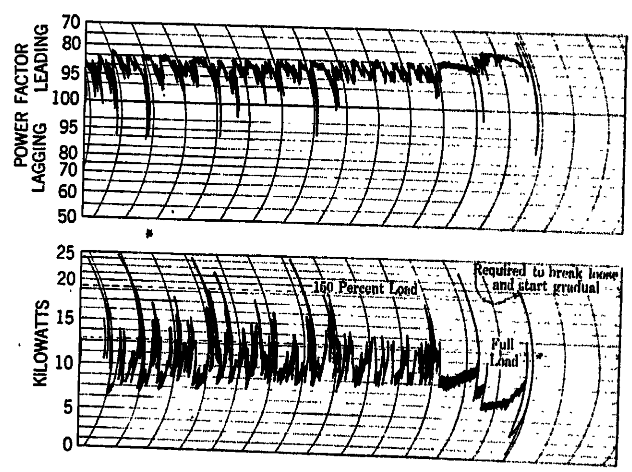

FIG. 30—POWER FACTOR AND KW. INPUT OF 15-H.P. MOTOR, OPERATING WET GRINDERS

is pulled out of step; and after the heavy overload is removed the motor immediately goes back into synchronous operation.

Fig. 30 shows the kilowatt input and power factor of this particular motor under the load conditions described.

Fig. 31 shows an installation where the motor operates a large drawing press. Here also heavy overloads occur extremely frequently.

Fig. 32 is a view of an installation in a marble cutting

plant. In this case, the constant speed of the machine has proven to be of exceptional value as the grade of polishing obtained is, to a large extent, dependent upon the uniformity of the speed with which this polishing operation is performed.

Another interesting feature of this installation is the large fly-wheel action of the grinding disks. It

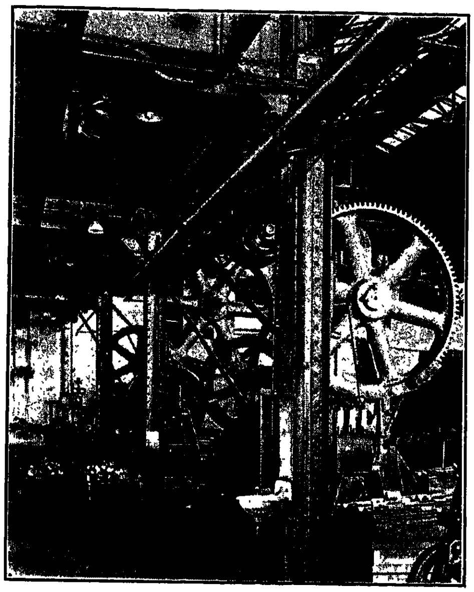

FIG. 31—7½-H.P. MOTOR OPERATING LARGE DRAWING PRESS

requires in the neighborhood of one minute to bring these large disks up to speed, and in spite of this heavy inertia, neither starting nor running difficulties of any kind have been experienced.

Fig. 33 shows a view of an installation in a cement

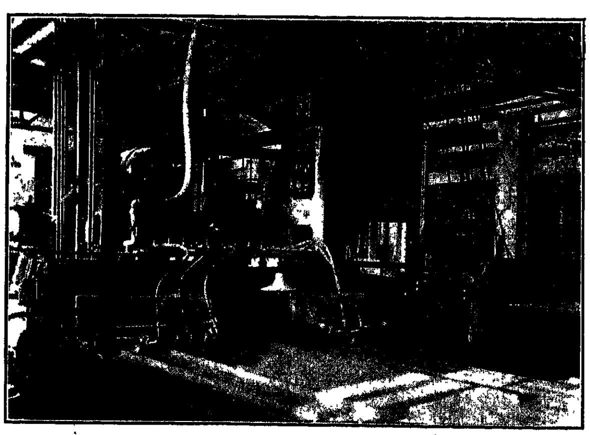

FIG. 32—75-H. P. MOTOR OPERATING MARBLE-WORKING MACHINE

mill. In this case the Fynn-Weichsel motor is operating sack-filling machines.

A great many other installations are in operation, such as motor-driven ice machines, compressors, machine shops, wire-drawing machines, and many other machines found in a variety of industries. It would lead too far to discuss in detail these installations.

Appendix No. 1

In the following, the derivation of the law is given which governs the torque of a polyphase machine at any instant. This law reads:

In a polyphase machine the torque at any moment produced by the current in a secondary phase is equal to the product of the instantaneous value of the current in this phase and the instantaneous value of an imaginary voltage whose magnitude is equal to the voltage induced in the secondary at standstill. This

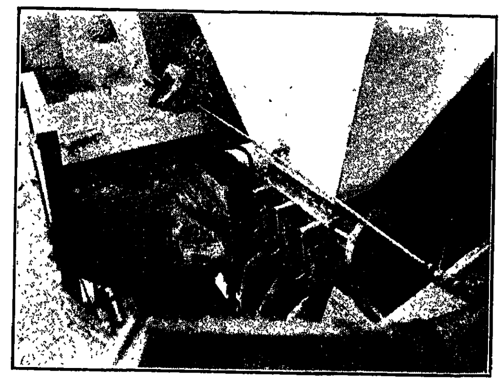

FIG. 33—25-H.P., SIX-POLE MOTOR OPERATING BAG-FILLING MACHINE IN CEMENT MILL

imaginary voltage has a frequency equal to the frequency of the secondary current. The phase relation of this voltage in respect to the secondary current is equal to the phase relation of the secondary current and the actual existing induced secondary voltage at the speed under consideration.

Use was made of this law in a previous chapter, in which the torque relations in the machine were discussed.

Assuming that the rotor is the primary member and the stator is the secondary member, and that the machine has neither ohmic resistance nor reactance in the primary, then the field produced by the primary

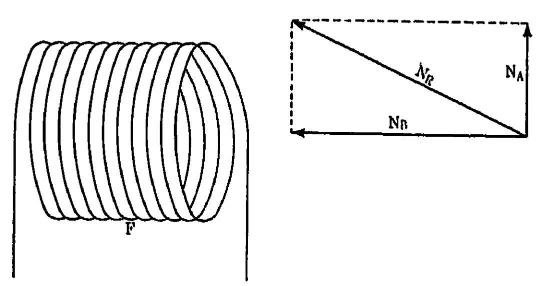

FIG. 34

has a definite magnitude and rotates in space at all rotor speeds except synchronous speed.

Fig. 34 represents the rotating field, $N\ R$, at a given moment. It can be decomposed into a component N_a, vertical to the axis of the winding F and the field N_b, parallel to the axis of the secondary winding F. The currents flowing in the winding F must produce a

torque with the field component N_a, because N_a and winding F, are at right-angles to each other, but F cannot produce any torque with the field N_b.

Both of these component fields, N_a and N_b, are alternating in time, but are 90 electrical degrees phase displaced from each other.

The torque produced at any moment by the interaction of the currents flowing in the F winding with the field component N_a is given by the following proportionality:

$$T_{F t} = i_{F t} \times N_{a t} \times s \qquad (1)$$

where $T_{F t}$ = the torque at any moment.

$i_{F t}$ = the current in the F winding at any moment.

s = the turns in the F winding.

$N_{a t}$ = magnitude of the field component in the A axis at the moment t.

Above it was shown that $N_{a t}$ follows the law:

$$N_{a t} = \overline{N}_a \text{ sine } (2 \pi f_x t) \qquad (2)$$

where $\overline{N}_a$ = the maximum value of the field component in the axis A.

f_x = the frequency of the flux N_a.

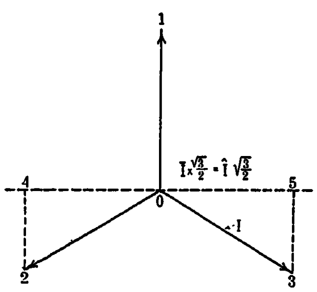

FIG. 35

This value, substituted in the equation 1 gives:

$$T_{F t} = i_{F t} \times \overline{N}_a \text{ sine } (2 \pi f_x t) \times s \qquad (3)$$

In the beginning it was shown that the maximum of the two components, N_a and N_b, are alike. Therefore, we can also write:

$$T_{F t} = i_{F t} \times \overline{N}_b \times s \times \text{ sine } (2 \pi f_x s t) \qquad (4)$$

The magnetic flux $\overline{N}_b$ can be expressed in terms of the voltage induced in the F winding when the armature is at standstill by:

$$E_0 = \overline{N}_b \times s \times 2 \pi f_0 \qquad (5)$$

where f_0 equals the frequency of the flux N_b with armature at standstill.

By solving the above equation for $\overline{N}_b$ and substituting it in equation No. 4, it follows:

$$T_{f_t} = i_{f_t} \frac{E_0}{2 \pi f_o} \text{ sine } (2 \pi f_x t) \qquad (6)$$

This equation is nothing more than a mathematical expression of the law stated in the beginning of this appendix. The correctness of this law is proven thereby.

Appendix No. 2

A statement has been made in the main article that, for otherwise equal conditions, the losses in the d-c.-exciting-winding are equal to those of a polyphase winding if the ampere-turns vectors in both cases have the same magnitude. This can be shown as follows:

Fig. 35 shows vectorially the currents flowing in the three-phase secondary of an induction motor. At the moment when one of these currents, 0-1, is zero, the currents in the two other phases have a value corresponding to their projections on the axis 0-4, and are equal, their numerical value being:

$$\hat{I} \,.\, \sqrt{3/2}$$

If the resistance of one phase is given by r, then the loss in these two windings at this moment is given by $\hat{I}^2 \times 3/2 \times 2 \times r$, but this is equal to the polyphase current loss in all three secondary windings.

If the condition for the moment given above for which the current 0-1 is zero is imitated by sending direct current through the two other phases, and selecting the direct-current so that it is of the same magnitude as the polyphase currents at the moment under discussion, then the loss must be equal to the total loss in the three-phase winding. As the magnitude of the rotating field is assumed to be of constant value, it follows that a d-c.-winding producing the same magnetization as a polyphase winding causes, under otherwise equal conditions, the same amount of loss.

A similar train of thought proves that the same relations also exist if standard two-phase windings or if any other combination of polyphase windings are used.

The copper loss due to the d-c. exciting current in a synchronous motor is, therefore, equal to the copper loss of the secondary winding of a polyphase motor provided both windings are so selected as to produce the same magnetic flux, *i. e.*, the same ampere-turns, and further assuming that both windings have the same mean-turn length and the same copper section per slot. But if the d-c. winding is so constructed as to have a smaller mean turn length and a larger copper section than the polyphase winding, then the d-c. exciting loss is less than the loss due to the polyphase exciting ampere-turns.

Appendix No. 3

An installation assumed to operate with a certain power factor and current draw, is represented in Fig. 36 by the vector $O\,I$. If this installation has its power factor corrected by having an apparatus operated in parallel which produces a leading current, $I\,C$, then the phase displacement of the resultant current is given by the vector $O\,C$ in respect to voltage vector $O\,E$.

This diagram assumes that no losses whatsoever occur in the idle running phase correcting device. In reality, a certain amount of loss exists in the phase correcting device and its loss may be represented by the line $C\,D$. The real phase displacement of the resultant current in this installation would then be given by the angle between the line $O\,D$ and the voltage

$O\,E$, but this phase displacement is so nearly equal to the phase displacement between vector $O\,C$ and $O\,E$ that no difference between these two phase displacements will be made in the following discussion. The loss in the phase-correcting device is given by the line $C\,D$, which is called a. The relation between kv-a.-input and loss in the phase correcting device is given by the expression: $a = p \times R.\,K.\,V.\,A. = p \times C$, where C equals length $C\,I$, and p is a constant.

If the same correction is obtained by removing a number of induction motors and replacing them by Fynn-Weischsel motors which have a leading phase displacement ψ_F, then the vector diagram is given by the lines O-3-C. This assumes that all induction motors operate with a power factor equal to the power factor of the installation and that the Fynn-Weichsel motors have the same efficiency as the induction motors which they replace. The kw-input of the Fynn-Weichsel motors under this assumption is given by the vector 3-1.

In order to operate this installation with the same overall efficiency, *i. e.*, the same total losses as the first mentioned installation, the power factor of which was corrected by idle-running-phase corrective devices, the input to the Fynn-Weichsel motors for the same output as before must be represented by the vector 3-2, where 1-2 is equal to $C\,D = a$.

Let 3-1 be equal to b and I-1 equal to k, and 1-C equal to m.

The efficiency of the replaced induction motors is given by $\eta_1 = \dfrac{\text{output}}{b}$. The efficiency of the Fynn-

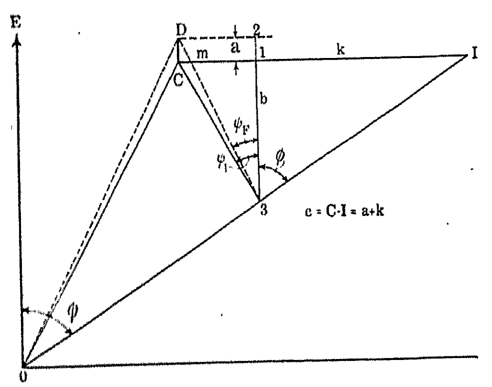

Fig. 36

Weichsel motors, in order to obtain the same overall efficiency as in the first mentioned installation, is given by $\eta_2 = \dfrac{\text{output}}{b + a}$. From this it follows that the ratio of the efficiencies is equal to:

$$\frac{\eta_2}{\eta_1} = \frac{b}{b+a} = \frac{1}{1 + \dfrac{a}{b}}$$

As $a = C \times p$, it follows that $\dfrac{a}{b} = C \times \dfrac{p}{b}$, and from the diagram it is known that $C = m + k$.

$$\text{Therefore, } \frac{a}{b} = \frac{C \times p}{b} = p\left(\frac{m}{b} + \frac{k}{b}\right)$$

$$\frac{m}{b} = \text{tang. } \psi_F \text{ and } \frac{k}{b} = \text{tang. } \phi.$$

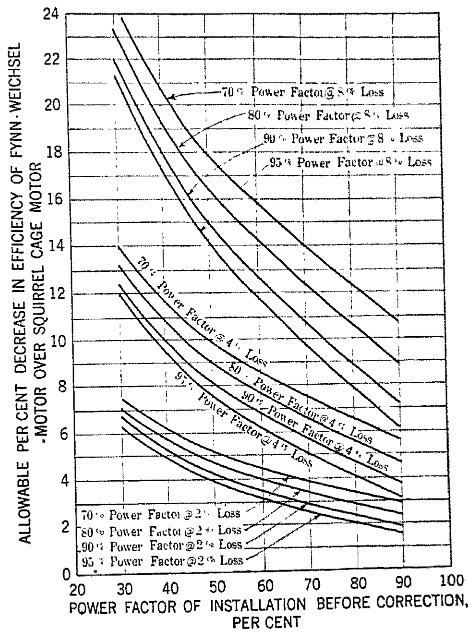

Fig. 37

This introduced in the above equation gives the relation:

$$\eta_2 = \eta_1\left(\frac{1}{1 + p\ (\text{tang. } \phi + \text{tang. } \psi_F)}\right)$$

This is a correct equation if the angle ψ_F is introduced, but a small error is made if this angle is replaced by the angle $\psi_F\epsilon$. An error made in this manner has the tendency to make the allowable efficiency calculated by this equation somewhat smaller than the real allowable efficiency. This error is, however, very small.

By aid of this equation, the curves in Figs. 37 and 38 have been calculated and the allowable drop in efficiency of the Fynn-Weichsel motor below the efficiency of the replaced squirrel-cage motor, has been plotted as ordinates and the power factor of the installation before corrective features were added, has been plotted as abscissa.

Families of curves have been calculated, assuming the Fynn-Weichsel motor operating at leading power factors of 70, 80, 90, and 95 per cent. The curve sets refer to a 2, 3, 4, 6, 8, and 12 per cent loss in the idle-running corrective device which produces the same total power factor as the Fynn-Weichsel motor installation. The use of these curves is as follows:

Assuming an installation with a power factor of 60 per cent. The power factor of the installation is to be improved to any desired value by the use of Fynn-Weichsel motors which operate with a leading power factor of 80 per cent.

The allowable decrease in efficiency of these motors below the efficiency of the replaced squirrel-cage motors is 5.9 per cent., as shown by Fig. 38, provided the overall efficiency of the installation is the same as if its power factor were corrected by the use of an idle-running phase correcting device which consumes 3-kw. for every 100-kv-a. reactive furnished.

If the idle-running phase correcting device has a 12 per cent loss and the conditions otherwise remain the same, then the efficiency of the Fynn-Weichsel motors could be 20 per cent below the efficiency of the replaced squirrel-cage machines.

These curves have been derived under the assumption that the induction motors which were replaced by Fynn-Weichsel motors operate with a power factor equal to the average power factor of the installation. In most cases, however, it will be found that, in an actual installation, some motors operate with better and others with poorer power factor than the average power factor of the installation.

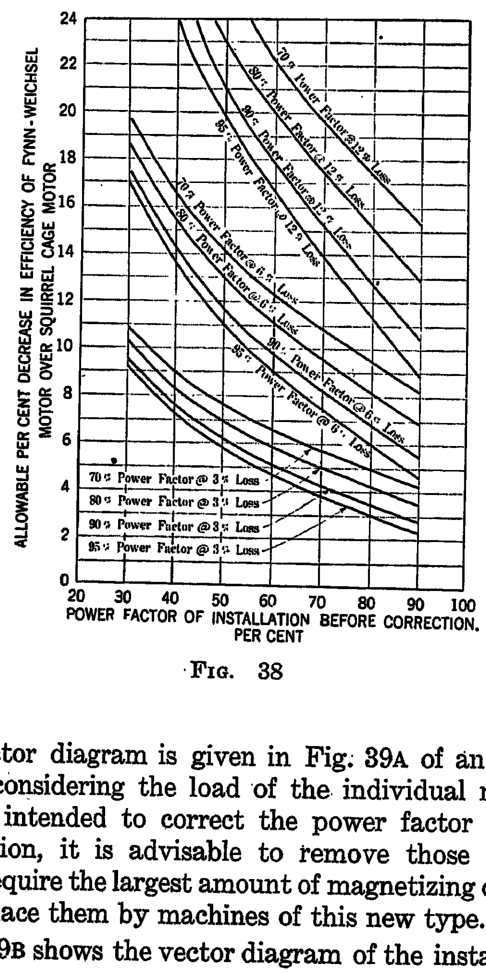

FIG. 38

A vector diagram is given in Fig. 39A of an installation, considering the load of the individual motors. If it is intended to correct the power factor in this installation, it is advisable to remove those motors which require the largest amount of magnetizing current and replace them by machines of this new type.

Fig. 39B shows the vector diagram of the installation after the induction motors requiring the largest magnetizing current have been replaced by the new type of motor. It will be seen that the capacity of the Fynn-Weichsel motors required in this case is considerably smaller than the capacity of Fynn-Weichsel motors required when all induction machines of the original installation operate at a power factor equal to the average power factor of the installation.

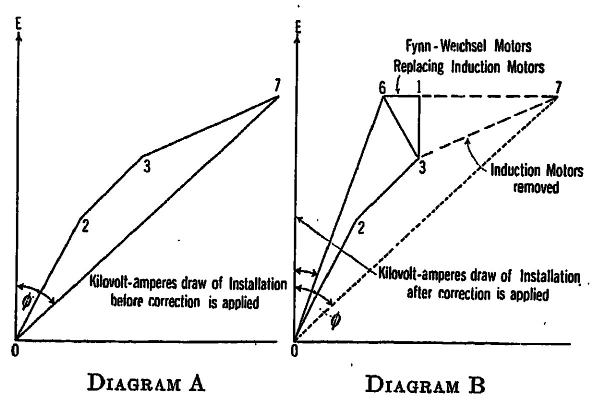

FIG. 39

From this it follows that in most cases the allowable decrease in the efficiency of the Fynn-Weichsel motors, below that of the replaced induction motors can be considerably larger than found from the curves given in Figs. 37 and 38.

For instance, if, due to the replacement of the motors which have considerably poorer power factor than the average power factor of the installation, the size of the Fynn-Weichsel motors has been reduced to one-half the value required if all motors have a power factor equal to the power factor of the installation, then the allowable drop in efficiency is twice the value which is found from the curves in Figs. 37 and 38.

In addition to this, it must not be overlooked that if the power-factor correction is obtained by replacing some of the induction motors by the new type of machine, it is possible to operate a large percentage of the wiring in the installation at unity power factor or thereabout. In this manner, the copper losses in the wiring system of the installation itself are quite materially decreased, a condition which does not necessarily exist in cases where the power-factor correction is accomplished by idle running phase-correcting devices.

A measure of the kv-a. rating of the required Fynn-Weichsel motors and of the idle running corrective device needed for accomplishing the same power-factor correction, is given by the vectors 3-6 and 6-7, respectively.

The cost of any electrical machine is a function of its kv-a. rating. Therefore, the length of the vectors 6-3 and 6-7 respectively can be readily used for determining the cost of a Fynn-Weichsel motor equipment and a corresponding idle-running corrective device.

Discussion

C. F. Scott: It happened to be my lot to be associated with Mr. Tesla in his early work in the development of his polyphase motor. I remember very well his statement that his motors were of two kinds: the synchronous motor, a splendid motor to run; and the induction motor, which he called a torque motor, that would start. The difficulty with the synchronous motor was first to get it started and second to excite it. The difficulty with the induction motor, primarily, was the lagging or magnetizing or exciting current which it required. That lagging current was a mysterious sort of thing; it was the practise to attribute anything we didn't understand in those early days to "lag."

A recent letter from Mr. Weichsel said that a score of years ago, when we were together in the Westinghouse Company in Pittsburgh, he attended one of the lectures that I gave to the students and remembered how I used yellow chalk horizontally for one kind of current and red chalk vertically for the other kind, and it gave him a clearness of conception of what was going on in circuits and an interest in it which continued. So maybe I can claim a sort of fatherly connection to the new motor, which is really a combination in one structure of those early beginnings which Tesla described as the torque motor and the synchronous motor.

The new motor has some rather striking and commendable features. The general simplicity is notable. The motor combines the starting characteristics of the induction motor and the running characteristics of the synchronous motor. It is two motors in one. It is self-contained; it has no outside exciter. There is an automatic transfer from one function ot the other, without any action of the attendant. It is simple in construction, with very simple additions or modifications to the regular induction motor.

In its construction, in its auxiliaries, in its operation, it is a simple and admirable machine, and to those of us who, back before these things were evolved, have contemplated the difficulties in the problem, and the great desideratum in getting a combination of these two motors in one simple arrangement, this solution is a most delightful one. From the engineering, inventive standpoint, it is a fine thing. And, to get a performance which is substantially that of the induction motor and of the synchronous motor, with some advantages in connection with each, is a splendid result.

W. L. Upson: This paper is a discussion of the design and operating characteristics of the now well-known Fynn-Weichsel motor and does not particularly go into the question of the demands for a power-factor-correcting motor. This latter subject has been quite fully discussed elsewhere. Fortunately this motor has now been in service long enough to establish its ability to do what is claimed for it and to demonstrate that what might seem like complications of structure are really of insignificant importance. Certainly any quantity of electrical apparatus containing as many or more complicated features is in constant use and accepted without question in practise. However, it is of interest to note that of these so-called complications the commutator, for instance, is actually much less of a problem in this motor than it is in other machines in general.

To my mind, by far the most interesting feature of the design of this motor is its small air-gap: a synchronous motor with an induction-motor air-gap. For some years I have been an advocate of smaller gaps and have felt that it was possible for the designer to obtain substantial advantages by working in this direction. In this connection I wish to quote from a discussion by Mr. H. M. Hobart contained in the TRANSACTIONS of the Institute, Vol. XXXII, p. 1595, 1913.

"Any proposition to consider the design of synchronous motors along the lines of the design of induction motors has always been handicapped by the necessity of a change of hands, as to who should design it, and bring about the evolution of the synchronous motor into a decent machine. It is at present an absurd caricature of what it might be .... I believe that the synchronous motor can be used to great advantage in much smaller sizes than has heretofore been considered desirable, in sizes which will lap over into the field that has been generally held by common consent to belong to the induction motor. If only the synchronous motor could be designed by induction-motor designers, working on the lines which have enabled them to see just what is needed for these starting and running-up conditions, the result would be for the good," and Mr. F. D. Newberry, taking part in the same discussion, admits the unsatisfactory development of the synchronous motor but imputes it to "the difference in the magnetizing current required by well a designed induction motor and a well designed synchronous motor."

It is true that a salient-pole synchronous motor would have an advantage over one with a round-rotor field providing both had the same air-gaps and both were of standard design, but in this new motor we have the restricted gap which, apparently for the first time, fulfils the desire expressed by Mr. Hobart, and in addition we have a self-exciting feature which practically overcomes the disadvantages usually encountered due to armature reaction. It would therefore seem highly desirable if we could have a comparative study of a Fynn-Weichsel motor and a standard salient-pole synchronous motor. The former exhibits such remarkable synchronizing power that it would appear that this feature might be made the basis of such a comparative study. It would be interesting to compare these motors on the basis of weight for equal capacities. On the basis of efficiency, the Fynn-Weichsel motor has every advantage, even that of commutator losses, if we take into consideration, as we should, the source of d-c. supply required by the standard synchronous motor.

There is one other feature I should like to mention, and that is that this motor requires a somewhat longer shaft between bearings than do other motors, and with the small gap, this becomes a feature in the mechanical design of considerable importance. The rotor must be truely centered, the shaft must be stiff and the bearings must not be subject to wear. These conditions might naturally be expected to add somewhat to the cost of the motor. However, there seems to be no good reason why they should not be met.

R. E. Ferris: With the operating men with whom I have talked, the cost of maintenance and continuity of service is a very important factor, of first importance, you might say. Therefore, it seems to me that all complications possible should be omitted, even at the expense of slightly reduced desirable operating characteristics.

There is one thing that has been introduced in this motor, and that is a double winding. As a d-c. designer, I have tried to avoid double windings consistently. When we got into the higher voltages, we were almost of necessity driven to double windings, especially on machines of lower capacity. However, I have even gone to the extent of designing two separate armatures, separating the commutators, and in that way the windings, in order to avoid, what seemed to me, the complication of a double winding.

L. M. Perkins: The Fynn-Weichsel motor or any high-power power-factor motor must cost more than a simple induction motor. It cannot be made to cost less, because it is exactly like the induction motor, with the addition of a commutator and extra brushes and winding.

The higher energy cost is inherent in the high-power-factor motor. If the motor has a high power factor, it means that the secondary current is thrown out of phase, very decidedly, with the field flux of the motor and, therefore, the torque for a given current and a given field is markedly decreased. The higher the power factor, the more this torque will be decreased. In addition to this, of course, there are the commutator and brush losses which again decrease the efficiency.

In his paper, Mr. Weichsel brings up a comparison of efficiencies or copper losses of the Fynn-Weichsel motor as against the plain induction motor. This appears in Fig. 24. While D is the primary current of the ordinary motor and C is the primary current of the Fynn-Weichsel motor, D is the current which flows in the stator winding and, therefore, the large winding of the normal motor, while C is the current which flows in the rotor winding or small winding of the Fynn-Weichsel motor. On the other hand, B is the current which flows in the rotor winding of the ordinary motor, while A is the current which flows in the stator winding of the Fynn-Weichsel. Therefore, A and D should be compared while C and B are also compared. C and B cannot differ very much, but A is much larger than D, and therefore entails much higher loss.

In addition to that, the point made about the concentric winding used in the stator of the Fynn-Weichsel motor can also be applied, of course, to the induction motor which can also use a concentric winding.

Further than this, the examples chosen, comparing the Fynn-Weichsel motor with the synchronous condenser, are not the most practical conditions because the Fynn-Weichsel is, in general, built in smaller sizes, and in those smaller sizes the commercial comparison will be made not between the Fynn-Weichsel and the synchronous condenser, but between the Fynn-Weichsel and the static condenser which has very low losses. For this reason, the Fynn-Weichsel motor cannot have a greater loss than the equivalent induction motor, without suffering a loss of efficiency of the system.

W. C. Kalb: In considering a motor of the type described by Mr. Weichsel there is one factor which should not be lost sight of, and that is the peculiarity of the operating characteristics of the motor when meeting overload conditions. On certain applications this represents a distinct advantage and may give the motor a preference over other types.

As a specific case, I have in mind a certain mill where it is essential that a product be ground to uniform mesh. The objection to an induction motor is that this apparatus is operated by unskilled labor, incapable of judging its operation by watching any form of indicating meter, and that the fineness of the material produced varies with the speed. As the mill becomes overloaded by too rapid feeding on the part of the operator, the drop in speed is gradual; it does not call itself to the attention of the operator by a change in tone, and variation in mesh results. The synchronous motor would be ideal from the standpoint of uniform speed, but the objection to it is that when the overload point is reached, the motor drops its load and the material circulating through the separating system drops back into the mill, stalling it completely, and making it necessary to open the mill and remove the charge.

With the peculiar characteristics of the Fynn-Weichsel motor, when this overload condition is reached the motor drops into induction operation at a sufficiently rapid rate so that the change in tone of the mill is noticeable. The operator at once recognizes that his machine is overloaded, ceases feeding until it has time to clear the load, and then proceeds without interruption and with but a momentary disturbance of the uniformity of his product.

F. G. Baum: The operating men and the designing engineers know that the induction motor as it is today and will probably continue for a long time is what might be called "the brute of the electrical system." That is, the induction motor not only throws on the kilowatt-hour load, but throws onto the system a kv-a. load which pulls down the voltage of the system. That burden that it throws onto the system, let us say, by making a power factor 0.80 in place of 1.00, may increase the current 25 per cent, which may increase the losses, say, 50 per cent in our transformers, in our transmission and in our generators. We have then to take account of the losses all the way through to the power station.

In the design of the generators, the worst thing that the generator designers have had to contend with in the last twenty-five years has been this question of the power factor. Low power factor not only adds a burden all the way through but we must carry probably 50 per cent higher excitation on the generators than we would for unity power factor. For example, we may have the generators excited for 100 amperes at open-circuit voltage, 200 amperes for unity power factor, and 300 amperes for power factor of 0.80. The high field called for by the low power factor is a menace to the system and it is, you might say, a pointed gun presented to cause trouble in case anything happens.

Anything that will tend to correct that, of course, will be beneficial. I have for years been hopeful that the synchronous-motor designers would design small units, and I believe they are doing that more and more. I think we are going to see more of that done in the future, for I believe we would have an entirely different kind of power system if we could get rid of this "brute" action of the induction motor on the power system. Such work as Fynn and Weichsel are doing is therefore of general interest to the electric power industry.

R. E. Doherty: I think there is no question whatever that in those cases of application in practise where the particular characteristics which these motors have are required and where the economics of the situation justify the investment, they have a real field. Those facts will determine, of course, the extent of the application.

With reference to the historical sketches of Professor Upson, which I believe dated back to 1913, I would call attention to the fact that very material progress has been made in the design of synchronous motors since that date. Whether in the future the synchronous motor is going to be further developed and this question of power factor solved by a simplified synchronous motor, or whether it is going to be solved by some form of commutator motor, will depend altogether upon the economic factors in the situation and the requirements of the loads.

A. M. MacCutcheon: I would like to ask Mr. Weichsel how the resistance is automatically cut out in starting this motor.

It seems to me that this type of motor surely has its place. I think Mr. Weichsel said that the cost of the motor was some 15 per cent, on the average, over that of a slip-ring motor of equal capacity. We all appreciate the increase in the price of a slip-ring motor over the very simple squirrel-cage. We appreciate that there are some disadvantages to the commutator, and to the extra windings. As a previous commentor has said, we must equate between the additional cost and the additional advantages. I suggest as a new idea that if we are going to go to the commutator, possibly we can correct the power factor either by a large size motor of this type or by a synchronous motor, if that is more economical, driving a direct-current generator and have a certain number of direct-current motors in a plant with all their consequent advantages.

Some eight years ago, I think, a good many felt that the day of the direct-current motor had passed. If I interpret the tendency in the commercial field today aright, there is a very decided tendency to use both alternating and direct current in any large plant as the ideal system. There are still many things that can be done with the direct-current motor which cannot be done with the very excellent Fynn-Weichsel motor. Therefore, if we increase the power factor by some form of large unit, either a Fynn-Weichsel motor or a synchronous motor, which could be easily maintained and inspected, it might be more economical than a large number of Fynn-Weichsel motors distributed throughout the plant, and we would have direct-current as well, with its very obvious advantages.

C. F. Scott: I don't know that we all recognize the fundamental basis of this discussion on motors. It happens that Faraday and Henry when they invented electromagnetic induction put in two things: motion, and magnetic field. Those two things—the motion and the field—for producing electromotive

force are the fundamentals of our electromagnetic machinery. Without the field, a generator or a motor is helpless.

We have been much troubled about the field. Alternators have exciters as a matter of course. The motor, too, must have its field and the question is: Can we produce that field more economically locally at the motor by having permanent magnets, by providing direct current for excitation from a battery or an exciter, or can we bring the exciting current in the form of alternating current (lagging or "wattless") from our alternator which supplies the in-phase power current? If we take magnetization for the motor from the alternator, we subtract from its magnetization and we must, as Mr. Baum says, put more d-c. excitation into the generator. We must produce somewhere the excitation for every machine in the system. One way is to produce all the excitation (as well as all the "motion") back in the power-house by putting in a bigger exciter and supplying magnetizing current through alternating mains. Another way is that of the motors described today, in which the commutator makes the motor self-exciting.

We are content to supply the motion, the power, the turbine, but everybody thinks it is all wrong that we should have to supply the magnetization. If Faraday and Henry had done differently we might do differently too, but as things stand we must supply both.

C. H. Sonntag: The Portland cement industry, with which the writer is identified, is one of those in which efficiency and high power factor in power transmission have been somewhat sacrificed to secure the greatest possible continuity of mill operation. This is particularly true in the case of the smaller motors. The tendency in recent years towards larger grinding machines has carried with it the demand for larger motors, which for application to individual machines now range in size from 75 h. p. to 500 h. p. Of these, the smaller ones are of the slow-speed squirrel-cage type, usually running at about 500 rev. per min. and so having only a moderately high power factor, while the large motors are usually of the synchronous type, which can be operated with leading current.

If these were the only motors to be run, the power factor of the system could be kept at a very satisfactory point. Unfortunately a cement mill needs a large number of small motors to drive conveyors, elevators, packers, kilns and other necessary machines. These motors will range in size from 5 to 25 h. p. or more, and to avoid excessive speed reduction, will run at a moderate speed—say about 700 rev. per. min.

The effect of these small slow-speed motors on the system power factor would be bad enough, even if they were fully loaded. But the cement-mill operator has learned from experience that such drives are frequently heavily over-loaded, due to slides of cement, accidental or necessary stoppages, and the general tendency of unskilled help to overload equipment. It is a peculiar fact that a screw conveyor handling cement, ground limestone or similar material will carry a very large load without excessive power demand as long as the material is kept moving, for the air that is mixed with the powder makes it almost as mobile as a liquid. But if the loaded conveyor is stopped for a few minutes, so that the contents have a chance to settle and pack, it will be found impossible to start it, if of any length, with a motor that is only large enough to run it as long as it is in motion. Such drives are usually over-motored at least 50 per cent, sometimes more, and the effect on the power factor can be imagined.

The cement manufacturer would welcome some way to correct for the low power factor of these small drives, and this way is now offered through the use of the Fynn-Weichsel motor that has just been described. What is needed is a machine that is reasonably simple so that the brutal treatment it will receive, and the constant presence of cement dust in the air will not put it out of business, and that does not require separate excitation. The Fynn-Weichsel motor is, in the writer's opinion, such a machine.

Some may think that the presence of a commutator makes this motor undesirable for use in dusty places. So far as the dusts found in cement-mill practise are concerned, this conclusion is not borne out by the facts. The commutator, instead of being cut and scored away by the dust, is given a high polish, and stays in excellent condition. When electric drive was first introduced into cement-mill practise, it was by the use of direct-current motors, and the excellent records made by the commutators of these old machines are still a matter of comment by those who were familiar with them.

Recently the writer had an opportunity to made a complete graphic record of the performance of one of the department circuits of a cement mill, on which were four 25-h. p., 1200 rev. per min., Fynn-Weichsel motors, together with seventeen squirrel-cage motors ranging in size from 50 to 5 h. p., most of them only half-loaded, and running at 690 rev. per min. The circuit was at 440 volts, three phase, 60 cycles. The Fynn-Weichsel motors were each driving, by direct connection through a flexible coupling, a three-tube Bates packer, which is a machine for filling bulk cement into bags. The average load on each was about 20 h. p. The other motors were driving screw conveyors, elevators, dust-collecting fans and a bag-cleaning wheel.

The sections of simultaneous charts from the graphic wattmeter and power factor meter shown herewith in Figs. 1 and 2 give a very good idea of the influence of the Fynn-Weichsel motors on the power factor of the circuit. The entire record is too long to show satisfactorily, so only the important parts are exhibited. The curves are somewhat irregular, because the entire equipment was working under commercial rather than laboratory conditions.

A number of squirrel-cage motors were started in order to get enough current through the power-factor meter to insure positive operation. The first was a 50-h. p. fan motor, partly loaded with a power factor of about 62 per cent. As smaller lightly loaded motors were started, the curves show very plainly that while the power demand increased, the power factor went progressively down until it went below 50 per cent, which was as low as the meter would register. The pen was against the stop when it drew the straight line at the point *D*. The indications on the wattmeter charge should be multiplied by 200 to get correct values.

At *E* the first Fynn-Weichsel motor was started, and the immediate increase in power factor from less than 50 per cent to about 78 per cent is very evident.

At *F* more small motors were started, bringing the load to 78 kw. and the power factor to 72 per cent.

At *G* another Fynn-Weichsel motor was started, bringing the power to 96 kw., the power factor to 83 per cent.

The load was further increased by adding two more Fynn-Weichsel motors and three small ones, with a final load of 125 kw. and a power factor of 83 per cent, which is excellent considering the underloaded condition of most of the small motors. Some of these are not needed continuously, and the effect of shutting them down is shown in Fig. 2.

At *P* a 10-h. p. squirrel-cage motor is shut down. The power falls to 118 kw. and the power factor rises to 88 per cent.

At *Q* another 10-h. p. squirrel-cage motor is stopped, the energy dropped to 110 kw., and the power factor rising to 94 per cent.

At *R* and *S* stopping two 20-h. p. and two 10-h. p. squirrel-cage motors drops the power to 63 kw. and raises the power factor to 84 per cent *leading*. At this point four Fynn-Weichsel motors and a few small ones were still running, but the load on the Fynn-Weichsel motors was falling off.

At *T* a Fynn-Weichsel motor was stopped and the power dropped to 55 kw., the power factor changing also to 88 per cent leading.

At *U* another Fynn-Weichsel motor was stopped, power falling to 39 kw. and power factor to 95 per cent leading.

Beyond this point the indications of the power-factor meter were not dependable, owing to the small current flowing in it. Taken in their entirety these charts show that the Fynn-Weichsel motor is of very real value in counteracting the poor power factor of underloaded slow-speed induction motors. Where conditions permit, this correction may be carried to the point where the resultant power factor makes the load a desirable one either for the central station or the isolated plant.

P. H. Thomas: While there can hardly be much new to be said at the present time on the subject of power-factor correction in industrial power-supply circuits, it still may be worth while to point out the fact that the indicated development of our power-supply systems is likely to throw a somewhat different emphasis on the importance of lagging current.

It goes without saying that considering the field in general, correction. The type of motor advocated by Mr. Weichsel will admirably meet many cases; sometimes the power factor may be better corrected through large synchronous motors. In this case the additional cost of the special apparatus must be balanced against any saving that can be made in the necessary correction in generators and feeders.

In those cases in which this correction must be made by installing additional apparatus, such for example, as additional generators or synchronous condensers or their equivalent, the advantage of using motors of the type proposed by Mr. Weichsel becomes very greatly enhanced, for the installation of new capacity in generating apparatus or condensers is a very different thing from operating existing machinery at a lower power factor. In other words, up to a certain point there is very little to be gained by the more expensive, higher-power-factor motor and

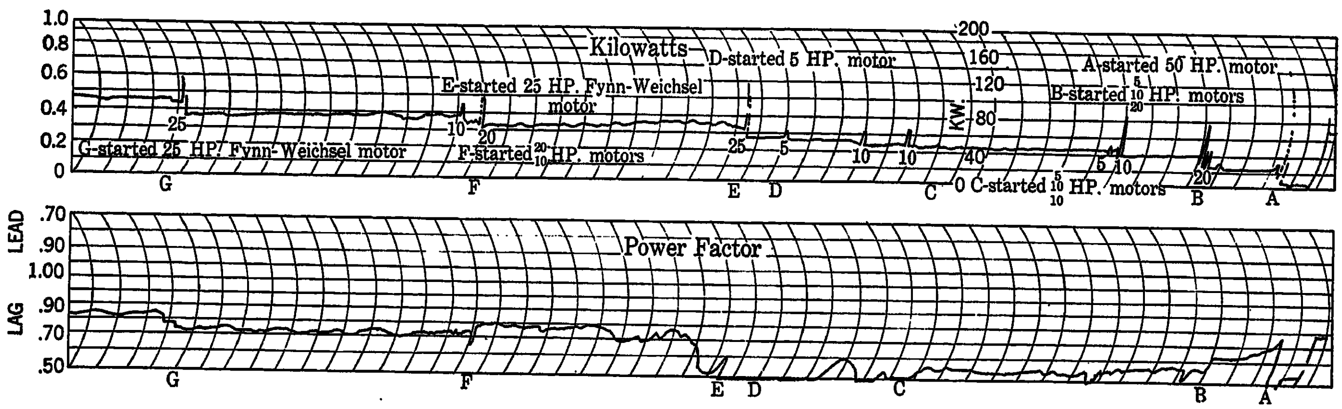

Fig. 1

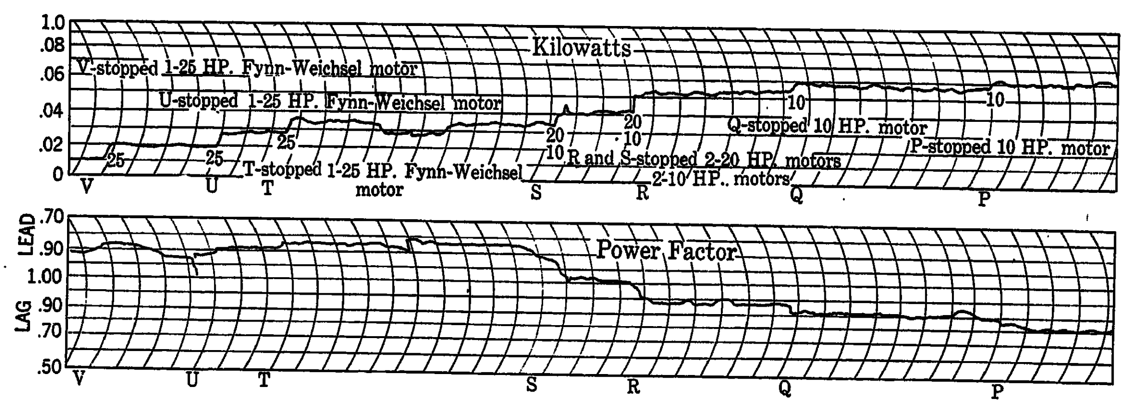

Fig. 2

Figs. 1 and 2—Load and Power Factor Charts of Mill having Fynn-Weichsel and Squirrel-Cage Motors

each actual situation must be considered by itself and they range all the way from conditions where power-factor correction is of no value to those in which power-factor correction is all-important.

Where the effect of lagging current is merely to lower the power factor of the load of a generator, leaving it still well within the proper operating range of the generator and where regulation and losses on transmission lines are not deleteriously affected, there is very little warrant for the additional expense or the lower efficiency of special forms of induction motors. This is because the use of such motors will not reduce the initial cost of the system or its operating expense. In cases, however, where the amount of lagging current is sufficient to load the generators beyond the safe current-carrying capacity of armature windings, or where the regulation is adversely affected, or in those cases where the local feeder voltage drop or line losses become excessive, power-factor correction at the load end of the feeders becomes worth while, but there is always a question as to the best method of making the other expedients may be cheaper; beyond this point the importance of the high-power-factor motor may become emphasized many times over; other remedies then become very expensive.

I would like to point out further that as interconnection and interchange of load forward and backwards between power systems grow, the situation is likely to call for high-power-factor load with considerable emphasis. To pass power forward and backward over the same line there must be a control of the power factor and if this power for both ways is anything like equal in volume it will be necessary to have it pass at leading power in one or both directions. Obviously this condition of leading power factor can be obtained only by providing means locally for carrying all of the lagging current of the local load and in addition supplying whatever additional leading current may be required. In this case the expense of bad power factor is very great because it must be corrected by carrying the lagging current on rotating

machines, at the same time carrying the load received over the interconnecting line.

As it is not possible to read the future of any particular system very far ahead, it may well be the part of wisdom to establish the policy of improving power factor of the general load from time to time as far as may be reasonable so that when the time comes when the high power factor is essential it will not be unduly expensive to secure it.

This brings forward another aspect of this matter. Since it is equitable and necessary that the purchasers of power shall ultimately pay the entire cost of furnishing the power plus a proper return on the investment and since bad power factor tends, in such cases as I have outlined, to increase very materially the cost of installation and to jeopardize the character of the service, there should be a premium in some form on a high power factor for consumers. At the present time in most cases while it is for the interest of the industry as a whole and the users in the aggregate that a good power factor should be established on a system, it is not to the interest of any individual consumer of power to have a high-power-factor load for it costs more money for him to get it and his individual bad power factor will not effect the cost of power as a whole enough to effect his rate. In other words if he establishes a high power factor he will make a benefit to the industry in general but will not improve his own rate for power. If these rates be so adjusted, as they are in some places, as to make a saving for individual consumers to establish high power factors, the burden of producing this general high-power-factor condition, which is good for the general industry, will be distributed over all the consumers of power in a more or less fair proportion. It seems to me that this is perhaps the most important aspect in the present discussion of the power factor.

G. S. Smith: The paper presented by Mr. Weichsel gives a very thorough and enlightening analysis of this new development in the line of motors. However, like most new developments, it may require some education on the part of the buying public as well as an added incentive from the power companies, before its true worth is realized.

It is needless to say that most plants using electric power are over-motored though not always without good reasons. However, there is a strong tendency for the superintendent in charge to favor a much larger motor than necessary, to avoid operating troubles, since the motor often gets less attention than the remainder of the machinery. Outside of the added investment in the first cost of the motor the power consumer is suffering no great loss unless he is penalized for the resulting poor power factor.

Since over-motoring a plant is often desirable, if not necessary, there is little doubt but that the future will see a great need for more power-factor correction, and this motor ought to supply that need since it has many desirable characteristics together with all the ease of starting found in any wound-rotor induction motor.

A series of demonstration tests were run on a 15-h. p. motor at the University of Washington, and the operation of the motor was found excellent. Its various characteristics were checked, and a number of oscillograms taken showing starting as well as various changes in operation from synchronous to induction operation and the reverse. The ease with which it synchronized even at high overloads, due to the so-called injected current, seemed the most remarkable part.

It might be desirable to afford some means of easily adjusting the power factor at which the machine operates after it is installed. Such an adjustment should be simple, though it might not be justified since every added adjustment usually means an added possibility for trouble.

There seems to be a decided fluctuation in the a-c. current drawn by the machine when it changes to induction-motor operation on overload. This, of course, is to be expected after the function of the injected current due to slip is understood, though it is not altogether desirable. The oscillogram in Fig. 3 herewith, shows this current variation and its relation to the induced currents in the two stator fields. The fluctuation indicated on the oscillogram is probably greater than would ordinarily take place since the change in load was made quickly in order to reduce the time and obtain a good record of the values both before and after the change. This doubtless resulted in some hunting of the larger machine used as load. However, the load at which it drops out of step is so high that it would seldom operate thus.

Inquiries have been made by engineers in this territory as to its operation as a generator when driving torque is applied to its shaft. It might thus be used to develop small water-power cities, floating on the line at periods of low water, and run as a self-excited alternator when water is available. Its power factor for both periods could probably be kept near to unity, or leading.

Some tests were run on a 7½-h. p. machine with the d-c. brush setting specified by the factory for motor operation. It was found that at small loads the machine would generate as a self-excited alternator but would soon drop out of step and operate as an induction generator with similar slip characteristics as given on motor operation at overload. Fig. 4 shows an oscillogram of various currents and voltages in the machine with this operation and may be of interest.

Tests were also made with several other d-c. brush settings, and with positions near 90 electrical degrees from the field axis, the machine would easily carry full load at synchronous speed, with a leading power factor, approaching unity as the load increased. At higher loads the machine dropped out of synchronism and continued as an induction generator but readily dropped back into step at about the same load it carried before when running at synchronous speed. The field current was slightly higher than for the same load on motor operation, but remained at about the same value throughout the range of load.

Fig. 5 shows an oscillogram of its performance changing from synchronous-generator to synchronous-motor operation near half load on each. The brush setting for this was about 67 electrical degrees from neutral in the direction of rotation. There is little change to be noticed except the phase difference of voltage and current. The oscillogram represents a little less than 0.5 sec. in time. The power factor was leading for both operations. Fig. 6 shows its performance as an induction generator pulling into step and continuing operation as a synchronous generator at the same brush setting as for Fig. 5. Here again the quick change required is responsible for a large part of the current variation. Oscillograms in Figs. 5 and 6 were taken on a 7½-h. p. motor, which is one of our laboratory machines.

Further tests were not made due to a lack of time, but, with the proper brush setting or some other adjustment, a generator operation might be found which is as desirable as its motor operation. The tests described simply show that it has possibilities as a generator.

It might be well to mention that at all brush positions tried, its starting and synchronizing characteristics as a motor were still very good, even though it was belted to a much larger machine.

From the educational point of view we have taken a great deal of interest in this machine since it is very illustrative of the possibilities of new developments by combination of the characteristics of well-known machines. We are interested in seeing the most made of its possibilities, as well as in the elimination of its disadvantages. It seems to be a big step forward toward supplying an increasing need which is not now satisfied.

C. R. Underhill (Communicated after adjournment): I regard this motor as a very important and timely device. Power-factor correction is an economic and operation proposition, and where motors having the general characteristics of the one described can be applied to an existing industrial-plant distribution system, particularly when placed close to motors whose power factors are to corrected, such motors should undoubt-

edly be used. However, before deciding upon any form of power-factor-correcting apparatus, a careful study of conditions should be made, a change to a higher voltage considered, and then the induction motors should be loaded to their maximum safe capacities by proper substitution, that is, by putting the right motors on the right jobs, the diversity of operation being duly considered. I have supplied induction motors for new drives without purchasing a single motor, and have put a number of motors in stock besides, while increasing the plant power factor above the penalty limit by loading the motors to their proper capacities, and that is, or should be, common practise.

In considering the use of synchronous motors, static condensers, or motors of the type described in the paper, it must be remembered that a current of abnormal strength flows between the induction motor or motors and the power-factor-correcting device or devices. For instance, connecting a synchronous motor or a static condenser across the plant terminals to correct above the penalty limit. Such managers have very poor conceptions of losses in their own plant conductors. They do not realize that higher voltages, or else larger conductors, would in many cases save them much money annually and pay good returns on the investment.

With the above reservations, I welcome the new motor, which I have studied and have witnessed in operation, as a general motor which, even if it has a commutator, is a distinct improvement over the present induction and synchronous motors. However, it should not be considered a cure-all, as in cases where plant conductors are too small or plant voltages are too low for the prevailing plant distribution system. There are instances within my own experience where there have been such excellent distribution systems and voltages that any savings in the distribution losses due to low power factor were not worth any expenditure for power-factor-corrective apparatus after the induction motors were fully loaded.

FIG. 4

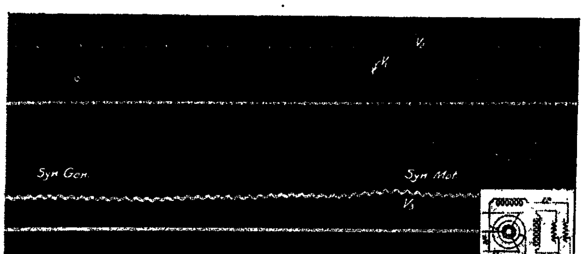

FIG. 5

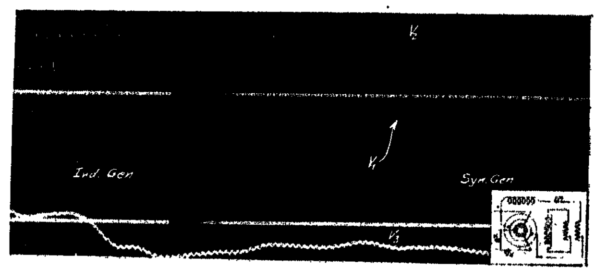

FIG. 6

FIGS. 3-4-5 AND 6—OSCILLOGRAMS SHOWING OPERATION OF FYNN-WEICHSEL MOTORS UNDER VARIOUS CONDITIONS

Figs. 4-5 and 6 are for a 7½ h. p.-motor

Fig. 3 is a 15-h. p., 220-volt motor dropping out of synchronism. V_1 is line current. It was 50 amperes before the motor dropped out of synchronism and 80 amperes afterward. V_2 is current in the auxiliary winding, and it was 41 amperes before dropping out of synchronism. V_3 is current in the field winding. The power factor was 0.81 leading before dropping out of synchronism and 0.72 lagging afterward.

Fig. 4 shows the change from motor to induction-generator operation. V_1 is line current. V_2 is current in the auxiliary winding. V_3 is field winding current.

Fig. 5 shows the change from synchronous-generator to synchronous-motor operation. The generator load is 2.7 h. p.; the motor load is 4.3 h. p. V_3 the generator field amperes are 15; the motor field amperes are 19. V_2 equals auxiliary-winding amperes. V_1 equals lines amperes.

Fig. 6 shows the change from induction-generator to synchronous-generator operation. The synchronous generator load is 5.3 h. p. The synchronous-generator field amperes, V_3, equal 11. V_2 equals line voltage.

the plant power factor does not remove the magnetizing current from the plant distribution system. Connecting static condensers across the terminals of individual induction motors minimizes the magnetizing current in the wiring system, but not in the conductors connecting a static condenser to a motor. Hence, the use of motors of the type described in the paper should be carried out with the full understanding that too great distances between induction motors and power-factor-correcting apparatus, or too small conductors, may be the cause of considerable losses in the connecting conductors.

Where two-charge rates prevail, for instance, control of the demand may be more important than correction of the power factor from a billing standpoint, and it is often difficult to impress upon plant managers the fact that further savings can be made after the demand has been minimized and the power factor raised

From my point of view, there is altogether too much stress placed on the efficiencies of motors. I prefer economy to efficiency. Would more efficient induction motors prove more economical if constructed from present available materials and and by present methods? I do not believe we could afford to buy much more efficient motors. From the industrial-plant manager's standpoint, the motor that will show the greatest saving in dollars is more important than the one that will show the greatest efficiency in per cent.

H. Weichsel: Professor Scott has presented, in a very vivid manner, the meaning of wattless and watt currents first by the "two-color" method which he devised years ago, and which has proven to be of an extraordinary help in explaining the more or less puzzling phenomena of watt and wattless currents, and second by the statement he made today that every electric

motor requires excitation, which may either be produced in the power house or at its place of consumption. It may be expected that his manner of explaining these phenomena will greatly contribute to a clearer conception of the advisability and reasons for installing power factor correcting devices.

I agree fully with Professor Upson that from the electrical engineer's point of view an electric machine should have as small an air-gap as is mechanically possible. Professor Upson is entirely correct that the distance between bearing centers in the Fynn-Weichsel motor is larger than in standard induction motors. May I add, however, that the increase in length is not very large, as the width of the commutator is usually less than that of the slip-rings of a standard induction motor. Therefore, no abnormal problems arise in the design of the shaft for sufficient stiffness to prevent abnormal deflection.

Mr. Ferris stated that, in d-c. machines, he has found it usually disadvantageous to use double-winding armatures. May I point out that, according to my judgment, the problem in standard d-c. machines is quite different from the one which presents itself in the design of Fynn-Weichsel motors. In d-c. machines, especially in those machines to which Mr. Ferris refers, a high voltage exists at the commutator and further, a high potential difference also exists between the two windings. In addition to the above, the energy carried by the commutators is quite appreciable.

On the other hand, in Fynn-Weichsel motors the voltage in the d-c. winding is extremely low and as there is no interconnection between the d-c. winding and the armature a-c. winding, no potential strain exists between these two windings. Further, the energy of the d-c. winding forms only a small percentage of the total output of the machine.

Finally, there is practically no possibility of a burnout of the d-c. winding on account of the peculiar characteristics of the exciting current of these machines. Tests, as well as theory, show that the exciting current between full load and maximum load varies only slightly.

Mr. Perkins points out that the copper losses in the stator member of a standard induction motor, when compared with the corresponding copper losses in the stator member of the Fynn-Weichsel motor, in his judgment, are materially larger for the Fynn-Weichsel motor than for the standard induction motor. This reasoning is based on the assumption that the concentric winding which is used in the Fynn-Weichsel motors can with equal advantage be used in standard induction motors. As I did not explain in detail the particular type of concentric winding which is used in Fynn-Weichsel motors, it can readily be seen why Mr. Perkins arrived at this conclusion.

The concentric winding, employed by me, cannot be recommended for standard induction motors, as it leads to uneven loading of the different phases. On the other hand, this winding is extremely advantageous in connection with Fynn-Weichsel motors, as it allows a better field distribution, shorter mean turn length, and a copper section in the axis of the main field winding which is larger than in the axis of the auxiliary winding. This results in a field winding loss materially below the values which Mr. Perkins estimated from the ratio of the vectors A and D in my Fig. 24. I may add here that this particular winding is covered by a United States patent.

Mr. Perkins further states that, in my paper, a comparison is made between an installation, the power factor of which is corrected by the Fynn-Weichsel motors and an installation with a power factor corrected by synchronous condensers. I am sorry that the paper conveyed this meaning to him. The paper makes repeated reference to "idle-running phase-correcting devices," meaning thereby either static condensers or synchronous condensers. Static condensers, as a rule, require transformers and the energy consumption of these units or any other apparatus capable of producing leading wattless current without doing useful work amounts to about three to four kilowatts for every 100 kv-a. corrected. In Appendix 3, an example shows that, with power-factor conditions as usually found in praxis the efficiency of the Fynn-Weichsel motors can be 5.9 per cent less than that of a squirrel-cage motor and still give the installation the same overall efficiency as if it would consist of squirrel-cage motors only and the correction being produced by static condensers. Elsewhere in the paper it has been shown, however, that the efficiency difference between squirrel-cage and Fynn-Weichsel motors is considerably less than 5.9 per cent. Often these efficiencies are alike, while in large units they are even sometimes better for the Fynn Weichsel motor than for the squirrel-cage motor.

Mr. Kalb mentions an experience with this new type of motor which is rather interesting. He states that the slight speed variation which occurs when these machines are sufficiently heavily overloaded to force them to operate as induction machines, has proven to be an advantage rather than a disadvantage. A condition similar to the one mentioned by Mr. Kalb has also been experienced in connection with protecting devices for these new motors. When the machines become sufficiently loaded to force them to operate as induction machines, the current draw from the line rises abruptly due to the change in power factor and to the small speed variations. This, in some instances, has resulted in a very positive operation of the protective devices.

Mr. Baum stated in a very able manner the great difficulties and dangers which arise in a system with poor power factor, which usually is caused by "the brute, the induction motor." His warning that the excitation in the generators, due to low power factor, is a point gun, and cannot be too much emphasized. According to present indications, Mr. Baum's hopes are soon to be fulfilled, as synchronous motors of small and medium sizes, especially of the type described in the paper, are becoming more popular every day.

Mr. Doherty refers to the possibility of correcting the power factor by a variety of means. There is no doubt that it is an economic question to decide which method for correcting the power factor is the most advantageous. In my way of looking at it there is no universal remedy for the ills of poor power factor. There appears to be a field of usefulness for almost any of the known power-factor corrective means. It is an economic, as well as an engineering, problem to determine from case to case the best means for achieving the desired results.

Referring to Mr. McCutcheon's discussion, I desire to state that the starting resistances for this new type of machine can be operated automatically in exactly the same manner as for standard slip-ring induction motors. He further points out the possibility of achieving the desired results of power-factor correction by using d-c. distribution and a-c. transmission, employing a converter or motor generator set as a link between the transmission and distribution systems. I believe that it will be found that such an arrangement is more expensive than a straight a-c. distribution and transmission system.

There is another point which should not be overlooked. In almost every industry there are certain places where nothing but squirrel-cage motors can be operated satisfactorily. Therefore, alternating current is required for these motors, and if direct current were to be used for the remaining machines, the wiring system would be unnecessarily complicated. For instance, this difficulty may be overcome by using straight a-c. distribution and correcting the power factor in the distribution system by using this new type of machine.

Mr. Sonntag contributed some very valuable information; his experience that the capacity of the squirrel-cage motors in cement mills must be selected in accordance with the starting torque rather than according to the running load, finds an analogy in a great many other industries. May I refer here, for instance, to the marble cutting plant which is discussed in the paper. By the use of Fynn-Weichsel motors, this difficulty is overcome and in a good many cases a smaller horse-power motor can be used. The advantageous results obtainable in this manner are very

forcibly demonstrated by the charts he presents. His statement that cement dust is not detrimental to slip-rings and commutators appears to me as rather important, since it is a conclusion based on many years of actual experience.

Mr. Thomas points out that there are cases where it is uneconomical to correct the power factor. The cases he cited may in general, perhaps, be called installations which are not working to their full capacity. The suggested method of gradually adding to the system power-factor correcting devices is, no doubt, very sound, because any system which is underloaded in the beginning will sooner or later be fully loaded, and it is then when the power-factor correction has the most beneficial effect.

Mr. Thomas' recommendation of operating transmission lines with high power factor reminds me of a statement made to me sometime ago by one of the engineers who was instrumental in bringing about our so-called "superpower system." He stated that the greatest difficulty encountered in these systems is caused by the lagging current, which is "kicked around" from one power plant to another like a football. When operator *A* finds excessive, wattless currents, he changes the excitation of his generator and shifts the current to operator *V* and vice versa.

Mr. G. S. Smith presents a very interesting oscillographic study of the Fynn-Weichsel motor when operating as a generator. These test results are extremely instructive and valuable. His test results throw a great deal of light on the somewhat puzzling conditions which arise when these machines operate as generators.

For those who are interested in this problem, a circle diagram of a Fynn-Weichsel motor is given in Fig. 7. A long time ago I derived this diagram and it has been used extensively in the actual design of machines. It is based on the assumption that the ohmic resistance in the primary member is negligible, a fact which is very nearly satisfied in actual machines. The angle found by the diameter of the circle forms and the vertical must be made equal to the angle between d-c. brush axis and d-c. field axis in the machine. The distance between any point of the circle from the horizontal line $O-1$ represents the input to the machine. When the angle, α, is zero, the brush axis coincides with the field axis. For this condition, all points of the circle lie above the base line, meaning that the machine can operate as a motor only. However, if the brush axis forms a certain angle with the field axis, one part of the circle lies below the horizontal $O-1$ and, q, therefore, represents negative input, meaning the machine operates as a generator.

If, for instance, the brush displacement is 90 deg. in direction of rotation, the machine is just as powerful as a generator as it is as a motor. If the brush axis is shifted 180 deg., then the entire circle lies below the horizontal $O-1$, meaning the machine can operate as a generator only.

This circle diagram also shows when the machine is capable of delivering magnetizing current to the line and when it draws magnetizing current from the line. As long as the points of the circle lie to the left of the line $3-4$, the machine delivers magnetizing current into the system, and when the points of the circle lie to the right of the line $3-4$, the machine takes magnetizing current out of the system. This is true whether the machine operates as a motor or as a generator.

Mr. Underhill recommends improving the power factor in an installation by properly selecting the size of the induction motors in respect to the load which they have to carry. There is no doubt that by this method a very great improvement in the power factor of the system can be obtained. I like to call attention, however, to some of its limitations. Many industries exist in which the load on the machinery is seasonal and in such cases it is not advisable to change the capacity of the motors in accordance with the seasonal business of the industry. There are also many cases where motors must carry, for a relatively short time, heavy loads and, for great periods of time, operate at no load or fractional load. Frequently the capacity of a squirrel-cage motor is governed rather by the starting requirements than by the running load.

These conditions can be particularly well cared for by installing machines which operate at unity or leading power factor for most of the time such as described in the paper. Installations of this kind also overcome the difficulty which Mr. Underhill pointed out that heavy leading currents exist in the wiring in such cases where the power-factor correction is obtained by centralized power-factor correcting devices, such as synchronous condensers or static condensers.

V. A. Fynn (Communicated after adjournment): In Mr. Weichsel's paper there appears to be an indefiniteness in his statements as to the torque conditions in general and particularly as to synchronizing-torque conditions of the machine known under the trade name Fynn-Weichsel motor.

The easiest way to avoid the numerous pitfalls scattered within this field and to gain a *true picture* and a true physical conception of what really happens in the machine is to deal separately with the torque produced by the currents *induced* in the windings *F* and *A* of Mr. Weichsel's Fig. 4 and that due to the currents *conduced* or injected into *F*.

The first is nothing more or less than the well known *polyphase*

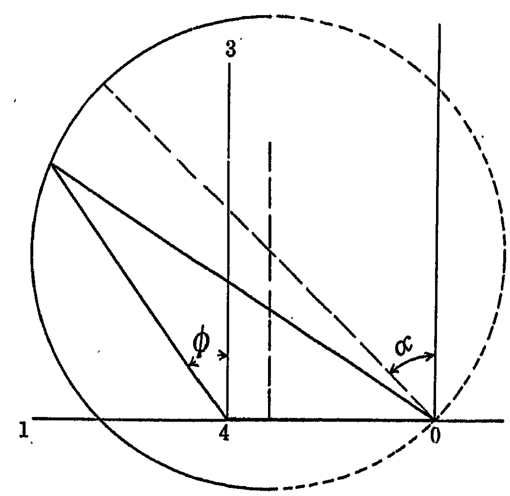

FIG. 7—CIRCLE DIAGRAM OF FYNN-WEICHSEL MOTOR

induction-motor torque. It is known that, under balanced conditions, this induction-motor torque is practically constant at subsynchronous speeds *and becomes zero at synchronism*. It is further known that its value may be varied by varying the impedance of the secondaries to which it is due. We are also advised of the fact that under unbalanced conditions, for instance with different impedances in the circuits of the several secondaries, this induction-motor torque loses its constancy and becomes undulating.

The *nature* of the second torque, that due to the currents *conduced into* the secondary winding *F* by way of the brushes cooperating with the commuted winding on the primary, and to which I refer as the *synchronizing torque*, is *entirely different*. The synchronizing torque in the motor under discussion is *never constant at subsynchronous speeds* and *does not become zero* at synchronism. At subsynchronous speeds this torque may be an alternating torque of double-slip frequency with equal positive and negative maxima or it may be a unidirectional torque; pulsating from zero to a maximum at slip frequency, all according to the magnitude of the angle α of Fig. 4. As synchronism is approached, the amplitude of the synchronizing torque *increases* and its frequency *decreases*, while the magnitude of the aforesaid induction-motor torque *decreases* and its frequency, which is zero throughout, remains *constant*. At synchronism the frequency of the synchronizing torque is zero, the magnitude of the induction-motor torque is zero and the synchronizing torque becomes the motive torque of the synchronous motor.

At the beginning the statements are indefinite and convey an erroneous idea of the function of the brush voltage in conjunction with the winding F, which incorrect idea is later fostered by the curves of Fig. 10.

A machine connected as in Figs. 5A and 5B starts and operates like an ordinary induction motor, approaches synchronism but never reaches it. Synchronism cannot be reached unless the winding F is connected to the brushes co-operating with the commuted winding which results in the production of an alternating synchronizing torque with equal or unequal positive and negative maxima, said torque being added to or superposed on the ordinary induction-motor torque.

The resistance, or more broadly, the impedance of the secondary circuits affects the induction-motor torque and the synchronizing torque in like manner and is *not* the determining factor in the situation. The difference between the two torques and that which makes it possible for the *conduced* ampere-turns in F to synchronize the motor is the fact that, while the amplitude of the voltage induced in F diminishes to zero with decreasing slip, that of the voltage conduced into F remains constant for all rotor speeds. See lines 1 and 2 of Fig. 7.

The fact that the frequency of the brush voltage is inherently the same as that of the voltage induced in the secondaries is not in itself sufficient to cause the additional torque to help the induction-motor torque. The determining factor in this case is *the phase* of said brush voltage with respect to that of the voltage induced in the secondary on which the brush voltage is impressed. The additional torque due to the brush current in F, may, according to the phase of the brush voltage, either help or oppose the induction-motor torque or alternately help and oppose same, but in no case is this torque constant and comparable to the induction-motor torque. At its best this additional "synchronizing" torque pulsates from zero to a positive maximum.

The amplitude of this superposed pulsating or alternating torque is practically independent of speed variations of the order of magnitude of the slip of an induction motor from no-load to maximum load for the reasons that the brush voltage is independent of the rotor speed and that whatever changes in the magnitude and configuration of the synchronizing torque do take place when the motor speed varies are due to changes in phase and magnitude of the brush current in F. These changes are brought about by the change in the frequency of the brush voltage, which frequency increases with increasing slip. *Such being the case, the machine described by Mr. Weischel cannot run at a constant speed as an induction motor.* The fact of the matter is that while the synchronizing torque is indispensable if the motor is to be operated synchronously, said torque *interferes* with the proper operation of the machine as an induction motor, causing the motor speed to pulsate continuously. It is therefore not correct to say simply that the Fynn-Weichsel motor will operate at a higher speed than an induction motor when operating under otherwise equal conditions. Except for the roughest kind of work this machine is unsuitable for use at other than synchronous speeds.

Judging by statements made in the paper, Figs. 8 and 9 have reference to an induction motor operating very near synchronism with a small slip, say, at full load or at less than full load; under no other conditions are secondary voltage and current nearly in phase. We all know that under these conditions the induction-motor torque in balanced circuits is constant and varies with the slip about as shown by Curve 1 of Fig. 10. All we are interested in is how the torque conditions are modified when the commuted winding located on the primary is included in the circuit of the secondary F. Mr. Weichsel's suggestion is that in case the brushes cooperating with the primary commuted winding are coaxial with F, the torque conditions are modified as shown in his Fig. 9c. This figure is qualitatively and quantitively incorrect, the quantitative error is so great as to give a quite erroneous impression of the true nature of the machine.

According to Fig. 8B and the second column on page 11, when the two secondary windings A and F are short-circuited, the resultant torque, $T = T_1 + T_2$, is constant. If so, then T_1, which is due to F, must be less when the brushes and the commuted windings are included in the circuit F, thus increasing its impedance. In Fig. 9c the sum of T_1 and T_2 must therefore be a wave and not a straight line. This is the qualitative error.

The very misleading quantitative error is found in the relative amplitudes assigned in Fig. 9c to the induction-motor torque $(T_1 + T_2)$ and to the synchronizing torque T_3. The ratio of these amplitudes scales 9.6 to 2.6.

At synchronism, or at very small slips $T_1 + T_2 = O$, or practically so and T_3 as stated in the paper, is 230 per cent of the full-load torque. The ratio of the amplitudes is then as O to 230 and Fig. 9c is clearly not drawn for nearly synchronous speeds.

At full-load asynchronous torque, the slip, according to Curve 1 of Fig. 10, is about 3 per cent. Since the amplitude of T_3 for a given brush angle α depends on the amplitude of the brush voltage which is constant and on the impedance of F which is zero at synchronism and increases with increasing slip, it is clear that for a 3 per cent slip T_3 is very little less than its synchronous value and the ratio of induction-motor torque amplitude to synchronizing-torque amplitude is practically as 1 to 2.3. Fig. 9c is evidently far from being correct for an asynchronous torque equal to the full-load torque of the motor.

But even quite near the maximum asynchronous torque, when the slip is 10 per cent according to Curve 1 of Fig. 10, the ratio in question is still as 2.9 to about 1.9. This is an extreme case quite outside the limits specified as those on which Fig. 9c is based, yet this figure no more applies here than it does at loads up to and including full load.

Making the amplitude of T_3 about 8½ times greater than shown or 2.3 times greater than that of $(T_1 + T_2)$ in Fig. 9c puts a *very* different complexion on the proposition and forcibly brings out the fact I have previously stated, *i. e.*, that such a motor *cannot* run at a constant speed when operating as an induction motor.

When the axis of the brushes cooperating with the commuted winding on the primary is displaced from the axis of F by a small angle such as α of Fig. 4, the synchronizing torque T_3 assumes the configuration indicated in Fig. 12, it becomes alternating with unequal maxima and still effectively prevents the machine from running at a constant speed when operating asynchronously. As the magnitude of the negative maxima increases, so does the asynchronous overload capacity decrease.

The Curves 4, 5 and 6 of Fig. 10 have evidently been derived on the assumption that the Curves 1, 2 and 3 represent the induction-motor speed-torque curves of the machine for given impedances of the secondary circuits, that the addition of the brush voltage e_c does not change said impedances and that e_c is constant and cophasal with the voltage induced in the winding into which it is introduced. If all this were true, which is not the case, then it would be permissible to say that the secondary current *in the phase into which e_c is introduced* and consequently *the torque due to that phase* is increased in the ratio of $e_o s_x$ to $(e_o s_x + e_c)$ *but* in his Fig. 10, Mr. Weichsel has not only represented this increased torque as if it were *constant* but as if it were applied to *both* secondary phases.

In Fig. 10, Mr. Weichsel has added *the maximum value of the single-phase, pulsating torque*, T_3, produced by the winding, F, *only* to the *constant* induction motor torque $(T_1 + T_2)$ represented by the Curves 1, 2, 3 and *offers their sum as the resultant torque of the motor!*

It is further to be noted that if the conditions were actually such as indicated by Mr. Weichsel's Fig. 10, the machine could not run synchronously unless the torque required was 230 per cent of the normal, see point A of Fig. 10. For smaller torque de-

mands the motor would run at speeds greatly exceeding the synchronous.

Errors of this kind are not so likely to occur if the synchronizing torque is dealt with quite independently of the induction-motor torque.

Pursuing this subject a little further, let us examine into the operation of the motor on the basis of the performance curves shown in Fig. 28. Further on, it is stated that the synchronizing torque T_3 for these motors as designed is from 90 to 95 per cent of the synchronous pull-out torque. For the 75-h. p. of Fig. 28 the synchronous pull-out torque is 196 per cent and the synchronizing torque is therefore at least 0.9×196 or 176 per cent. We can simplify the argument without missing the moral by assuming that T_3 remains constant down to the asynchronous breakdown point. We, of course, know that this torque actually diminishes with increasing slip. Upon the demand of a 197 per cent torque, which is slightly in excess of the maximum synchronous, the machine lapses into asynchronism and the synchronizing torque of 176 per cent reappears but is alternating with very unequal maxima. If $\alpha = 20$ deg. and the positive maximum is 176 per cent, then the negative maximum is 5.6 per cent. The positive maximum is almost sufficient to handle the load and a very small asynchronous slip corresponding to a 20 per cent asynchronous torque will supply the difference. When T_3 is at its negative maximum the slip must be sufficient to counteract this negative torque and to handle the load, which means that the slip must correspond to a 202.6 per cent asynchronous torque. The motor speed must and does vary accordingly as can be observed on any such motor.

Again, Mr. Weichsel says that the inherent slip of the so-called Fynn-Weichsel motor should be made as small as possible. This means that the winding A of Fig. 4 must have about as much copper as the winding F. Since A is *idle* at synchronism and comes into play only in asynchronous operation, at starting and under loads in excess of the maximum synchronous load, a large amount of copper in A can only be justified if the asynchronous overload capacity is actually utilized. I have shown that this asynchronous overload capacity is only available for the roughest kind of work because the speed then fluctuates continuously and Mr. Weichsel's Fig. 28 clearly indicates that the asynchronous overload capacity is not really relied upon by the makers of this machine. The synchronous overload is about 188 per cent for the 15 and 196 per cent for the 75-h. p. motors to which said figure refers. This overload is ample for all ordinary purposes and the asynchronous overload which rises to 300 per cent and 308 per cent respectively is pure waste, it cannot be and is not utilized.

Mr. Weichsel's third conclusion states that the injected current must be about twice as large as the full-load secondary current of the motor. This means that the commutator must carry at least twice the normal full-load secondary current near the synchronous break-down point and if the asynchronous overload capacity is really utilized, as suggested in the paper, then *the commutator must carry more than three times the normal full-load secondary current* when the machine operates near its asynchronous break-down point. I do not think it can be fairly said that such a commutator has relatively small dimensions, yet such is Mr. Weichsel's contention.

Much is made in the paper of a really insignificant detail and a quite erroneous impression is conveyed: Fig. 21 purports to show that the axis of the unidirectional magnetization on the secondary does not coincide with the axis of the winding F because of the d-c. ampere-turns in the primary commuted winding and it *also* purports to show that these primary d-c. ampere-turns are neutralized by the a-c. ampere-turns on the primary.

In the paper, it is also stated that the armature, *i. e.*, the primary, d-c. ampere-turns are about 5 per cent of the primary a-c. ampere-turns. It is stated that α shall be zero, or very small. From Fig. 18, and in fact without it, we know that the secondary ampere-turns in synchronous operation must be greatly in excess of the primary ampere-turns. In Fig. 21 the vector $A\ T_{adc}$ must then be much less than 5 per cent of the vector $A\ T_f$ and the angle between the two should be smaller rather than greater than that shown. How can these insignificant primary d-c. ampere-turns influence the location of the "resultant direct-current field" to any appreciable extent? In Fig. 21 the "d-c. armature field" is shown as amounting to 54 per cent of $A\ T_f$, hence the delusion.

As to the suggestion that these primary d-c. ampere-turns are neutralized by some of the primary a-c. ampere-turns,—of course they are, *but* he must either say that the "d-c. armature field" is neutralized by some of the a-c. ampere-turns and continue to figure with $A\ T_f$ only or he must figure with the "resultant direct-current field" and forget about this neutralization.

In dealing with commutation, Mr. Weichsel says that the reactance voltage is similar to the reactance voltage in a standard d-c. machine. It would be quite correct to say that it is identical, *i. e.*, identical in nature, but it is not even similar as to magnitude. The sides of the coil undergoing commutation in the standard d-c. machine lie in the open, *i. e.*, in the interpolar space; in this machine these coils are surrounded by laminations separated by an induction-motor air gap and, for otherwise equal conditions, the reactance voltage in this case is a multiple of that of a standard d-c. machine. The brush voltage and the current per conductor must be kept low.

When $\alpha = 0$ the coils undergoing commutation cut the full resultant magnetization, *i. e.*, the full field flux of this motor at no load, and cut no field flux at maximum synchronous load. For other values of α the no-load conditions improve, the maximum load conditions get worse.

Mr. Weichsel's arguments as to the advantages of a concentric over a diamond winding are beside the point for either can be used in an ordinary induction motor. As to his arguments in Appendix No. 2, it is true that by taking $^2/_3$ of the three-phase secondary and feeding into it a d-c. equal to $\hat{\imath}\sqrt{3/2}$ the flux and the loss will be the same as with an effective three-phase current $\hat{\imath}$ in each of the three rotor phases, *but* this loss will be distributed over two instead of three phases and the *heating* will be considerably greater.

Furthermore, the secondary ampere-turns in synchronous operation, with unity or leading power factor, are *considerably greater* than the secondary ampere-turns for corresponding asynchronous operation as is shown in Mr. Weichsel's Fig. 24 where the secondary ampere-turns for a certain load are $1-2$ or A for synchronous, and 1—3 or B for the non-synchronous operation. The ratio of A to B is as 30 to 19, and the d-c. in the two phases of Mr. Weichsel's Fig. 35 must therefore be $\hat{\imath} \times \sqrt{3/2} \times 30/19$ or 1.58 times greater than indicated by him.

If the amount of copper on the secondary of the synchronous induction motor is no greater than that used when the machine is designed as a straight induction motor and if two-thirds of that copper is used for the unidirectional ampere-turns in synchronous operation, then for the load conditions of Fig. 24 the secondary copper losses will be 2.49 times as great as the corresponding slip losses in non-synchronous operation and the cooling surface for this loss will have been reduced to two-thirds of that available in the straight induction motor.

The question may well be asked, why not also use the third phase of Fig. 35? One reason is that it is necessary to have a *polyphase* winding on the secondary not only for starting but also to prevent hunting in synchronous operation and to take care of loads in excess of the maximum synchronous load and give the motor a chance to work back into synchronism when a sudden overload causes it to lapse into asynchronism. Mr. Weichsel even thinks, (see his conclusion No. 2 on the eighth page,) that this polyphase winding should be such as to reduce the induction motor slip to very small values. The third phase of Fig. 35 is really the winding A of Fig. 4.

Another reason for not using all three secondary phases to

carry the unidirectional ampere-turns is the fact that when so used they form a winding distributed over *all* the pole surface and with but one axis per pole pair. To get the same flux with three phases in circuit instead of only two would require a further increase of 33 per cent in the ampere-turns and a consequent 77 per cent increase in copper losses. But utilizing the third phase

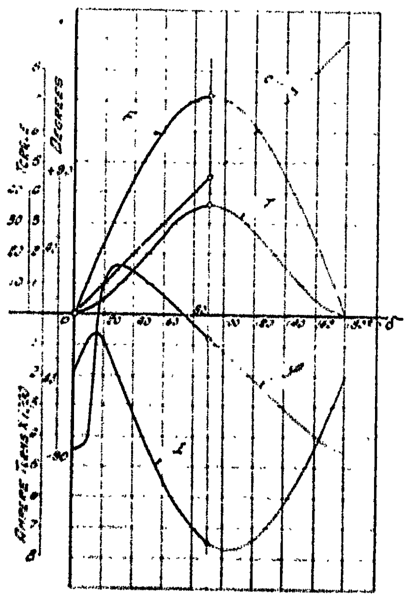

Fig. 8

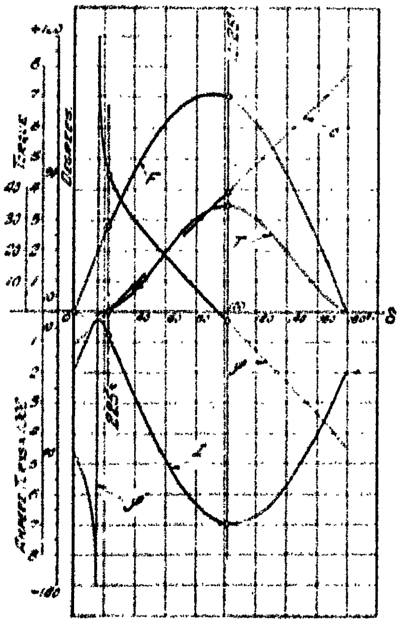

Fig. 9

Figs. 8-9 —Power-Factor-Load Characteristics of Synchronous Induction Motor

increases the amount of copper by 50 per cent so that by using all three secondary phases, *i. e.*, all of the available secondary copper, for carrying the secondary unidirectional ampere-turns the secondary copper losses become equal to $2.49 \times 1.77 \times {}^2/_3 = 2.94$. This means that for the load conditions of Fig. 24 and on the assumption of an unchanged amount of copper on the secondary, *all* of said copper being used to carry the d-c. ampere-turns, the secondary copper losses in synchronous operation are practically *three times as great* as those in non-synchronous running while the *cooling surface is the same.*

The watts loss per unity of cooling surface is some 22 per cent less when all three instead of only two of the secondary phases are used for carrying the secondary unidirectional ampere-turns but the total secondary copper loss is 18 per cent greater and no copper is available for the additional secondary winding *A* of Mr. Weichsel's Fig. 4.

The fact is that a synchronous induction motor of the form under reference *can* be built in which the secondary copper losses are not materially greater than the corresponding losses in an equivalent induction motor *but* such a machine must have *much more active material than the equivalent induction motor and must be correspondingly more costly.*

My opinion is that this so-called Fynn-Weichsel motor is much better suited for use as a synchronous condenser than as a motor.

The ordinary synchronous condenser is difficult to start and is very sensitive to line voltage or to frequency disturbances. It is very liable to fall out of step and cause oscillations throughout the system. The machine under reference is very easy to start and if it does fall out of step it will automatically go back to synchronism without fuss or trouble so soon as the disturbance is over.

The fact that the primary is on the revolving member and the primary currents are taken to it over slip rings is a serious objection to the machine as a motor, but much less so as a synchronous condenser. Slip-rings which carry current all the time

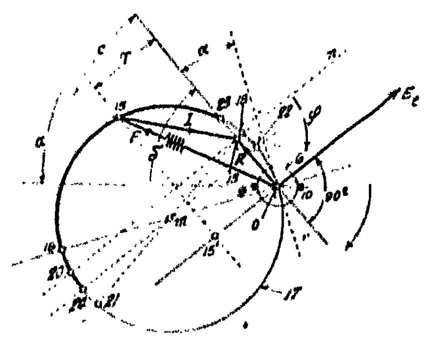

Fig. 10—Circle Diagram of Synchronous Induction Motor

are almost as touchy as a commutator. As a synchronous condenser the machine can be located without reference to any other machinery and therefore in some dry, clean and sheltered spot favorable to slip-ring operation.

The fact that the commutator carries load as well as exciting currents and the fact that any accident to the brush circuit must put the machine out of commission, since the winding *A* alone is insufficient to permit the machine to operate as an induction motor, also militate against its general use as a motor for no one cares to run the risk of an interruption in production. These same facts lose much of their significance when the machine is used as a synchronous converter. The sheltered position to which it can then aspire makes commutator operation easier and a breakdown less likely. If one does occur, it does not entail an interruption in production but merely the temporary loss of the advantages conferred by a synchronous condenser.

Another important point, relates to the power-factor-load-characteristic of such machines. The fact is that the possible inherent compounding or power-factor-load-characteristics of this machine do not permit of operation at unity power factor at all loads as clearly appears from my Figs. 7 and 8 herewith. Generally speaking, the power factor leads considerably at light loads, tends towards unity with increasing load, reaches unity near maximum synchronous torque and lags thereafter. This characteristic is suitable for a synchronous condenser but not for a general-purpose motor. It cannot be sufficiently emphasized that in so far as losses are concerned, whether in the

motor, in the transformers, in the line or in the generators, a leading current is just as objectionable as a lagging one. The one exception is in connection with the exciting current of the generators.

For the benefit of those who desire to study the compounding characteristic possibilities of these machines more closely, I append the circle diagram Fig. 10. The terminal voltage is E_t and the resultant motor magnetization is R, corresponding to $A\ T_m$ of Mr. Weichsel's Fig. 18. The brush angle is α, the location of the winding F is indicated by the coil on vector $O-15$. The locus for the unidirectional secondary magnetization F is the circle 17, the primary current is I, the phase angle is φ, while c and δ are the angular displacements between R and F and between R and the brush axis respectively. The vectors E_t and R are supposed to be stationary in space and the brushes and the winding F are moved counterclockwise through 180 deg. while retaining their proper angular relation α. This covers all possible load conditions for either polarity. The curves in Fig. 9 were calculated from the diagram of Fig. 10. The angle α is 22.5 deg. in both figures.

In my opinion, the motor described by Mr. Weichsel *is not a general-purpose motor.*

H. Weichsel (by letter): After carefully reading Mr. Fynn's later discussion of my paper, I conclude that while he and I approach the theoretical analysis of this type of motor somewhat differently, the reader will not be interested in a prolonged discussion of such differences from our respective points of view, particularly when actual commercial results secured with the Fynn-Weichsel motor bear out the analysis presented in my paper. I will confine my closing remarks in the discussion to a reference to some of the points in Mr. Fynn's discussion where his conclusions are erroneous and where the actual service performance of the motors conclusively supports my point of view. I shall make no reference to those paragraphs which I deem of minor importance.

While participating in the early theoretical development of the Fynn-Weichsel motor, Mr. Fynn has not had the advantage of contact with the commercial development and has probably not had access to actual performance test data of the character to which I refer below.

Before replying to some of the different criticisms which Mr. Fynn has made in his communication, I desire to state that those parts of my paper which deal with the working principle of this machine have, as their main object, the presentation of *fundamental* laws which govern the working of this new type of machine. It was my purpose to free these explanations, as much as possible, from any secondary considerations that would tend to obscure the main fundamental laws.

I regret, therefore, that Mr. Fynn has found it advisable to criticise several of my statements and conclusions on the ground that they lack accuracy, and also that he has entered into a discussion of various details.

In presenting the theory of the starting and synchronizing performance, my reason for the line of discussion pursued in my paper grew out of my desire to give the reader the train of thought which had led me to the discovery that a motor of this type must develop a very powerful torque when the d-c. brushes coincide with the axis of the d-c. field winding, and develop a diminishing synchronizing torque as the brushes are moved out of this position.

The first public statement giving the reasons for the remarkable synchronizing torque of this new type of motor was made by me, February 16, 1924, before the Association of Iron and Steel Electrical Engineers in Pittsburgh.

In the early part of his written communication, Mr. Fynn repeats, in different wording, the statement made in my paper in connection with Figs. 6 and 12 and also the conclusions referred to by me in regard thereto; as well as further statements made in connection with Figs. 9, 11, 12, and 13 of my paper; also, my Fig. 10 and corresponding text.

By some of these statements, Mr. Fynn conveys the impression that I set forth variations in resistance as the "determining factor" with respect to synchronizing torque. It will, however, be found that I also fully discuss the bearing of the phase of the brush voltage upon this matter.

Considerable emphasis is laid by Mr. Fynn upon the fluctuations of torque after the motor has been overloaded to a point pulling it out of synchronism and resulting in its operation as an induction motor. As stated in my paper, it is true that there are very rapid pulsations in torque under these conditions, but it must be remembered that there are not corresponding variations of speed of the motor.

The corresponding speed variations of the motor are considerably less than the torque variations, because of the inertia of the rotor and of the driven load. These relations are similar to those which hold the speed fluctuations of a reciprocating engine low. Fig. 11 herewith illustrates an oscillogram taken by the University of Washington, showing the line-current fluctuations under such conditions. These fluctuations are of somewhat of the same order of magnitude as the torque fluctuations. In practise, neither the current nor speed variations are found detrimental to the electric service, nor to the durability of the motor when such temporary overload conditions are not excessively prolonged. A very interesting demonstration of this fact is a commercial installation of the Fynn-Weichsel motor driving a high-speed grinding wheel. On every service use of the grinding wheel the Fynn-Weichsel motor is pulled out of synchronism, immediately returning to synchronism on the withdrawal of the excessive load from the face of the emery wheel. This installation has been in operation for over a year and while not a recommended type of service for the Fynn-Weichsel motor, it has proved a very interesting application, having been made solely for the purpose of testing the physical result of such service upon this type of motor, and having demonstrated two important factors—

First, that the service does not disturb adjacent motors operating from the same circuit;

Second, that there has been no deterioration of the Fynn-Weichsel motor under these conditions of service.

A further fact might be noted—that the operator of the grinding wheel is unconscious of the motor changing from the synchronous to the induction operating characteristic. Actual tests made with a tachometer on a 100-h. p., 600-rev. per min. motor, as well as on several smaller sizes, showed no measurable speed fluctuations when the machine operated as an induction motor; *i. e.*, beyond its horse power capacity as a synchronous machine.

Mr. Fynn attacks my Fig. 9c on the ground that this figure represents conditions when the motor operates very nearly at synchronism, and he states that, under such conditions, the ratio of torque $T-3$ to $T-1$ plus $T-2$ is materially larger than shown in my Fig. 9c.

The error in Mr. Fynn's statement will be found in his sentence "with a small slip at full load or at less than full load and under *no other conditions* are the secondary voltages and currents nearly in phase."

In that part of my paper which precedes my discussion of Fig. 5, it is clearly stated that the secondary voltage and currents in a machine containing leakage are nearly in phase when the currents do not materially exceed the full-load value.

Such a condition exists not only when the machine operates with small slip and no external resistance in the secondary but *also* when the machine operates with large slip and large resistance in the secondary, such as, for instance, occurs during the starting period of the machine. This is in exact agreement with the phenomena which occur in this respect in connection with standard slip-ring induction motors.

My Fig. 9c pictures correctly the conditions represented in my Fig. 10 by Curves 2 and 5 for a speed of about 80 per cent of synchronous speed and a load approximately equal to full load torque. Mr. Fynn's arguments and conclusions in this connection are, therefore, wrong, due to the faulty assumption upon which they have been based.

He states that serious mistakes exist in my Fig. 10 and asserts that I had represented the increased torque due to the injected voltage e_c not only as if it were constant but as if it were applied to both secondary phases. Further, he states that I added the maximum value of the single-phase, pulsating torque, $T-3$, produced by winding F, to the constant induction motor torque, $T-1$, plus $T-2$, and offered their sum as the resultant torque of the motor. This is a misunderstanding of the statements made in my paper. In connection with Fig. 9, I fully explained that the torque due to the injected voltage, e_c, is pulsating. In the first part of my paper there is a statement as follows: "Therefore, if the load connected to the primary has a fairly large amount of inertia the *average* torque available on the motor lies about half way between the induction motor speed torque curve and the speed torque curve which is shown in Fig. 10." This statement definitely contradicts Mr. Fynn's assertion that I had assumed the torque due to the injected voltage as constant.

Referring to his second claim, that I presented the increased torque due to injected e. m. f. as if it were applied to both secondary phases, I state: "The conditions in the winding A cannot

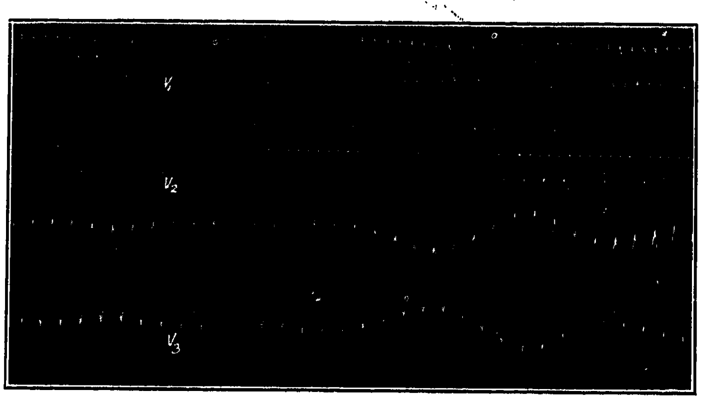

Fig. 11—Synchronous to Induction Operation of Fynn-Weichsel Motor

V_1 is the timing wave. V_2 is the line voltage. V_3 Line current.

in any manner be altered by injecting a current in winding F, and, therefore, the torque produced by winding A remains unaltered, etc."

The mistake made by Mr. Fynn lies in *his assumption* that the horizontal difference between Curves 1 and 6, or 2 and 5, or 3 and 4, represents an *average* torque. However, no such statement has been made by me, but one to the contrary in that part of the paper just cited, where I pointed out that this torque difference fluctuates. The length of the horizontal line between Curves 5 and 6 represents the time maximum of the torque due to the injected voltage. That this relation must exist not only follows from the text of my paper but also directly from Fig. 10, where the length of the line, $100-A$, represents the *maximum* torque of the motor when operating at synchronism; and the maximum torque of a motor at synchronism must, by the nature of things, be also the maximum torque immediately before synchronism is reached.

The wrong assumptions made by Mr. Fynn also led him to the misstatement in regard to the resultant torque of the motor.

The most erroneous statement is where he says that if conditions are actually as indicated in my Fig. 10 "the machine could not run synchronously unless the torque required was 230 per cent of normal. For smaller torque demands the motor would run at speeds greatly exceeding this synchronous speed." This statement is in contradiction to my Fig. 10, where the speed-torque curve of the motor, with no external resistance in the secondary, is given by the curve, $100-A-6$. The part $100-A$ of this curve corresponds to loads from zero to 230 per cent and during this part, the speed torque curve is a horizontal line passing through the 100 point, which means that the speed is independent of the load.

Statement is made that an asynchronous overload of 300 per cent is pure waste. This is completely overlooking the fact that an important factor in this type of machine is its synchronizing ability. A machine whose maximum torque as a synchronous motor is 200 per cent can synchronize a load of 200 per cent, provided the load is a pure friction load. If, however, the inertia is very excessive, the same machine can synchronize only about 100 per cent full load, as explained in my paper. However, this latter extreme condition is never accounted for in practise. Therefore, in order to provide an ample margin for safely synchronizing full-load torque, or more, under almost any kind of load which may be met in practise, it is *essential* to give these motors a maximum synchronous horse-power capacity in the neighborhood of 200 per cent. The overload capacity of the machine as an asynchronous motor is incidental and is achieved without extra expense.

Later in his written discussion, Mr. Fynn appears to create the impression that the commutator must be dimensioned for three times normal load secondary current. Anyone familiar with the design of motors knows that it is useless to dimension electrical parts of a machine in accordance with the momentary overload which the machine can carry. A glance at Fig. 3 of my paper justifies my statement there that the commutator is relatively small.

Again my Fig. 21 is criticized because it is not drawn to scale. It is a generally accepted expedient to do this in such cases in which some of the vectors would otherwise nearly coincide. The main object, as indicated by the italicized letters in the text belonging to this figure, is to show that, at any load, the d-c. armature ampere-turns are counterbalanced by equivalent a-c. ampere-turns. Mr. Fynn now thinks that this is selfevident. My diagram Fig, 21 proves that the Fynn-Weichsel motor does *not* operate as a synchronous converter, because only a *small* part of the a-c. ampere-turns is used to counterbalance the d-c. ampere-turns, while in a converter, the a-c. and d-c. ampere-turns are essentially of the same magnitude and opposed.

Further on, he criticizes my statement that this new motor operates from commutating point of view similar to a neutralized d-c. machine in which the neutralizing winding is weaker than the d-c. armature reaction. In my judgment, this statement pictures the analogy quite correctly in view of the fact that the d-c. armature field is, at any time, completely neutralized as shown in my Fig. 21, but the component of the resultant field, which is in line with the brush axis, is not wiped out. If the brushes are shifted in the direction of rotation, which is the only practical way of shifting them, the commutation conditions for the maximum load point frequently first improve, and, by a still further shift, become more difficult. By suitably selecting the magnitude of different constants of the machine, such as brush-angle, leakage-reactance, etc., it is possible to obtain the point of theoretically correct commutation for almost any load point desired.

Still further on Mr. Fynn arrives at certain conclusions regarding the heating and losses of these machines. His reasoning that, for equal losses, a winding covering only two-thirds of the circumference must be very much hotter than a winding having the same losses but with them distributed over the whole circumference, is a quite common argument, but actual experience has proved this to be wrong. If his views were correct, it would be necessary to use larger sizes of copper for certain coils in the arma-

ture of a standard synchronous converter, and this practical experience has proven to be unjustifiable.

In the "induction type of synchronous motors," such as is built in Europe, one part of the winding has four times the loss of the remaining winding, when equal copper section is used for all coils. Experience has shown that equal copper section for all coils can be used without resulting in unallowable inequality of heating.

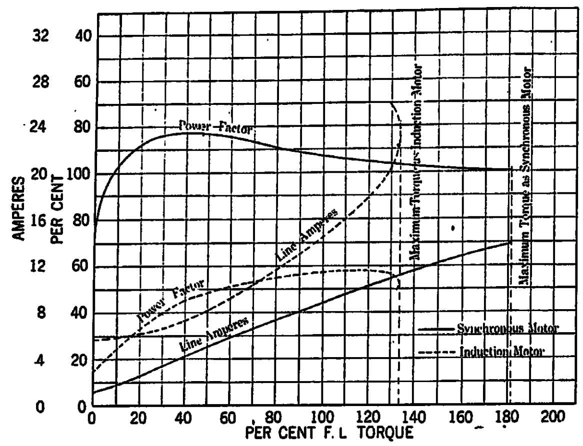

FIG. 12—7½-H. P., 60-CYCLE, FOUR-POLE, THREE-PHASE FYNN-WEICHSEL MOTOR OPERATING AS SYNCHRONOUS MOTOR AND INDUCTION MOTOR

The Metropolitan-Vickers Company, in their circular No. 1041, December, 1921, describing this type of motor, state on page 7: "For manufacturing reasons the cross-section of the conductors is kept the same in all three phases, so that the heating is slightly unequal in the different parts of the winding. But due to the relatively large heat capacity of the iron, the temperature rise is practically uniform around the rotor."

With reference to Mr. Fynn's theoretical objection to the

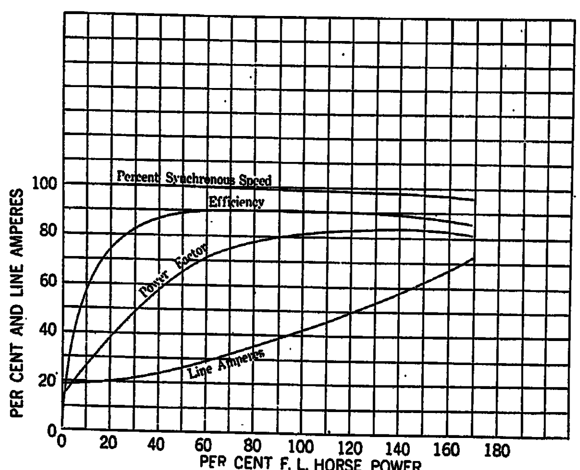

FIG. 13—PERFORMANCE CURVES FOR FYNN-WEICHSEL MOTOR

15-h. p., Four-pole, Three-phase, 60-cycles, 220-volts. Operated at normal voltage as an Induction Motor.

Fynn-Weichsel motor, that the primary currents are supplied through slip-rings, I shall merely say that extended and satisfactory experience with a large number of installations using these machines as general-purpose motors should be considered sufficient answer.

Mr. Fynn also suggests that any trouble with the commutator or brush mechanism will "put the machine out of commission." He quite overlooks, or neglects to state, that if the exciting current were suddenly broken, the Fynn-Weichsel motor would continue to operate as a polyphase induction motor with a single-phase secondary and load characteristics as shown in Fig. 12 herewith.

Normal load capacity of the motor under such circumstances can be fully restored by short-circuiting the excitation field winding, in which event, the motor will operate as a normal slip-ring, induction-type motor, as illustrated in Fig. 13. Figs. 12 and 13 are characteristic curves of all sizes of Fynn-Weichsel motors when operated under the conditions indicated.

Mr. Fynn expresses the view that the Fynn-Weichsel motor

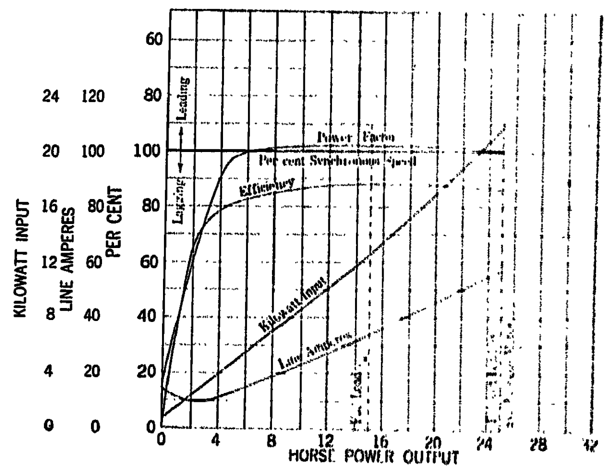

FIG. 14

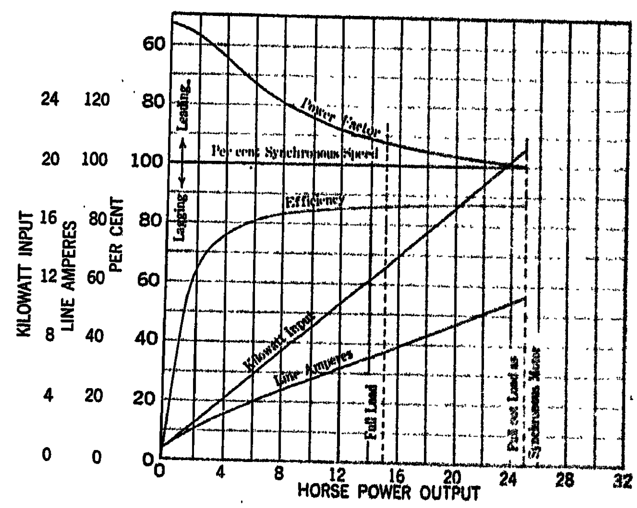

FIG. 15

FIGS. 14-15—CHARACTERISTIC CURVE OF FYNN-WEICHSEL MOTOR

This is a 15-h. p., four-pole, 60-cycle, three-phase motor. In Fig. 14 it is shown adjusted for approximately unity power factor. In Fig. 15, it is adjusted for leading power factor.

is not a general-purpose motor. It is being marketed as such and as such, is meeting with a most favorable reception. It can be installed whenever a good general-purpose d-c. motor can be installed, and the manufacturers are finding a surprising number of installations where the synchronous-speed characteristic is proving more advantageous for production purposes than the primary service of power factor correction. A large number of commercial installations in sizes of motors ranging from 5 h. p.

to 150 h. p., all made as general-purpose motor installations, suggests conclusively that the Fynn-Weichsel motor is, in fact, a general-purpose motor.

Mr. Fynn infers that the Fynn-Weichsel motor cannot operate at unity power factor. Fig. 14 illustrates a commercial test made by the Commonwealth Edison Company at Chicago, and it will be observed that the power factor is practically unity throughout the normal load range of the motor, this being a motor not designed for exact unity power factor operation but rather for operation as illustrated in Fig. 15.

Fig. 15 represents the same motor, also tested by the Commonwealth Edison Company, with no other modification than a slight change in the position of the exciting brushes, for the purpose of giving a strong leading power factor and thus compensating for the lagging power factor of an ordinary induction motor of the same size operating in the same plant, giving unity power factor on the two motors in combination.

Numerous corresponding tests have been made by a large number of the leading electric light companies of the country, and what the motor will do with respect to unity or leading power factor is not a matter of theory but of demonstrated fact, and while the above curves are test results on the 15-h. p. motor, similar characteristic performance results are given by motors of all sizes.

Mr. Fynn's employment of a diagram to establish statement that the Fynn-Weichsel motor cannot be designed to operate at approximately unity power factor over a large load range is erroneously employed, assuming design constants which would not be used were the Fynn-Weichsel motor to be designed for unity power-factor service.

Mr. Fynn's argument suggests that it would be advantageous and preferable to have these motors operate at unity power factor; in his argument he has overlooked the actual conditions which exist in present installations and probably will for many years to come. Due to the use of a relatively large percentage of induction motors in all installations, it is desirable to have the remaining machines in the installation operate with leading power factor in order to provide the necessary magnetization for the induction motors of this installation.

The Single-Phase Induction Motor

BY L. M. PERKINS[1]

Member, A. I. E. E.

Synopsis.—*The operation of the single-phase induction motor is presented according to the cross-field theory as distinguished from the theory of oppositely rotating fields. The mathematics used require only a knowledge of algebra and trigonometry and no factors, such as cross-field iron loss and cross-field magnetizing current, are neglected.*

In addition to the derivation of the vector diagram, its transformation into an accurate circle diagram, which requires no assumption except sine wave voltage and primary field distribution, is shown. The result is a circle diagram practically identical with that derived by Branson (A. I. E. E. PROCEEDINGS, *June, 1912) from comparison of the two-phase and single-phase induction motors, except that the derivation should be more easily followed and the result is a simpler diagram to construct and use.*

THE single phase induction motor consists of a primary winding connected to a source of alternating potential and placed in inductive relation to a short-circuited secondary winding which can move relative to the primary winding. A complete iron path, except for the air-gap necessary to allow relative motion between the two windings, is provided for the flux which interlinks the two windings. This interlinking flux is produced by the primary winding because of its connection to a source of alternating potential, and it is the effect of this flux on the short-circuited secondary winding in which we are interested.

The motor is shown schematically in Fig. 1. Although the secondary is considered as being wound

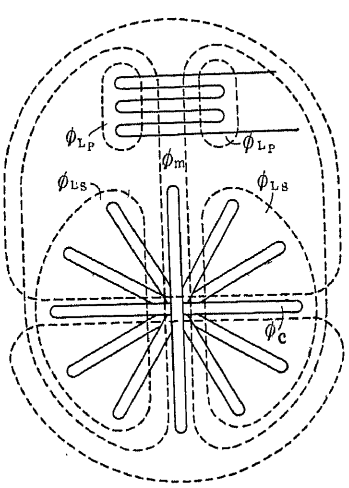

FIG. 1

with a number of individually short-circuited coils, in practise this construction is not used as it is mechanically so much easier to short circuit all the coils to each other by means of common-end rings. If the resistance of the end rings is negligible with reference to that of the bars, the two systems give identical results. Although high resistance end rings tend to distort the distribution of the secondary current from that of a true sine wave; this effect is negligible in practise so it will not be considered in this analysis. We will assume that the primary winding is so distributed as to produce a sine wave field form, and that the impressed voltage has a sine wave form.

In addition to the interlinking flux mentioned above, there are leakage fluxes around the different windings which do not link with all the windings. As shown in Fig. 1, there is a flux ϕ_{LP}, threading through the primary winding in addition to the mutual flux ϕ_m, which threads through both primary and secondary windings. Also there is a leakage flux ϕ_{LS} threading through the secondary but not the primary. Furthermore, there is another flux ϕ_C, as will be shown later, which does not thread the primary winding but only the secondary along an axis at right angles to the axis of the primary flux. The total flux threading through the primary is $\phi_{LP} + \phi_m$ which we will call ϕ_1, while the total flux threading through the secondary along the axis of the primary is $\phi_{LS} + \phi_m$ which we will call ϕ_2, and the total flux threading through the secondary at right angles to the primary axis is ϕ_C. In addition to being threaded by fluxes each coil cuts fluxes.

A voltage is generated in a coil by a change in the total flux threading the coil, whether this change is caused by a change in the total amount of flux; or whether, with a constant flux, the coil turns so as to be threaded by more or less of the total flux. The voltage induced in a coil by a change in the total flux is generally known as a transformer voltage and is proportional to the frequency of variation of the flux and to the total flux. The voltage induced in the coil as it turns so as to include more or less of the total flux is known as the cutting voltage and is proportional to the speed of cutting and to the density of the flux at the point where the coil cuts it. If the flux is varying as the coil turns the net voltage generated is the sum of the voltage generated by transformer action and cutting action.

We will assume an alternating flux ϕ_2 threading the secondary along the primary axis and will investigate the voltages generated in the various coils by their cutting this flux, and the voltages generated in the same coils due to the alternation of this flux through the coils. Also we will find what other voltages, currents, or fluxes are produced by these voltages.

1. Westinghouse Electric & Mfg. Co.

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 9-12, 1925.

A coil at *a*, Fig. 2, will not cut any of the flux ϕ_2, while a coil at *d* will cut the flux ϕ_2 at the point of maximum density. The voltage generated in the coil *a* will then be zero while that generated in coil *d* will be a maximum. Since the flux ϕ_2 is assumed to have sine wave distribution, the voltage generated in any coil will be proportional to the sine of the angle between that coil and the coil *a*. This voltage causes a current to flow in each coil and these currents produce a flux ϕ_c along the axis at right angles to the original flux

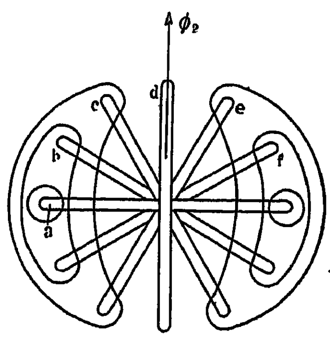

Fig. 2

ϕ_2. We will assume that this flux has a sine wave distribution, although this assumption will have to be justified later. Since the flux ϕ_2 is alternating the voltages generated in the coils by cutting this flux will also be alternating voltages, having maximum values at the time ϕ_2 is maximum and minimum values when ϕ_2 is minimum. The flux ϕ_c will also alternate because the currents producing this flux alternate with the voltages producing them. The alternating flux ϕ_c induces a transformer voltage in the coils threaded by this flux.

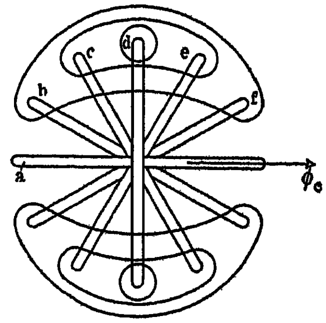

Fig. 3

Since the coil *d* includes all of this flux the voltage induced in it will be a maximum while the voltage induced in the coil *a* will be zero as it is not threaded by any of this flux. As we have assumed sine wave distribution of the flux ϕ_c the transformer voltage induced in any given coil will be proportional to the sine of the angle of the coil from the coil at *a*. Then in coil *d* there is a voltage E_3, Fig. 4 induced by the coil cutting the flux ϕ_2 and this voltage is in phase with this flux, as shown above. In addition to this voltage, another voltage E_6 is generated in this coil by transformer action of the flux ϕ_c. This voltage lags 90 deg. behind the flux ϕ_c because the transformer voltage always reaches its maximum 90 deg. later than the maximum of the flux which generates the voltage. Since the flux ϕ_c is the total flux, produced by the currents I_3, threading through the secondary along the axis at right angles to the primary axis, the only additional impedance to the current I_3 in the coil *d* is the resistance of the coil *d*. Then the $I\,r$ drop of the coil *d* will be overcome by the voltage which is the difference between the voltages E_3 and E_6, or $I_3\,r_2$ in Fig. 4. Due to iron loss, the flux ϕ_c is not exactly in phase with the current I_3 but lags slightly behind by the angle λ. For this reason, the voltage $I_3\,r_2$ is not exactly at right angles to the voltage E_6. We will assume in this analysis that the iron loss

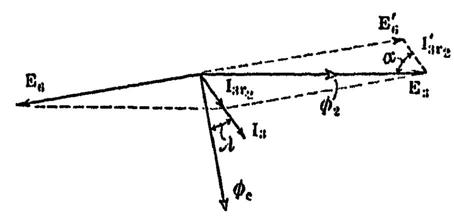

Fig. 4

is proportional to the square of the flux density in the iron, which is very close to the truth. With this assumption, the angle between the current I_3 and the flux ϕ_c is constant. Since there is no other winding threaded by the flux ϕ_c, than the secondary winding, the angle between E_3 and E_6 will remain constant as will the angle between ϕ_c and ϕ_2. Since E_3 depends on the speed, being a cutting voltage, the value of the different vectors will vary through a wide range but this will not vary their relative values nor the angles between them.

There are similar voltages to the voltages E_3 and E_6

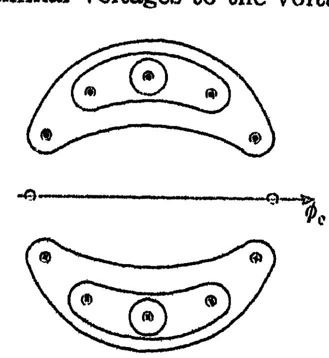

Fig. 5

generated in each of the coils *a*, *b*, *c*, *e* and *f*, although these voltages are not of the same value as the voltages generated in the coil *d* as was shown above. However, the voltage E_3' generated in any coil by that coil cutting the flux ϕ_2 will have the same phase as the voltage E_3 generated in the coil *d* by cutting the same flux. In the same way the transformer voltage E_6' generated

in any coil by the flux ϕ_c will have the same phase as the voltage E_6 in coil d but will be smaller. As shown above, these voltages are both proportional, in the different coils, to the sine of the angle between the given coil and the coil at a. It follows then that the difference between these voltages will also be proportional to the sine of the angle between the coil in question and the coil at a. But since the current I_3 in any coil is proportional to the difference between the voltages E_3 and E_6 it follows that the current I_3 in any given coil will be proportional to the sine of the angle between that coil and the coil at a. In other words the currents I_3 are in phase in the different coils and the current is distributed according to the sine law as shown in Fig. 5. It follows that the flux ϕ_c produced by these currents will have a sine wave field form. But this was the assumption made in the beginning so that all conditions for the production of the flux ϕ_c with sine wave field form have been met, and that will be its field distribution.

In addition to these voltages E_3 and E_6 there are two

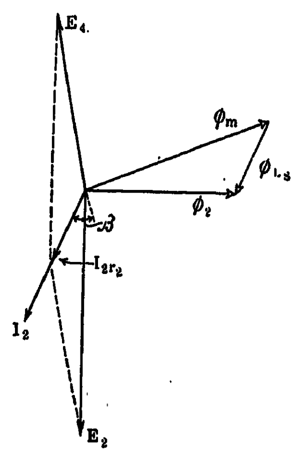

Fig. 6

other voltages generated in each coil, first a transformer voltage due to the flux ϕ_2 threading the coil and second a cutting voltage due to the coil cutting the flux ϕ_c. This transformer voltage is maximum in the coil a which is threaded by all of the flux ϕ_2 and minimum in the coil d which is threaded by none of the flux ϕ_2, and is proportional in the different coils to the cosine of the angle between the given coil and the coil at a. Also the voltages induced by the coils cutting the flux ϕ_c is maximum in the coil a and zero in the coil d, being proportional to the cosine of the angle between the given coil and the coil at a, since the flux ϕ_c has sine distribution. The vector diagram for coil a is shown in Fig. 6 where E_2 is the transformer voltage due to the flux ϕ_2 and E_4 is the voltage due to the coil a cutting the flux ϕ_c. E_2 lags 90 deg. behind ϕ_2 while E_4 is 180 deg. from ϕ_c. Since all leakage fluxes are considered in ϕ_2 the voltage difference between E_2 and E_4 will overcome the $I\,r$ drop of the coil a and force a current I_2 through the coil in phase with this voltage difference $I_2\,r_2$. Since both E_2 and E_4 are proportional to the cosine of the angle between any given coil and the coil at a, the current I_2 in that coil will be proportional to the cosine of the angle between that coil and the coil at a. It follows that the current I_2 will be distributed in the various coils according to the sine law as shown in Fig. 7.

In any other coil than a or d all four voltages E_3, E_6, E_2 and E_4 will be generated and the net current in that coil will be proportional to the net difference between all these voltages. However, this net current will be equal to the sum of the two currents I_3 and I_2 assumed

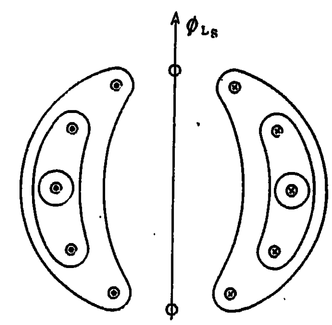

Fig. 7

to flow in the given coil in the above analysis. It makes no difference whether the net current or the two components are considered. Fig. 8 shows the vector diagram for the coil b 30 deg. from coil a. As shown, the total current I_S is the sum of I_3^1 and I_2^1, the voltages E_3^1 and E_6^1 being one half (or sine 30 deg.) of their values in coil d while the voltages E_2^1 and E_4^1 have .866 (or cos 30 deg.) of their values in coil a.

As shown in Fig. 5, the current I_3 is so distributed

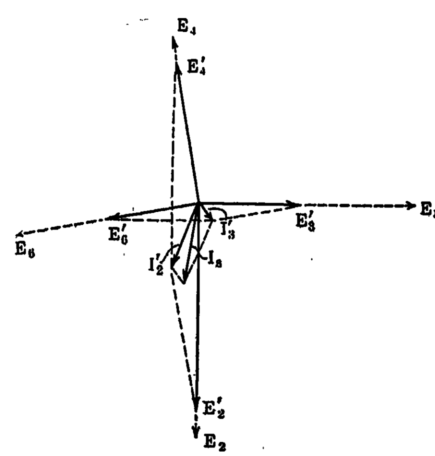

Fig. 8

in the secondary as to produce no ampere-turns along the primary axis, and will not affect the primary winding directly. However, the currents I_2 are so distributed as to act directly on the same flux path as the primary winding so that this current will be transferred to the primary by transformer action.

The flux ϕ_c is the total flux produced by the currents I_3 but the currents I_2 produce a leakage flux ϕ_{LS} in phase with I_2 along the primary axis and as we saw

above the flux ϕ_2 is the sum of ϕ_m and ϕ_{ls}. Therefore, the flux ϕ_m is the difference between the flux ϕ_2 and ϕ_{ls}, as shown in Fig. 6.

In order to force the flux ϕ_m (Fig. 9) across the air gap a resultant magnetizing current must flow in the primary winding producing ampere turns slightly leading the flux ϕ_m by the angle λ_1. (This angle is caused by the iron loss as we saw above.) But before these ampere-turns can act on the flux path the ampere-

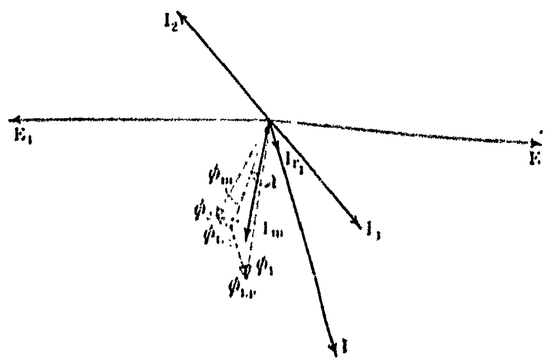

FIG. 9

turns produced by the currents I_2 acting on this same path must be neutralized by equal and opposite ampere-turns produced by the primary winding. Then the total primary current will be equal to the sum of a current I_1 (Fig. 9) equal and opposite to the secondary current (assuming one to one ratio) and a magnetizing current I_m leading the flux ϕ_m by the angle λ_1. The total current will be I in Fig. 9.

Due to this current I a leakage flux ϕ_{lp}, in phase with I is produced threading the primary winding as shown

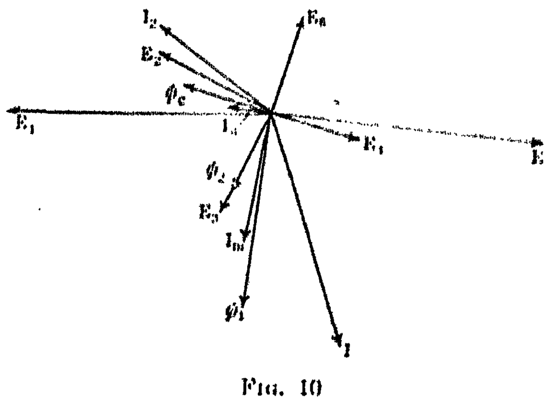

FIG. 10

in Fig. 1, and the total flux threading the primary is ϕ_1 the sum of ϕ_m and ϕ_{lp} as shown in Fig. 9. Due to this flux ϕ_1 a transformer voltage E_1 is induced in the primary winding and the voltage difference $I\,r_1$ between the line voltage and this transformer voltage, forces the current I through the resistance of the primary winding.

The complete vector diagram for the conditions assumed is shown in Fig. 10. Although Fig. 10 shows the complete diagram, it is in such form as to make it very hard to follow such changes as are produced by a change in speed. A simplified diagram which shows all the component vectors is shown in Fig. 11. As will be noted, the two component primary currents I_1 and I_m are considered instead of the total current I, and since I_2 is equal to I_1, the net result is as though the current I_2 flows through both primary and secondary windings while an additional magnetizing current, I_m flows through the primary winding only. There is an additional magnetizing current I_3 in the secondary but as was shown, it does not directly affect the primary. The voltages $I_m\,x_1$, $I_2\,x_1$ and $I_2\,x_2$ are reactance voltages

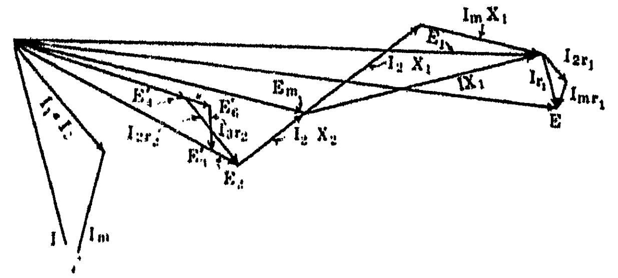

FIG. 11

generated in the windings by the leakage fluxes produced by the currents I_m in the primary and I_2 in both primary and secondary. The voltage $I\,x_1$, which is the sum of $I_m\,x_1$ and $I_2\,x_1$ is the transformer voltage produced in the primary winding by the total primary leakage flux ϕ_{lp}. $I\,x_1$ is at right angles to ϕ_{lp} (Fig. 9). In the same way $I_2\,x_1$ and $I_2\,x_2$ are at right angles to and proportional to I_2. $I_m\,r_1$ has the same phase as I_m while $I_2\,r_1$ and $I_2\,r_2$ have the same phase as I_2.

For the time being we will consider that the primary resistance is zero and that there is no primary iron loss, so that I_m is in phase with ϕ_m and λ_1 is zero. Later we will show the effect of these two losses on the diagram. With this assumption, the vectors E and $I\,r_1$ ($= I_m\,r_1 + I_2\,r_1$) drop out and the diagram which we are considering is shown in Fig. 12.

Since I_m is in phase with ϕ_m, $I_m\,x_1$ will be parallel to E_m because both $I_m\,x_1$ and E_m, being transformer

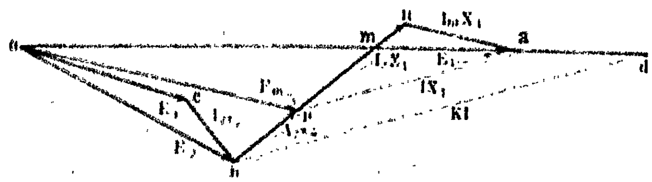

FIG. 12

voltages, are at right angles to the current producing the transformer flux. Also we know that $I_m\,x_1$ will have a constant ratio to E_m because $I_m\,x_1$ is the voltage generated by a leakage flux produced by the current I_m while E_m is the voltage generated in the same winding by the useful flux ϕ_m produced by this same current I_m. The ratio between $I_m\,x_1$ and E_m is the ratio between

the permeance of the leakage flux path and the permeance of the useful flux path. If we let $\frac{E_m}{I_m} = z_m$, $\frac{E_m}{I_m x_1}$ will equal $\frac{z_m}{x_1}$ where $\frac{z_m}{x_1}$ is the ratio between the permeance of the useful flux path and the permeance of the leakage flux path.

Since E_m and $I_m x_1$ have a constant ratio, regardless of other changes in the diagram, it follows that the lines $o\,m$ and $m\,a$ in Fig. 12 are proportional and have a constant ratio (similar sides of similar triangles $o\,p\,m$ and $m\,n\,a$) and that the point m is a fixed point on the line $o\,a$ regardless of other changes in the diagram. Furthermore, because $p\,m$ and $m\,n$ are the other sides of these same triangles, they will also be similar and, therefore, proportional

to $\frac{z_m}{x_1}$

$$\frac{m\,n}{p\,m} = \frac{x_1}{z_m} \qquad \frac{m\,n + p\,m}{p\,m} = \frac{z_m + x_1}{z_m}$$

$$m\,p = \frac{z_m}{z_m + x_1} \times p\,n$$

$$p\,b + p\,m = I_2\,x_2 + I_2\,x_1\left(\frac{z_m}{z_m + x_1}\right)$$

Therefore,

$$m\,b \text{ (which } = p\,m + b\,p) = I_2\left(x_2 + x_1\frac{z_m}{z_m + x_1}\right)$$

Since x_2, x_1 and z_m are constants, it follows that the line $m\,b$ is proportional to I_2.

The line $p\,a$ is proportional to $I\,x_1$ and therefore to I, but we do not wish to have to find the point p in the final diagram so we will find another line from b which will be proportional to I. From b draw the line $b\,d$ parallel to $p\,a$ until it intersects $o\,a$ at d. Then $\frac{b\,d}{p\,a} = \frac{m\,b}{m\,p}$. But $\frac{m\,b}{m\,p}$ is a constant, so it follows that $\frac{b\,d}{p\,a}$ is a constant and $b\,d$ is therefore, proportional to I, since pa is proportional to I.

Since the sides $m\,b$ and $m\,p$ of the similar triangles $a\,m\,p$ and $d\,m\,b$ have a constant ratio and since $a\,m$ is constant as proved above, it follows that $m\,d$ will also be constant and, therefore, that the point d is a fixed point on the line $o\,a$, regardless of any changes in the diagram due to changes in the load or speed of the motor.

To prove

$$\frac{o\,a}{o\,d} = \frac{z_m}{z_m + x_2}$$

and

$$\frac{o\,m}{o\,d} = \left(\frac{z_m}{z_m + x_1}\right)\left(\frac{z_m}{z_m + x_2}\right)$$

Let

$o\,m = z_m$, then $m\,a = x_1$ and $a\,d = x_2\left(\frac{z_m + x_1}{z_m}\right)$

$$o\,d = z_m + x_1 + x_2\left(\frac{z_m + x_1}{z_m}\right)$$

$$= \frac{(z_m + x_1)\,(z_m + x_2)}{z_m}$$

$$\therefore \frac{o\,m}{o\,d} = \frac{z_m^2}{(z_m + x_1)\,(z_m + x_2)}$$

$$o\,a = z_m + x_1$$

$$\therefore \frac{o\,a}{o\,d} = \frac{(z_m + x_1)\,z_m}{(z_m + x_1)\,(z_m + x_2)} = \frac{z_m}{z_m + x_2}$$

Redrawing Fig. 12, and leaving out unnecessary lines, we have Fig. 13, where $X_2 = x_2 + x_1\frac{z_m}{z_m + x_1}$ and $o\,d = E_1 \times \frac{z_m + x_2}{z_m}$

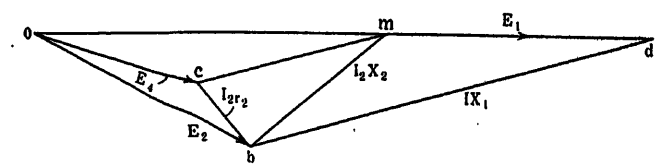

FIG. 13

It was proved in connection with Fig. 4 that the angle between the fluxes ϕ_2 and ϕc is constant regardless of other changes in the vector diagram. Since E_2 is 90 deg. from ϕ_2 and E_4 is in line with ϕc it follows that the angle between E_2 and E_4 is constant. It has also been proved that the lines $m\,b$ and $b\,c$ are both proportional to the secondary current I_2 so the triangle $m\,b\,c$ will always have the same shape and proportion of parts regardless of its size. We know further that the ratio $\frac{E_6}{E_3}$ is constant, from Fig. 4. It is also true that the ratio $\frac{E_4}{E_6} = \frac{\text{speed}}{\text{syn. speed}}$ because E_4 is the voltage generated in the coil a by putting the flux ϕc while E_6 is the voltage generated in the identical coil d by transformer action of the same flux ϕc and the cutting voltage becomes equal to the transformer voltage at synchronous speed. In the same way $\frac{E_3}{E_2} = \frac{\text{speed}}{\text{syn. speed}}$ Then it follows that $\left(\frac{\text{speed}}{\text{syn. speed}}\right)^2 = \frac{E_4\,E_3}{E_6\,E_2} = \frac{E_4}{E_2}$ times a constant. Knowing these

relations, the effect of changes of load on the diagram can be followed more easily.

If the load is decreased, the triangle $m\ b\ c$ becomes smaller while if the load is increased, the triangle becomes larger. But, regardless of its size the vertices b and c must remain on the opposite sides of the constant angle $b\ o\ c$ having its vertex at o. In order to fulfill these conditions the angle $b\ o\ c$ must swing down as the triangle $m\ b\ c$ increases in size. Fig. 14 shows how the diagram changes with reference to that shown in Fig. 13 when the load is increased over that in the case of Fig. 13. Since the line $o\ c$ is much shorter, in proportion to the line $o\ b$, in Fig. 14, than it is in Fig. 13, it follows that the speed for the condition of Fig. 14

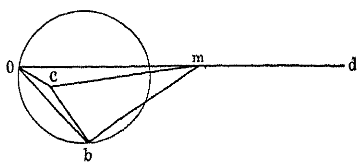

Fig. 14

will be lower than that for Fig. 13. If the line $o\ c$ is made equal to zero or in other words, the speed is zero, the diagram changes to that shown in Fig. 15. If, on the other hand, the load is decreased so that $o\ c$ becomes longer and the triangle $b\ o\ c$ swings up, at synchronous speed the diagram takes the form as shown in Fig. 16. In this case $o\ c$ represents both E_4 and E_6 while the line $o\ b$ represents both E_3 and E_2. Then triangle $b\ o\ c$ will be similar to the triangle shown in dotted lines in Fig. 4 and composed of the sides E_3, E_6^1, and $I_3\, r_2$. It is evident that, since the line $b\ c$ coincides with the line $I_3\, r_2$ and $b\ c = I_2\, r_2$, at this speed I_2 will equal I_3.

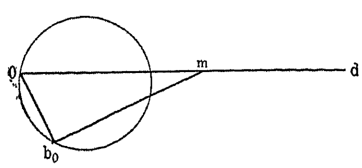

Fig. 15

In Appendix A, will be found the proof of two propositions; first that if two circles are drawn on similar parts of the hypotenuse and one leg of a right triangle, any right triangle having one vertex at the vertex of the original triangle and the other two vertices on the respective circles will be similar to the original triangle; and second, that the two vertices on the circles will lie on the two sides of a constant angle having its vertex at the intersection of the two circles. But these are the conditions to be fulfilled in the diagram above as the load changes, namely that the triangle $m\ b\ c$ must always be the same shape with its vertex at the point m and the two vertices b and c must lie on the two sides of the constant angle $b\ o\ c$, between the voltages E_2 and E_4. Therefore, the point b will follow a circle as the load changes while the point c will follow another circle as the load changes. It is then necessary to determine the location of these circles with respect to the line $o\ d$.

A circle is determined by three points on its circumference. We know three points on the circle locating the point b as follows.

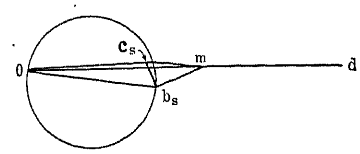

Fig. 16

First, both circles must pass through the point o, as the vertex of the constant angle must lie on their intersection.

Second, Fig. 15 gives the location, b_0, Fig. 17, of the point b for zero speed conditions.

Third, the diagram of Fig. 16 gives the location, b_s Fig. 17, of the point b for the synchronous speed condition.

Then, the first circle locating the point b can be drawn through these three points. The second circle is determined from the first by the use of the first proposition in Appendix A. A line $m\ b_2\ b_1$ is drawn from m through the center of the first circle (Fig. 17) and on this line as one leg, the triangle $m\ b_1\ c_1$ is constructed similar to the triangle $m\ b_0\ o$. Then the line $c_1\ c_2$ is laid off so that $\frac{c_1\ c_2}{b_1\ b_2} = \frac{c_1\ m}{b_1\ m}$; $c_1\ c_2$ is the diameter of the second circle.

Then any line such as $m\ b$ drawn to the first circle and the line $b\ c$ at right angle to $m\ b$ form the two legs of the right triangle showing the voltage drops due

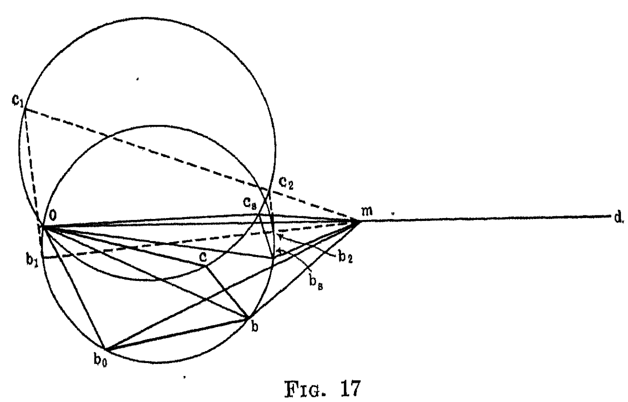

Fig. 17

to the load current and the line $o\ c$ represent E_4 while the line $o\ b$ represents E_2. Since speed is proportional to $\sqrt{\frac{E_4}{E_2}}$ it follows that the speed for the load shown by the line $m\ b$ can be found from the lengths of $o\ c$ and $o\ b$.

It will be shown later that the torque produced may also be found from the two lengths $o\ c$ and $o\ b$. It has already been shown that the primary current is represented by the line $d\ b$ in amount but that $d\ b$ is at right angles to the current I, while $m\ b$ represents the secondary current in amount, but 90 deg. out of phase. Fig. 17, therefore, shows speed, torque, primary current and secondary current and the phase of the two currents. This diagram may be very much simplified without destroying its usefulness.

Since the line $o\ c$ is the only one determined by the second circle, it is very desirable to find a line in the first

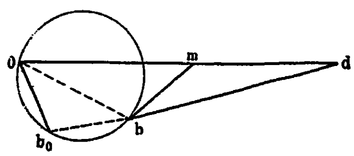

FIG. 18

circle proportional to $o\ c$. Such a line proportional to $o\ c$ is the line $b\ b_0$ Fig. 17, as is proved in Appendix *B*. The diagram may then be drawn as shown in Fig. 18, where the different lines represent the following quantities.

$o\ d$ represents E_1 to scale and in phase.

$o\ b$ represents E_2 to a different scale and in phase.

bb_0 represents E_4 to a still different scale but not in phase.

$b\ d$ represents I to a certain scale 90 deg. from correct phase.

$m\ b$ represents I_2 to a different scale 90 deg. from correct phase.

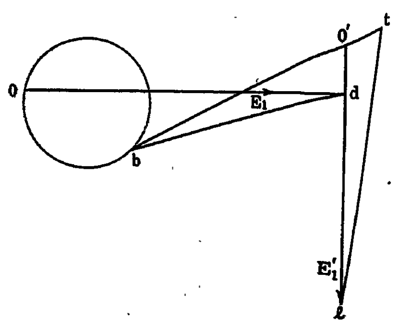

FIG. 19

So far we have neglected the primary iron loss and the primary copper loss in drawing the diagrams.

The iron loss in the stator is proportional to the flux ϕ_1 squared. Since we are assuming a constant voltage E_1 and therefore a constant flux ϕ_1 the stator iron loss will be constant. The rotor iron loss due to the primary flux is proportional to the flux ϕ_2 squared, so it will decrease as the load increases since the flux ϕ_2 decreases with an increase in load. But the motor slows down as the load increases and the rotor iron loss is very small at synchronous speed and larger at lower speeds, so the iron loss will increase for a given flux ϕ_2 at lower speeds. The increase in loss, due to the lower speed offsets the decrease in loss due to the decrease of the flux ϕ_2. For this reason, it is justifiable to assume that the total primary iron loss is constant if E_1 is constant. This loss may be considered as being supplied from the line by means of a small additional current I_{Fe} flowing through the primary n addition to the current I, considered so far. Since $b\ d$ represents I in amount but is 90 deg. from the proper phase, if we wish to add the current I_{Fe} to I we may do so by drawing a line $d\ o^1$, Fig. 19, representing I_{Fe} to the same scale as $b\ d$ represents I and at right angles to its correct phase. Then the total primary current I^1 will be $o^1\ b$ Fig. 19, to the same scale as $b\ d$ represents I.

Due to this current I^1 there is a voltage drop $I^1\ r_1$ in the primary caused by the primary resistance r_1. This voltage is in phase with the current I^1 and there-for at right angles to the line $o^1\ b$, when $o\ d$ represents the phase of the voltage E_1 and $o^1\ b$ is 90 deg. from I^1. In order to simplify the diagram, we will let $o^1\ b$ repre-

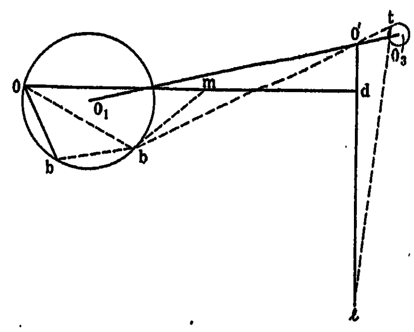

FIG. 20

sent the phase of the primary currents in which case the primary voltage must be represented by a line $o^1\ e$ at right angles to $o\ d$, and the primary resistance drop $I^1\ r_1$ is represented by a line $o^1\ t$, Fig. 19, in line with $o^1\ b$. Since the total line voltage is the sum of E_1 and $I^1\ r_1$, we will lay off $E_1 = o^1\ e$ from o^1 at right angles to $o\ d$ in which case $e\ t$ represents the line voltage to the same scale as $o^1\ e$ represents E_1.

Since $o^1\ t$ and $o^1\ b$ are both proportional to I^1 and the point b lies on a circle at all loads, the point t will also follow a circle. The two circles will have the ratio of diameters of $\frac{o^1\ t}{o^1\ b}$ and the centers of the two circles will be on the same line passing through the point o^1. The centers will also be at such distances that $\frac{o^1\ o_1}{o^1\ o_3}$ (Fig. 20) $= \frac{o^1\ t}{o^1\ b}$ (Fig. 19). Then Fig. 20 shows the complete circle diagram in which the different lines represent the following quantities.

$o^1\ b$ represents primary current in phase and to scale,

$e\ t$ represents line voltage in phase and to scale,

cos of angle $o^1\ t\ e$ equals power factor,

the lines $o\,b$ and $b\,b_0$ will give the speed and torque, the efficiency may be obtained from $\frac{\text{speed} \times \text{torque}}{E \times I^1 \times \cos o^1\, l\, e}$

If secondary current is desired it is represented by $m\,b$ to scale and phase.

It only remains to find the various constants and scales of the lines representing these quantities, so that the numerical results may be read from the diagram, and so that the diagram may be constructed when the constants of the given machine are known.

Torque

Torque is produced by the reaction of a current in a conductor on the flux cutting the conductor. Its instantaneous value is proportional to the product of the instantaneous current and the flux at that instant. If the flux and current are both alternating and in phase the maximum torque is proportional to the product of the maximum current and the maximum flux. If the current and flux are not in phase the maximum torque is proportional to the product of the maximum flux and maximum current and the cosine of the angle between them.

Since the cutting voltage is proportional to the flux times the speed, the flux will be proportional to the $\frac{\text{cutting voltage}}{\text{speed}}$ and this voltage will represent the flux in phase. It follows then that the torque is proportional to the

$$\frac{\text{cutting voltage} \times \text{current} \times \text{cos of angle between them}}{\text{speed}}$$

The secondary coil a Fig. 2, carries the current I_2 as shown in Fig. 6 and has the voltage E_4 generated in it by the flux ϕ_c. Then the torque produced will equal $\frac{E_4\,I_2\cos\beta}{\text{speed}}$. Each of the other coils will have a similar current and, therefore, will produce an additional torque. The total torque will be proportional to that in coil a. In the same way the current I_3 in coil d produces a torque with the flux ϕ_2, as do the currents I_3^1 in the other secondary coils and the total torque produced by all these currents is proportional to the torque produced by the coil d, or to $\frac{I_3\,E_3\cos\alpha}{\text{speed}}$

Since I_3 is less than 90 deg. from the cutting voltage E_3 as shown in Fig. 4, while I_2 is more than 90 deg. from the cutting voltage E_4 as shown in Fig. 6 it follows that one of these torques will be positive and the other will be negative. Then the net motor torque will be proportional to $\frac{I_2\,E_4\cos\beta - I_3\,E_3\cos\alpha}{\text{speed}}$

In order to evaluate this expression it is necessary to go back to Figs. 4 and 6 to find the relations between the various quantities. In Fig. 21, draw E_2 equal to E_2 in Fig. 6 and E_4^1 equal to but opposite to E_4 in Fig. 6. Then the line $I_2\,r_2$ will be equal to and in phase with the line $I_2\,r_2$ in Fig. 6. Along E_2 lay off a length equal to E_3 Fig. 4. Then a line at the same angle with E_3 as that between E_3 and a vector opposite to E_6 (Fig. 4) will fall along E_4^1. This is because the angle between E_2 and E_4^1 equals the angle between E_3 and E_6^1 since E_2 and E_3 are at right angles and E_4 and E_6 and also at right angles.

We see from Fig. 21, that $I_2\cos\beta = \frac{E_2\cos\theta - E_4}{r_2}$

and that $I_3\cos\alpha = \frac{E_3 - E_6\cos\theta}{r_2}$.

but

$E_3 = E_6\frac{\sin(90 + \lambda)}{\sin\alpha} = E_6\frac{\cos\lambda}{\sin\alpha}$ so that $I_3\cos\alpha =$

$$\frac{E_6\left(\frac{\cos\lambda}{\sin\alpha} - \cos\theta\right)}{r_2}$$

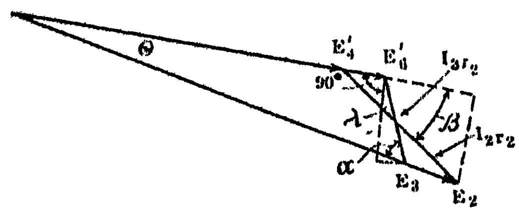

Fig. 21

and $\frac{E_3}{E_2} = \frac{\text{speed}}{\text{syn. speed}}$ while $\frac{E_6}{E_4} = \frac{\text{syn. speed}}{\text{speed}}$

so that $I_3\,E_3\cos\alpha = \frac{E_2\,E_4}{r_2}\left(\frac{\cos\lambda}{\sin\alpha} - \cos\theta\right)$

Then the net torque will be proportional to

$$\left(\frac{E_2\cos\theta - E_4}{r_2 \times \text{speed}}\right)E_4 - \frac{E_2\,E_4}{r_2 \times \text{speed}}\left(\frac{\cos\lambda}{\sin\alpha} - \cos\theta\right)$$

or $$\frac{E_2\,E_4\left(2\cos\theta - \frac{\cos\lambda}{\sin\alpha}\right) - E_4^2}{r_2 \times \text{speed}}$$

From Fig. 21, we see that $\frac{\cos\lambda}{\sin\alpha} = \frac{I_3\,r_2\cos\lambda}{E_6\sin\theta}$ but $I_3\cos\lambda$ is the current producing the crossfield flux ϕ_c by its magnetizing action ($I_3\sin\lambda$ furnishes iron loss in the same way as I_{e_r} furnishes primary iron loss.) so that E_6 is proportional to $I_3\cos\lambda$.

Since ϕ_c includes both the flux that goes into the stator (around a path having the same permeance as the path followed by the flux ϕ_m) and the flux following the path of the secondary leakage flux ϕ_{ls}, the total permeance of the path for the flux ϕ_c is proportional

to $z_m + x_2$, so that $E_6 = \dfrac{I_3 \cos \lambda}{z_m + x_2}$

$$\therefore \frac{\cos \lambda}{\sin \alpha} = \frac{r_2}{(z_m + x_2) \sin \theta}$$

and the net torque is proportional to

$$\frac{E_2 E_4 \left(2 \cos \theta - \dfrac{r_2}{(z_m + x_2) \sin \theta} \right) - E_4^2}{\text{speed}}$$

Speed

As has already been shown $\left(\dfrac{\text{speed}}{\text{syn. speed}} \right)^2$

$$= \frac{E_3}{E_2} \times \frac{E_4}{E_6} = \frac{E_4}{E_2} \times \frac{E_3}{E_6}$$

but, $\dfrac{E_3}{E_6} = \dfrac{\cos \lambda}{\sin \alpha} = \dfrac{r_2}{(z_m + x_2) \sin \theta}$

Therefore, speed = syn. speed

$$\times \sqrt{\frac{E_4}{E_2}} \times \sqrt{\frac{r_2}{(z_m + x_2) \sin \theta}}$$

Primary Current I^1

As shown above $b\,d$ represents I to a certain scale and $o^1 b$ represents I^1 to the same scale.

but $b\,d = p\,a \left(\dfrac{m\,b}{m\,p} \right)$ and $p\,a = I\,x_1$ while $\dfrac{m\,b}{m\,p}$

$$= \frac{x_1 \dfrac{z_m}{z_m + x_1} + x_2}{x_1 \dfrac{z_m}{z_m + x_1}}$$

Therefore,

$$b\,d = I\,x_1 \frac{x_1 \dfrac{z_m}{z_m + x_1} + x_2}{x_1 \dfrac{z_m}{z_m + x_1}} \text{ or } I \left(x_1 + \frac{z_m + x_1}{z_m} x_2 \right)$$

and it follows that

$$o^1 b = I^1 \left(x_1 + \frac{z_m + x_1}{z_m} x_2 \right) = I^1 X_1$$

Secondary Current I_2

As was shown above

$$m\,b = I_2 \left(x_2 + \frac{z_m}{z_m + x_1} x_1 \right) = I_2 X_2$$

so it is evident that $m\,b$ does not represent I_2 to the same scale as $b\,d$ represents I^1.

Magnetizing Current I_m

When the current I_2 is zero, the only currents in the primary will be the magnetizing + iron loss currents or I_m^1. The actual magnetizing current will be I_m represented by $d\,m$.

Then $$d\,m = I_m X_1$$

The location of the circle with reference to the line $o\,d$ is more easily found than by drawing it through the three points o, b_o and b_s, as will be shown below in Fig. 22. On the line $o\,m$ construct the triangle $o\,m\,b_o$ having $\dfrac{m\,b_o}{b_o\,o} = \dfrac{X_2}{r_2}$. Then the circle will pass through o and b_o. Unless the secondary resistance is too large, the circle will cut the line $m\,b_o$ at some other point such as b_L Fig. 22. Then for this load the triangle $m\,b_o\,o$ becomes $m\,b_L\,c_L$ and c_L will lie on the line $o\,m$. Since angle $o\,b_o\,b_L$ is a right angle and the three points o, b_o and b_L all lie on the circle, $o\,b_L$ must be the diameter of the circle. Then the angle $c_L\,o\,b_L$ is the constant angle θ between $o\,c_L$, representing E_4, and $o\,b_L$, representing E_2. Draw the line $b_L\,k$ from b_L perpendicular to $o\,m$ at k.

From Fig. 21, we know that

$$\tan \theta = \frac{r_2}{z_m + x_2 + r_2 \tan \lambda}$$

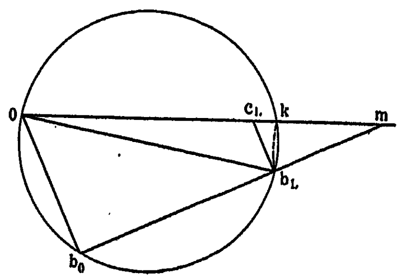

Fig. 22

so that

$$\frac{b_L\,k}{o\,k} = \frac{r_2}{z_m + x_2 + r_2 \tan \lambda}$$

also

$$\frac{b_L\,k}{m\,k} = \frac{r_2}{X_2}$$

Therefore

$$\frac{o\,k}{m\,k} = \frac{z_m + x_2 + r_2 \tan \lambda}{X_2}$$

and

$$\frac{m\,k}{o\,m} = \frac{X_2}{X_2 + z_m + x_2 + r_2 \tan \lambda}$$

but

$$o\,m = \left(\frac{z_m}{z_m + x_2} \right) \left(\frac{z_m}{z_m + x_1} \right) \times o\,d$$

so that

$$m\,k = o\,d \times \frac{X_2 \left(\dfrac{z_m}{z_m + x_2} \right) \left(\dfrac{z_m}{z_m + x_1} \right)}{X_2 + z_m + x_2 + r_2 \tan \lambda}$$

Therefore,

$$b_L\, k = o\, d \times \frac{r_2 \left(\dfrac{z_m}{z_m + x_1}\right)\left(\dfrac{z_m}{z_m + x_2}\right)}{X_2 + z_m + x_2 + r_2 \tan \lambda}$$

and

$$d\, k = o\, d \times \left[1 - \frac{(z_m + x_2 + r_2 \tan \lambda) \left(\dfrac{z_m}{z_m + x_1}\right)\left(\dfrac{z_m}{z_m + x_2}\right)}{X_2 + z_m + x_2 + r_2 \tan \lambda} \right]$$

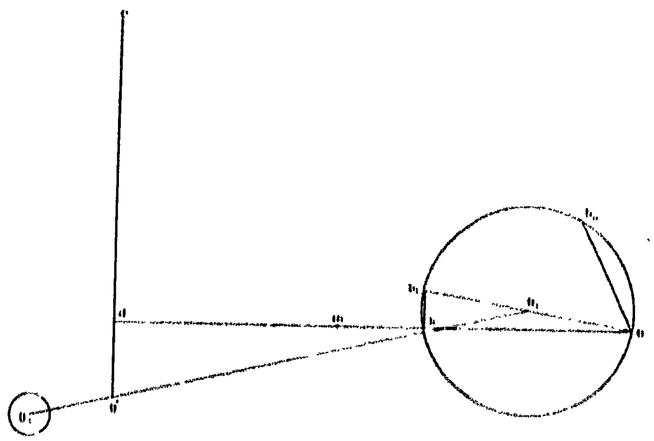

FIG. 23

THE FINAL CIRCLE DIAGRAM

Since the line $b\, b_o$ does not represent E_4 to scale, and since E_2 which is represented by $o\, c$, must be multiplied by a constant before using, regardless of whether it is to scale or not, there is no reason for drawing the part of the diagram d, o, o^1, c, b, to the same scale as the part $o^1\, e\, t$. On the other hand, it is more convenient to use a different scale for the currents than is used for voltages. The lines $o^1\, e$ and $o\, b$ will no longer represent E_1 and E_2 to the same scale.

Let S_e = volts per inch to which $o^1\, e$ represents E_1
and S_1 = amperes per inch to which $o^1\, b$ represents I.

Then

$$o^1\, e \text{ (Fig. 23)} = \frac{E_1}{S_e}$$

$$o^1\, d = \frac{I_{Ve}}{S_1} = \frac{\text{watts iron loss}}{E_1\, S_1} \quad (= \tfrac{1}{2} \text{ polyphase iron loss})$$

$$d\, o = \frac{E_1}{X_1\, S_1}\left(\frac{z_m + x_2}{z_m}\right)$$

$$d\, m = \frac{I_m}{S_1}$$

$$\tan \lambda = \frac{I_{Ve}}{I_m} = \frac{o^1\, d}{d\, m}$$

$$d\, k = o\, d$$

$$\left[1 - \frac{(z_m + x_2 + r_2 \tan \lambda)\left(\dfrac{z_m}{z_m + x_1}\right)\left(\dfrac{z_m}{z_m + x_2}\right)}{X_2 + z_m + x_2 + r_2 \tan \lambda} \right]$$

$$k\, b_L = o\, d \frac{r_2 \left(\dfrac{z_m}{z_m + x_1}\right)\left(\dfrac{z_m}{z_m + x_2}\right)}{X_2 + z_m + x_2 + r_2 \tan \lambda}$$

Then, $o\, b_L$ is the diameter of the circle locating the point b with its center at o_1.

$$o^1\, o_3 = o^1\, o\, \frac{r_1\, S_1}{S_e}$$

$$\text{diameter of circle } o_3 = o\, b_L\, \frac{r_1\, S_1}{S_e}$$

$$o\, b_o = \frac{r_2}{\sqrt{r_2^2 + X_2^2}}\left(\frac{z_m}{z_m + x_1}\right)\left(\frac{z_m}{z_m + x_2}\right) \times o\, d$$

Then on this diagram

$S_e \times o^1\, e$ = line voltage

$S_e \times e\, t$ = equivalent line voltage

$$S_1 \times b\, o^1 \left(\frac{o^1\, e}{e\, t}\right) = \text{primary amperes}$$

$$S_1 \left(\frac{z_m + x_1}{z_m}\right) \times m\, b \left(\frac{o^1\, e}{e\, t}\right) = \text{secondary amperes}$$

$$\frac{(o^1\, t)^2 + (e\, t)^2 - (o^1\, e)^2}{2\, (o^1\, t)\, (e\, t)} = \text{per cent power factor}$$

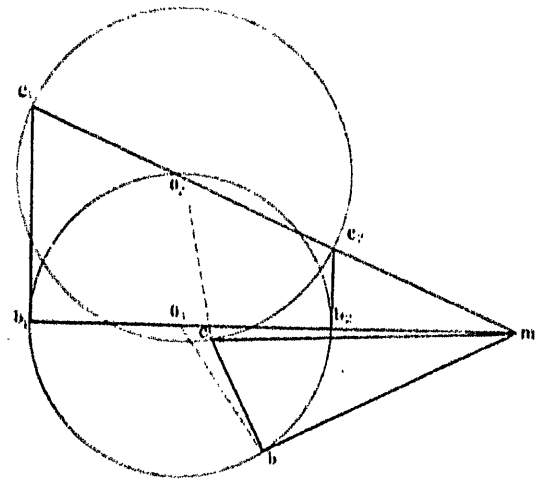

FIG. 24

$$K_1 \sqrt{\frac{b_o\, b}{o\, b}} = \text{speed (in rev. per min.)}$$

$$\left(\frac{o^1\, e}{e\, t}\right)^2 [K_2\, (o\, b)\, (b_o\, b) - K_3\, (b_o\, b)^2 .] - [\text{Friction (in h. p.) and windage}] = \text{h. p. output}$$

$$\text{Torque oz. ft.} = \frac{\text{h. p. output}}{\text{speed}} \times 84000$$

Efficiency

$$\frac{\text{h. p. output} \times 0.746}{\text{Primary volts} \times \text{primary amperes} \times \text{power factor}}$$

Where

$$K_1 = \sqrt{\frac{r_2}{(z_m + x_2) \sin \theta}} \times \sqrt{\frac{r_2^2 + X_2^2}{X_2^2}}$$

$$K_2 = 0.00134\, \frac{X_2}{r_2}\, \sqrt{r_2^2 + X_2^2} \left(\frac{z_m + x_1}{z_m}\right)^2 S_1^2$$

$$K_3 = 0.00134 \frac{r_2^2 + X_2^2}{r_2} \left(\frac{z_m + x_1}{z_m} \right)^2 S_1^2$$

Appendix A

Proposition 1. To prove that if two circles are drawn on similar parts of the hypotenuse and one leg of a right triangle, any right triangle having its vertex at the vertex of the original triangle and its other two vertices on the respective circles will be similar to the original triangle.

Construction, Fig. 24. Draw the triangle $m\, b_1\, c_1$ and the similar triangle $m\, b_2\, c_2$ and draw the two circles having their centers at o_1 and o_2 on $b_1\, b_2$ and $c_1\, c_2$ as diameters.

Then $\dfrac{m\, c_2}{m\, b_2} = \dfrac{m\, c_1}{m\, b_1} = \dfrac{c_1\, c_2}{b_1\, b_2} = \dfrac{o_2\, m}{o_1\, m}$

Draw in any line $m\, b$ and the line $m\, c$ at an angle from $m\, b$ so that angle $c\, m\, b$ = angle $c_1\, m\, b_1$, until it cuts the circle o_2 at a similar point to the position of b on the circle o. That is, if $m\, b$ does not cross the circle o_1, then $m\, c$ must not cross o_2. Connect c and b and draw the radii of the two circles $o_2\, c$ and $o_1\, b$.

Then $\dfrac{o_2\, c}{o_1\, b} = \dfrac{o_2\, m}{o_1\, m}$ (by construction)

And angle $o_2\, m\, c$ = angle $o_1\, m\, b$ (same angle $o_1\, m\, c$ added to equal angles $o_2\, m\, o_1$ and $c\, m\, b$). The triangles

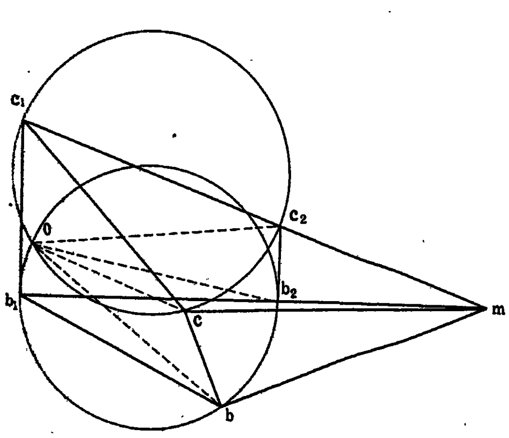

FIG. 25

$o_2\, m\, c$ and $o_1\, m\, b$ have two sides proportional and one angle equal. The two triangles are similar if the above limitation (that $m\, c$ shall not cross the circle o_2 if $m\, b$ does not cross the circle o_1) is placed on the double solution given by the triangles with two proportional sides and similar angles, (not the included angles) equal.

Then $\dfrac{m\, c}{m\, b} = \dfrac{o_2\, c}{o_1\, b} = \dfrac{m\, o_2}{m\, o_1}$ (similar sides of similar triangles)

Therefore, triangle $m\, b\, c$ is similar to triangle $m\, b_1\, c_1$ having two sides proportional and the included angles equal.

Proposition 2. To prove that the two vertices (on the circles) of the above triangle lie on the two sides of a constant angle having its vertex at the intersection of the circles.

Construction Fig. 25. Draw the circles o_1 and o_2 on the triangle $m\, b_1\, c_1$, as above, and call their point of intersection o. Draw the lines $o\, c_2$, $o\, b_2$, $o\, c$ and $o\, b$. To prove that angle $b\, o\, c$ = angle $b_2\, o\, c_2$. Draw in the lines $c_1\, c$ and $b_1\, b$.

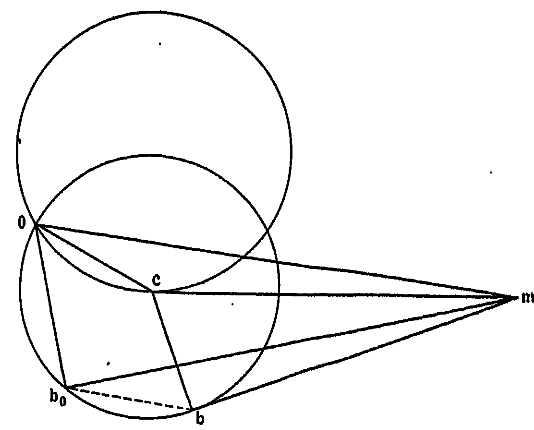

FIG. 26

Then since $\dfrac{m\, c}{m\, b} = \dfrac{m\, c_1}{m\, b_1}$ (proved above)

And angle $c_1\, m\, c$ = angle $b_1\, m\, b$ (same angle $b_1\, m\, c$ added to equal angles $c_1\, m\, b_1$ and $c\, m\, b$).

Triangles $c\, c_1\, m$ and $b\, b_1\, m$ are similar and angle $c\, c_1\, c_2$ = angle $b\, b_1\, b_2$

But angle $c\, c_1\, c_2$ = angle $c\, o\, c_2$ (each measured by ½ of same arc $c_2\, c$)

and angle $b\, b_1\, b_2$ = angle $b\, o\, b_2$ (each measured by ½ of same arc, $b_2\, b$)

Therefore, angle $b\, o\, c$ = angle $b_2\, o\, c_2$ (same angle $c\, o\, b_2$ subtracted from equal angles $b\, b_1\, b_2$ and $c\, c_1\, c_2$)

Appendix B

In Fig. 26, the two circles are drawn on similar parts of the triangle $m\, b_1\, c_1$ as in Fig. 24, and the triangle $m\, b\, c$ is any right triangle having one vertex at m and the other two vertices on the respective circles. Draw in the right triangle $m\, b_o\, o$, (similar to $m\, b\, c$ by Appendix A, Proposition 1,) and the lines $o\, c$ and $b_o\, b$.

Then, triangles $m\, c\, o$ and $m\, b\, b_o$ are similar having two sides proportional and the included angles equal.

Then $\dfrac{b\, b_o}{o\, c} = \dfrac{m\, o}{m\, b_o}$ or $\dfrac{b\, b_o}{o\, c}$ = ratio of diameters of two circles.

$\dfrac{m\, o}{m\, b_o}$ = ratio of diameters of two circles as shown in Appendix A.

Discussion

V. Karapetoff: The problem treated by the author is quite old, and a complete absence of correlation with the work of previous investigators is rather deplorable. Thus, the whole set of papers and a voluminous discussion before the Institute in 1918 are entirely ignored, as well as the subsequent contributions to the theory of this class of machines. In 1921 I showed the equivalence of the two theories of the single-phase induction machine JOURNAL, Vol. 40, page 640) and gave a new equivalent diagram, only one branch of which contains variable slip. A circular locus and a general-performance equation follow from this diagram directly. In Vol. 41 of the TRANSACTIONS there is a paper by Mr. Kostko which to me only shows that elementary mathematics is inadequate to lead to a simple theory of the machine, on the basis of two oppositely revolving fields. Mr. Perkins' paper shows that elementary mathematics is also inadequate in the cross-field theory. I hope, therefore, that this method of approach will now be definitely abandoned in favor of more advanced and shorter mathematical tools. In the JOURNAL for 1923 (Vol. 42, page 1181) I indicated the use of the scalar product of vectors in the solution of problems on locus diagrams of electrical machinery. This new use of vector analysis has already proved to be quite fruitful in a derivation of the exact circle diagram of the polyphase induction motor, without inversion or long formulas. The next step is to try this method on the single-phase machine, preferably using the unified equivalent diagram mentioned above.

Instead of a laborious step-by-step method, we ought to be able to write at once a few vectorial equations which represent all the essential relationships in the machine. For a solution of these simultaneous equations an advanced mathematical method (or some mechanical device) should be used, leaving the physical relationships "transparent" to the end. Of course, in numerical computations there will be products of complex quantities to evaluate, but there already are a few computing devices for a convenient handling of complex quantities, and probably in a few years computations with such quantities will be not nearly so tedious as they are now.

W. B. Hall: I have found considerable confusion existing in the minds of students and engineers concerning the fundamental analytical reasoning employed in the cross-field analysis of the single-phase induction motor.

We are accustomed to consider a conductor or circuit. We determine the voltage generated in this conductor, the resistance and reactance of its circuit, and we say that the current lags the voltage by an amount determined by the ratio of resistance to reactance, or we may consider the reactance as a voltage, and determine the net voltage acting in the circuit. The current flow will then be in phase with this net voltage, which is the $I\ R$ drop.

In analysis of polyphase motors, we sometimes use these methods of thought. We consider the voltage induced in conductor *d*. We say that the current will flow later, because of the reactance of the circuit, *and that d will then be in some other position*, where *e* or *f* were at first. This same attack may be applied to the single-phase motor. But it leads to unnecessary complexity.

So in single-phase-motor analysis another method of attack is used, as in this paper, but this new method has never to my knowledge, been clearly and definitely described. It has been rather assumed without distinct description, resulting in much confusion of thought on the part of many readers.

The new idea, which needs to be clearly stated, is that E_3 is not the voltage in any one conductor. If we plotted the value of the voltage in each successive conductor as it passd through the position *d*, we should obtain a sine wave, for ϕ_2 varies thus with time. A vector, E_3, may obviously be used to represent this sine wave, but it must be constantly kept in mind that E_3 does not represent the voltage in any one conductor, but represents the successive values of the voltage in each conductor as it passes through the position *d*.

Our usual ideas of reactance and resistance will not longer apply, since we have no circuit, but a succession of circuits. Hence Mr. Perkins abandons the idea of reactance and uses the method of determining the net voltage and considering that the instantaneous current flow in any of the successive circuits is directly proportional to the instantaneous value of this net voltage, which is the $I\ R$ drop at the successive instants of passing through position *d*.

Thus, in Fig. 4, E_3 represents the successive values of voltage in the rotor conductors due to cutting ϕ_2 at the instant that each passes through position *d*. E_6 represents the successive values of transformer voltage due to ϕ_c at the instant that each conductor passes through position *d*. I_3 is *not* the current in a coil *d* or in any coil, but represents the successive values of the current in each conductor as it passes through position *d*.

With this distinction clearly in mind some erroneous conclusions may be avoided, and some hazy conceptions made clearer.

P. L. Alger (by letter): Mr. Perkins has given a very complete description of a circle-diagram method of calculation for single-phase motors, based upon the cross-field theory. The clear inference is that he considers this method and this theory preferable to their alternatives, the equivalent-circuit method and the revolving-field theory. It is my opinion that the second method is greatly preferable to the first, and that the latter theory is more accurate than the former.

The equivalent-circuit method seems preferable because it avoids the time consumption and the errors of graphical construction; it permits the constants of the motor to be varied to take account of saturation, eddy currents, or heating without duplication of the work; it affords a clear visualization of the fundamental application of Kirchoff's laws for the electric circuits to the motor; and it permits the study of the motor to be carried to any degree of approximation or of refinement without change in the method. Two advantages are generally claimed for the circle diagram method, that it avoids the use of vector algebra and that it permits an easy visualization of the variation of motor characteristics with speed. The first advantage appears rather to be a handicap, as it avoids the use of a very convenient and simple means of calculation in a place where it is most fitted for use. The second advantage is an important one, but it is obtained at the expense of another sort of visualization which may be equally satisfactory. It is generally true in the history of mathematics that graphical methods are developed first, but are later supplanted by abstract calculational methods as familiarity with the work is acquired and the need for increased accuracy and decreased time consumption becomes important.

The cross-field theory is, according to all the books, precisely equivalent to the revolving-field theory, so that any result may be obtained by either method. This equivalence of the two theories was again brought out by Mr. Kimball and myself in our recent paper on "Torque Pulsations of Single-Phase Motors," A. I. E. E. JOURNAL, December 1924, page 1142, when we derived the same formulas for the double-frequency torque by the two methods independently. However, there is one phenomenon, that of eddy currents in the squirrel-cage winding, that can be better taken into account by the revolving-field theory. If a double squirrel-cage winding, or its equivalent is employed, the secondary resistance is much higher at double line frequency than at slip frequency. Thus, different values of secondary resistance must be used for the forward and backward field currents in the revolving-field theory. But in the cross-field theory, the secondary current in either axis is considered as a whole, instead of being divided into its slip frequency and double-frequency components. Thus, the resistances used in the secondary circuits of the cross-field theory must be intermediate between the high and the low value, but just what values they

should have is a problem that has not been solved. In short no method has been published of properly taking into account eddy currents in the secondary by the cross-field theory, and so in this respect the revolving-field theory is superior.

L. M. Perkins: Professor Karapetoff brought up a very desirable feature: that we use as few operations as possible in deriving our vector diagrams. But he is pointing toward Utopia, I think, on account of the difficulty of making direct analysis without use of step-by-step methods.

One point which Prof. Karapetoff brought up is that he secures by his method a single variable, which variable is of course the slip. In the single-phase induction motor this variable is slip $\times$ (2 — slip) which comes out in this paper as well as in the oppositely-rotating field theory, the slip being, of course, the slip with reference to the forward rotating field, and the (2 — slip being the slip with reference to the oppositely rotating field.

In Fig. 21 of my paper there is a diagram showing the counter e. m. f., E_4' and the e. m. f. generated in the secondary conductors by the net flux, which is E_2. If from E_4' a line is drawn perpendicular to E_4' until it intersects E_2, the intercept between this line and E_2 (that is, the end of the vector) will be the length of this variable, $s\ (2 - s)$. If this is carried through, you will find that in the final diagram the circle having the one variable s and $(2 - s)$ is the one shown.

Another point brought up was the question of considering the rotor conductor as stationary. If you want to find what the current is in the rotor as it turns, there is no better method than using the oppositely rotating fields, but if you want to know what the primary input is, what power factor you will get for a given load (since the primary is stationary and the only way the primary can transfer energy to the secondary is by a stationary field), it is best also to consider the secondary as stationary, taking care of the effects of rotation by considering the counter generated by rotation.

A good illustration of the trouble gotten into when considering the rotating-field method is apparent when one wishes to determine the effect of increasing the reactance of the secondary winding. According to the rotating-field method, there are two separate currents in the secondary winding, one of slip frequency and one of $(2 - s)$ frequency. But what happens if you increase the reactance as far as it affects the slip frequency? There is no large change, but according to the normal way of looking at it, the current of the $(2 - s)$ frequency would be cut out almost entirely. It is rather hard to see how the performance is really affected, unless one follows this method, which shows that all currents in the rotor are really of line frequency and that, therefore, an increase in reactance of the secondary will cut down or will affect all rotor currents; the slip frequency current, as well as the $(2 - s)$ frequency current due to the oppositely rotating field.

The original purpose of this paper was to bring out the theory of the single-phase induction motor in such a way that the average engineer could follow it, although of course it is still very complicated. There are no assumptions as are necessary when you consider the oppositely-rotating-field theory.

Effect of Full Voltage Starting
on the Windings of Squirrel-Cage Induction Motors

BY J. L. RYLANDER[1]
Member, A. I. E. E.

***Synopsis.**—This paper discusses the effect on the windings when starting squirrel-cage induction motors with full voltage. The data is presented in four groups: namely, (1) Special tests made with a vibrograph instrument on a 50-h. p. and a 500-h. p. induction motor: (2) Observation tests made on a number of motors when starting with full voltage: (3) The condition of some windings which failed in service: (4) Formulas which show the main factors involved in the bracing of induction motors. Induction motor coil bracing in general is discussed.*

* * * * *

It is well known that a heavy starting current is required when starting squirrel-cage induction motors with the customary auto-transformer starter. When starting these motors by connecting them directly to the line a starting current that is even heavier is drawn from the line, which, in itself, is undesirable. However, on certain applications it is desirable to have motors start from rest or at some reduced speed without the aid of an attendant when the power on the line fails and then comes again. This is accomplished by omitting the customary auto-starter and connecting the motor directly to the line, thereby impressing on the winding full-line voltage instead of reduced voltages of 50, 65, or 80 per cent.

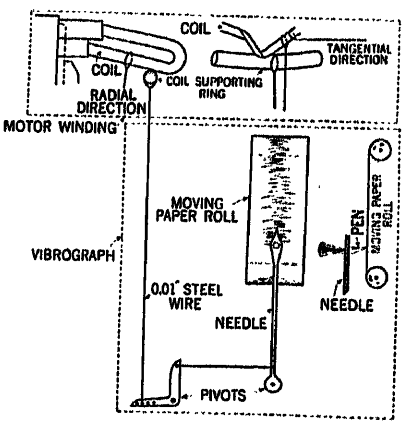

FIG. 1—DIAGRAMMATIC SKETCH OF VIBROGRAPH MACHINE AND METHOD OF CONNECTING IT TO WINDINGS

The effect of full voltage starting on the windings of squirrel-cage induction motors is discussed under four subheadings; namely—

The special tests made on two motors.

The tabulated observations on a number of motors when starting with full voltage.

The condition of windings which failed in service.

And in formulas which show the main factors involved in the bracing of induction motor windings.

Two motors were chosen for making thorough tests; one was a 50-h. p., three-phase, six-pole, 440-volt, 60-cycles, 1160-rev. per. min., squirrel-cage motor, the other a 500-h. p., three-phase, four-pole, 2220-volt, 25-cycle, 724-rev. per. min. squirrel-cage motor. The windings were of the open-slot type. There was no special coil bracing on these motors.

The deflection of the coils was measured with the aid of a special measuring device called the "vibrograph". The vibrograph is an instrument which transfers motion to a place where it can be recorded as well as magnified. It consists essentially of a moving roll of paper on which a pivoted ink-pen records the movements of the pen, which is fastened, through an arrangement of levers, to the place of motion. The purpose of the levers is to magnify the motion. The vibrograph, therefore, shows the characteristics and magnitude of the deflections. A 0.01-in. diameter steel wire was fastened around the part of coil or supporting ring on which the vibration was to be measured, and this wire

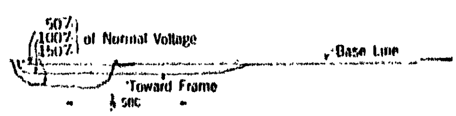

FIG. 2—DIAGRAM OF COIL MOTION, 50-H. P., 440-VOLT, SIX-POLE, 1160-REV. PER MIN. INDUCTION MOTOR (THREE SEPARATE VIBROGRAPHS GROUPED TOGETHER)

was connected to a leverage arm of the vibrograph machine. Measurements were taken at the middle and the end of the coils on the outside circumference and also on the coil supporting ring which is roped to each coil. In most of the readings taken the steel wire was in a radial position and in others the wire was in a tangential direction at right angles to the coil. Fig. 1 shows a diagrammatic sketch of the vibrograph machine and the method of connecting it to the windings. Oscillograph curves of the current were also taken at the same time.

Fig. 2 is a tracing of three separate vibrograph diagrams grouped together for convenience. This shows the effect of starting the 50-h. p., 440-volt motor with 220, 440 and 660 volts, which corresponds to 50, 100 and 150 per cent of the normal voltage. The motor was connected directly to the line with a three-pole switch. The motor was without load. With 220

1. Westinghouse Electric & Manufacturing Co., East Pittsburgh, Pa.

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 9-12, 1925.

volts, the coils moved 0.002 inch, and several seconds were required to bring the motor to full speed. With 440 volts the coils moved 0.01 inch and required 1 second for the motor to reach full speed. With 660 volts the coils moved outward 0.016 inch for 0.4 second until the motor reached full speed. In all three cases the winding pulled away from the rotor and toward the frame. With 440 and 660 volts, the movements could

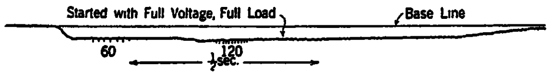

Fig. 3A—Coil Movement of 50-H. P., 60-Cycle, 440-Volt When Started with Full Voltage and Full Load

be observed with the eye and appeared to be larger than the measurements recorded by the instrument. The movement is for the radial direction.

Fig. 3A shows the coil movement of the 50-h. p., 440-volt, 60-cycle motor when started with full voltage and full load. The motor was connected directly to the line with a 3-pole knife switch. The winding moved outward toward the frame 0.01 inch, when the motor was started, and then vibrated while in this position for 1¼ seconds until the motor attained full speed. This curve indicates that the winding vibrated 60 times per second soon after the closing of the switch, but the vibrations soon changed to 120 per second. The motion is in the radial direction. Fig. 3B shows the oscillograph curve of the current which was taken simultaneously with Fig. 3A. The maximum current was 360 amperes, or 6.3 times the full-load current.

Fig. 4A shows the coil movement of the 50-h. p.,

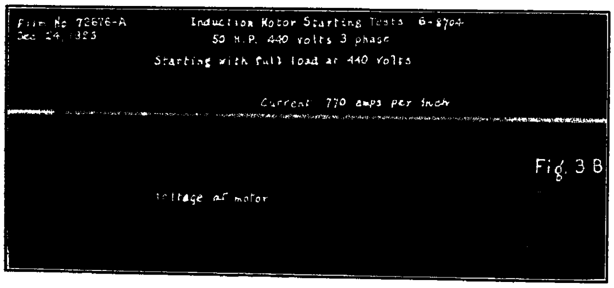

Fig. 3B

440-volt, 60-cycle motor when started with a standard auto-transformer starter. The starter was set at the 80 per cent voltage tap. The first part of the curve shows the coil movement when starting with 80 per cent voltage, and the second part of curve taken after a lapse of about two seconds shows the coil movement caused when changing from 80 per cent voltage to the full-line voltage by means of an auto-transformer starter which opens the circuit momentarily to make this change in voltage. The coil motion is for the radial direction. It will be noted that the winding moves quickly toward the frame as soon as the motor is started, and then gradually returns to the normal position and then toward the rotor; then when the change is made from the 80 per cent voltage to full voltage there is a quick movement toward the rotor followed quickly by another movement in the reverse direction of greater force than the preceding one. The winding then returned to the normal position. The cycle of movement to return to normal position required ½ second from the time the line voltage was applied. The writer has no explanation to offer for the first part of the curve for its peculiarity. This

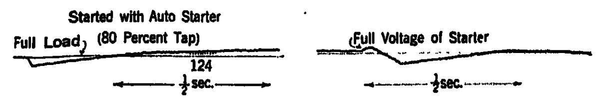

Fig. 4A—Coil Movement of 50-H. P., 440-Volt, 60-Cycle Motor When Started with Standard Auto-Transformer

peculiarity does not occur in the corresponding curve in Fig. 6B. The explanation for the movement of the winding in opposite directions as shown in the second part of Fig. 4A is that the normal direction of movement is toward the frame as in Figs. 3 and 5, and that when the circuit was momentarily opened, the residual

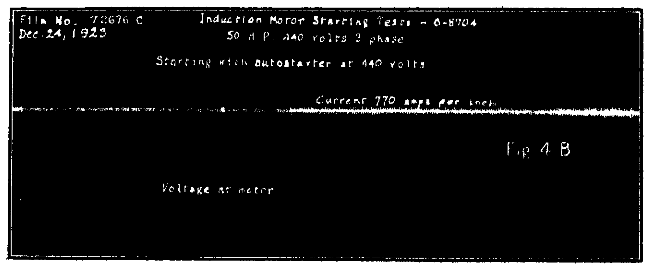

Fig. 4B

magnetization of the rotor induced a corresponding voltage in the primary, and this voltage was out of phase with the line-voltage which was then applied. Fig. 4B shows the oscillograph curve of the voltage and amperes taken simultaneously with Fig. 4A. The current at starting was 250 amperes, but the maximum current of 380 amperes flowed at the instant the line voltage was applied.

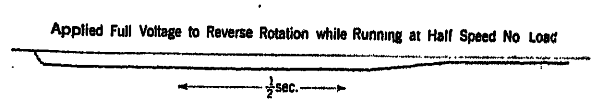

Fig. 5A—50-H. P., 440-Volt, 1160-Rev. per Min. Motor Started with No Load

In Fig. 5A the 50-h. p., 440-volt, 1160-rev. per min. motor was started with no load and the circuit was opened until the speed dropped to 600 rev. per min. Two of the primary leads were reversed while the motor was slowing down to 600 rev. per min. so that the motor would stop almost instantly and reverse its rotation. The switch was then closed. Fig. 5A shows that the windings moved 0.008 in. toward the

frame, and the total time required to stop the motor from half speed and bring it to full speed in the opposite direction was 1.3 seconds. Fig 5B shows the oscillograph curve of the current which was taken simultaneously with Fig. 5A. The current taken was 380 amperes for the first second, which is 6.7 times the normal full-load current.

Fig. 6 is a tracing of four separate vibrograph dia-

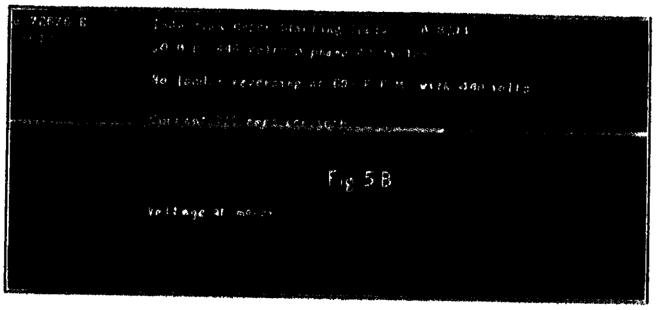

Fig. 5B

grams grouped together for convenience. These four curves are all for the 50-h. p., 440-volt motor, but in each case the motor was run on a 550-volt circuit. Curve *a* is for starting with 550 volts applied directly

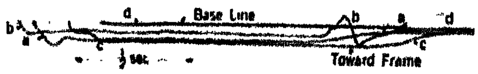

Fig. 6—Four Separate Vibrographs Grouped Together

to the winding. Curve *b* is for starting with an auto-starter on the 80 per cent voltage tap. In Curve *c* the rotation was reversed while running at half speed with no current by reversing two of the leads and then

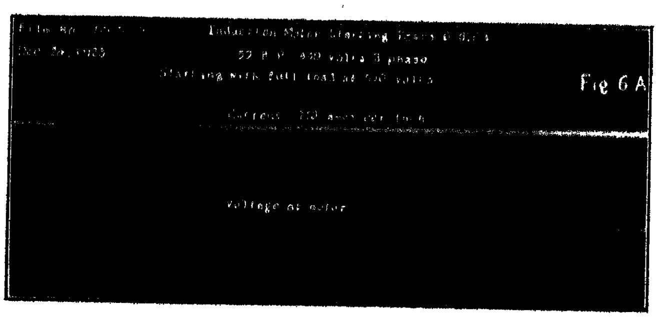

Fig. 6A

applying 550 volts. Curve *d* is the same as Curve *a* except that a coil-supporting ring was added to brace the winding. This ring was made from a ¼-inch diameter steel rod and each coil was tied to it with one turn of heavy twine. By adding the coil support the movement of the coil was reduced from 0.012 inch to 0.002 inch. The *b* curve shows the coil movement quickly reversed itself in a more marked manner than occurred in Fig. 4A. The movement was radial and toward the frame for all curves except the *b* curve, which had a momentary movement toward the rotor before changing from the 80 per cent auto-transformer tap to the line voltage. Figs. 6A, 6B and 6C show the oscillograph curves of the voltage and current for the vibrograph curves, 6 *a*, 6 *b* and 6 *c* respectively. In Fig. 6C the light in the oscillograph failed momentarily and therefore, omits the middle part of the curves.

Fig. 7 shows the coil motion for the 500-h. p., 2200-volt induction motor when it was started without load at 1100 volts. Note that the winding did not shift to either side but vibrated an equal amount about its normal position. The vibration is in the radial direction. This may be compared with Fig. 8, which is the the same except that it is for full voltage (2200) starting. With 1100 volts, the coils vibrated 1/16 inch for 2.7 seconds until motor was up to speed, and with 2200

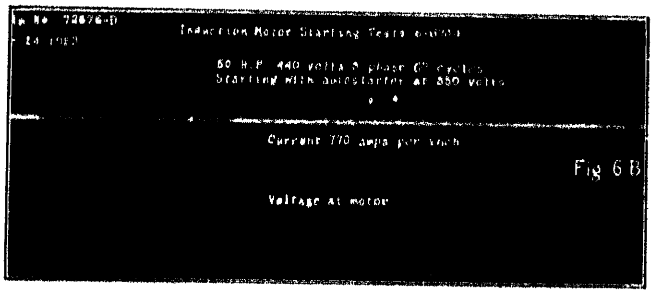

Fig. 6B

volts the coils vibrated ¼ inch (⅛ inch on each side of the normal position) for the 0.65 second required to bring motor to full speed. In Fig. 8, the coils vibrated 3/16 inch toward the rotor and 1/16 inch toward the frame and then held the position of 1/16 inch toward the frame after the motor was up to full speed. This curve gives the impression that the coils vibrated against something on the frame side 1/16 inch from normal, which prevented the winding from moving or vibrating beyond that point. This curve is for radial motion with the wire fastened at the middle of the end extension.

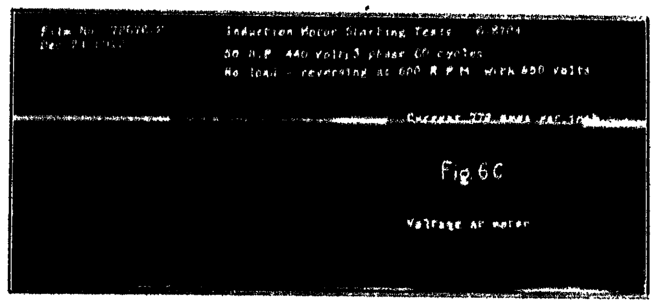

Fig. 6C

Fig. 9 is for tangential motion; otherwise it is the same as in Fig. 8. It shows that the tangential motion was almost ¼ inch (⅛ on each side of normal) and therefore about the same value as the radial motion. It also shows that the coils have a sidewise displacement of 1/16 inch to one side, which remains after the motor is up to full speed.

Fig. 10A was taken to show the effect of opening and closing the circuit similar to the action that occurs when using an auto-transformer starter. The motor was started with full voltage, then the switch was opened at the end of one second and closed again at the end of two seconds, and then opened at 2¼ seconds and closed after 3 seconds, then opened after 3⅓ seconds. The vibration was ¼ inch when the switch was closed

tained by exerting a force through a spring balance and measuring the deflections by the vibrograph.

Fig. 14 shows the radial force exerted on a coil of the 50-h. p. motor at the different voltages. It is plotted from data in Figs. 12 and 13.

General Discussion of Curves

These curves show that there was either quivering,

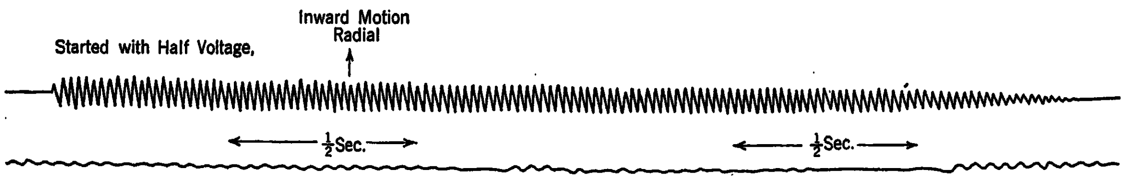

Fig. 7—Diagram of Coil Motion for 550-H. P., 2200-Volt Induction Motor When Started Without Load at 1100 Volts

the second and third time, the same as when started the first time with full voltage. Fig. 10B shows the oscillograph curve of the voltage and current which was taken simultaneously with Fig. 10A. Fig. 10B, as well as curves in Figs. 3B and 6A, shows that a voltage

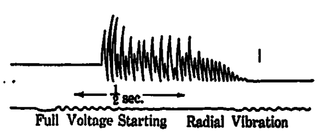

Fig. 8—Diagram of Coil Motion for 550-H. P., 2200-Volt Induction Motor When Started Without Load at 2200 Volts

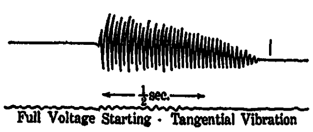

Fig. 9

is induced in the primary winding after opening the switch to the supply circuit.

Fig. 11 has been plotted from test data of the 50-h. p. motor, to show the effect of different voltages on the time in bringing the motor up to full speed. Like-

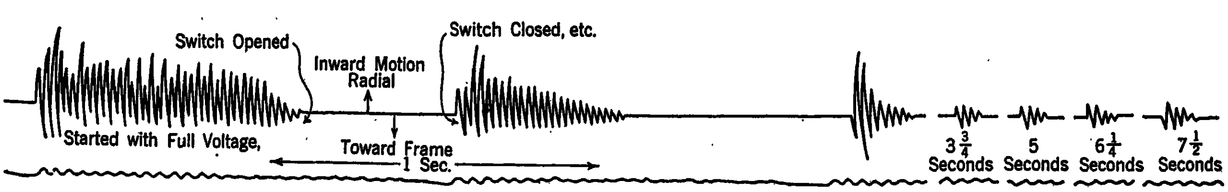

Fig. 10A—Effect of Opening and Closing Circuit Similar to Action Which Occurs When Using Auto-Transformer Starter

wise, Fig. 12 shows the actual displacement of the ends of the coils as a function of the voltage.

Fig. 13 shows that the radial displacements of a stator coil are directly proportional to the force applied to the coil within the limits measured. This was ob-

vibration or displacement of the windings when the motor was started in all of the tests on these two motors. The severity of the motion or displacement increased as a function of the square of the voltage applied to the particular winding; that is, a 440-volt or 2200-volt motor is no worse than a 220-volt motor with regard to

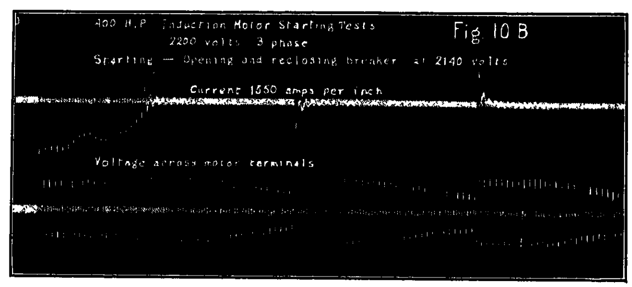

Fig. 10B

the effect of voltage alone, but 440 volts will produce four times as much coil displacement as 220 volts on a particular winding regardless of the voltage rating.

When the windings were displaced, the displacement was toward the frame in all cases except when starting the motor with an auto-transformer starter. The windings move and vibrate in both radial and tangential directions.

The amount of coil movement and its duration, as shown in the vibrograph curves, correspond with the starting current on the oscillograph curves taken simul-

taneously with them. The length of time that the windings are displaced by the starting current for any two voltages on a given winding is inversely proportional to the square of the ratio of these voltages. The that the windings vibrate, multiplied by the coil displacement in inches, will give a constant value regardless of the voltage applied. The addition of a coil supporting ring, as in Fig. 6 (*d*), shows that additional coil bracing reduces the coil movement considerably.

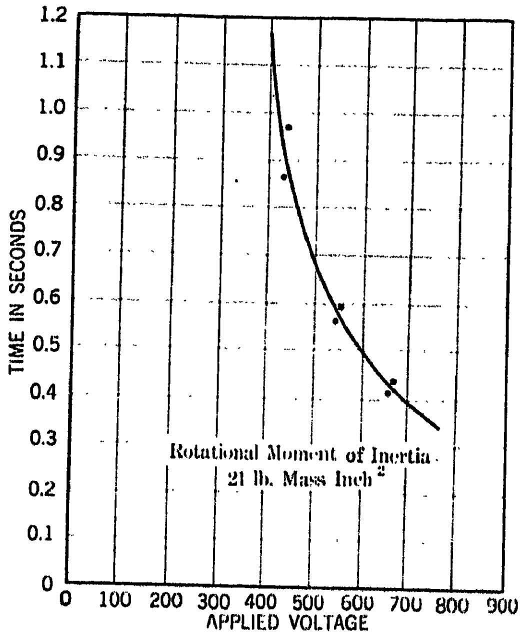

FIG. 11—EFFECT OF DIFFERENT VOLTAGES ON TIME IN BRINGING MOTOR TO FULL SPEED

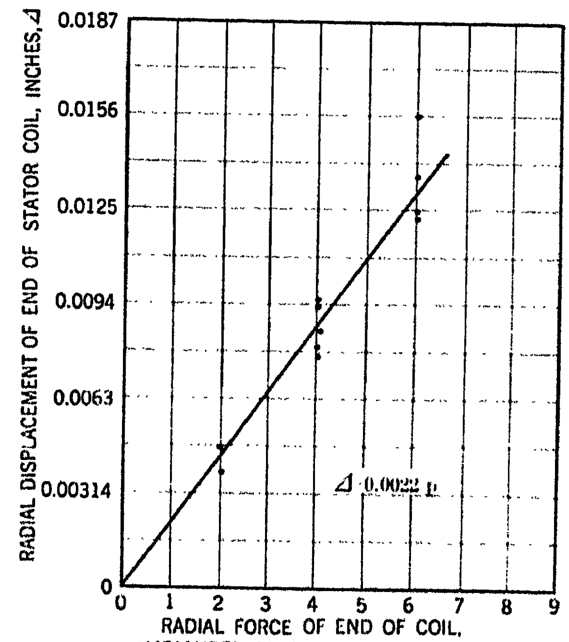

FIG. 13—RADIAL DISPLACEMENT OF STATOR COIL

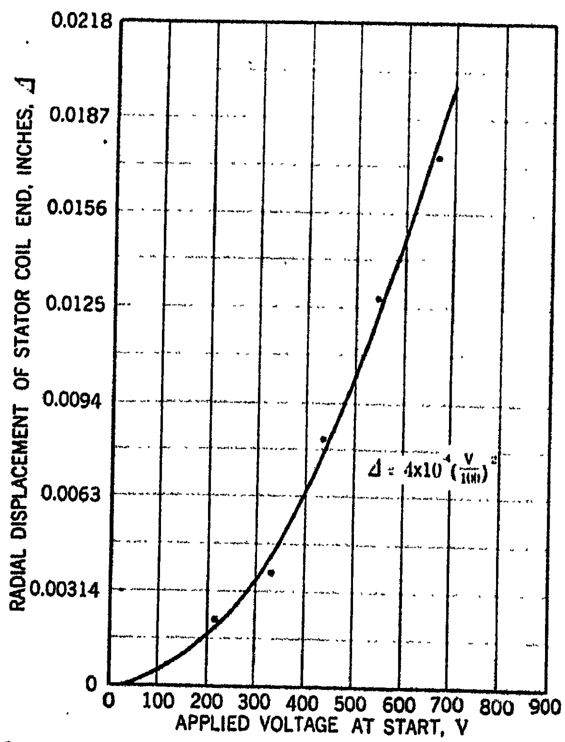

FIG. 12—ACTUAL DISPLACEMENT OF ENDS OF COILS AS A FUNCTION OF VOLTAGE

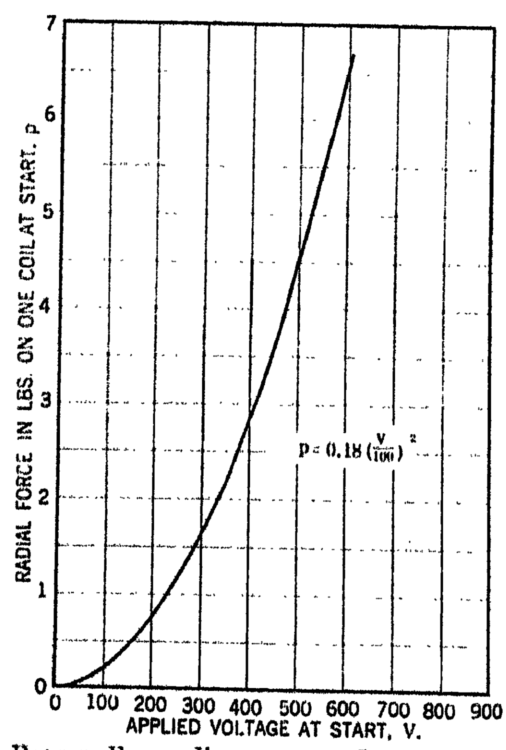

FIG. 14—RADIAL FORCE EXERTED ON COIL OF MOTOR FOR DIFFERENT VOLTAGES

radial displacement of the stator-coil ends for any two voltages applied to these windings was proportional to the square of the ratio of the voltages within the limits measured. Therefore, the length of time in seconds

Figs. 3B, 6A and 10B show that there is a voltage at the motor terminals after disconnecting the supply circuit from squirrel-cage induction motors. For the 50-h. p. motor with full load, the induced voltage is

25 per cent of normal voltage, half a second after open-the switch, and on the 500-h. p. motor with no load, the induced voltage is 50 per cent of full voltage ¾ second after opening the switch and 35 per cent after 1¾ seconds. In the primary, this voltage is induced by the residual magnetism of the rotor, and the frequency is directly proportional to the speed of the rotor which is slowing down.

Starting motors with full voltage produces a severe strain for a short period, whereas the use of an auto-transformer starter produces a less severe strain for a longer period and also a momentary strain that may be more severe than when starting with full voltage. The auto-starter may produce two severe shocks on the winding in opposite directions. This is accounted for by the voltage which is produced by the winding being out of phase with the line voltage at the instant of changing from the lower-voltage tap to the full voltage tap of the auto-starter.

What Observation of Windings Has Shown

In addition to the two motors on which oscillograph and vibrograph curves were taken, other machines as listed below were started with the full-rated voltage on the terminals and the effect observed:

H. P.	Volts	Poles	Coil Extension	Starting Current	Effect on Winding
50	440	6	4 1/2	6 × Full Load	Moved slightly
400	2200	4	11	7.5 × Full Load	Considerable movement on coils and complete winding
250	220	24	5 3/8	4.4 × Full Load	Quivered slightly
400	2200	24	5 5/8	5.7 × Full Load	Quivered slightly
600	2200	2	9	9.8 × Full Load	Appreciable movement of complete winding
10	220	4	3 3/8	5.2 × Full Load	No effect: This winding is made solid by dipping the complete winding in varnish and baking it. No other bracing used.

When the effect on the windings is slight, nothing is seen with the eyes, but any quiver or vibration of the windings is felt with the hands without difficulty. Some of these windings not only vibrated but had a definite movement which lasted as long as the heavy starting current flowed through the windings. These movements of the windings were such as to separate the windings wherever the phases change and for the winding to move away from the rotor and toward the frame. When the vibration of the winding is severe, a distinct hum is heard.

Motors Failing Due to Distortion of Windings

Some machines which had been in service for years finally failed due to distortion of the windings. These machines had used the customary auto-starter method of starting. Whether the cause of the distortion was due to the starting current or to some other disturbance, such as short circuits on the line near the motor, was not known. These windings showed the following effects:

1. The windings had separated between phases.
2. The windings had moved away from the rotor and toward the stator.
3. The top and bottom layers of coils had drawn together.

The separation between phases and the movement toward the frame were also seen on some of the windings that were observed while they were being started. The action of top and bottom layers on each other cannot very well be observed, but from the formulas which follow, it should be expected that the top and bottom layers should draw together at certain places.

Derivation of Working Formulas

There is an attraction or repulsion between each and every other conductor and also between each conductor and the magnetic field of the secondary, and also with the stray leakage flux of the primary. On account of the complications involved, and because the action of conductors on each other is the main force involved, formulas have been worked up for this action only.

The force exerted between two parallel conductors is:

$$P = \frac{4.5 \times I^2 L}{a \times 10^8}$$

where P is the force in pounds, L is the length of the conductors in inches spaced a inches apart and having I amperes flowing in both wires. This force attracts when the current is in the same direction and repels when the current flows opposite directions.

The deflection of the conductors can be derived from the formula

$$D = \frac{P L^3}{48 E M}$$

where E is the modulas of elasticity $(11 \times 10^6$ for copper) and M is the moment of inertia =

$$\frac{b h^3}{12}$$

and where h is the dimension of the beam in the direction parallel to the applied force and b is the dimension at right angles to the applied force. D is the deflection in inches when b, h and L are expressed in inches, and the deflection

$$D = \frac{1.02 I^2 L^4}{a \times b h^3 \times 10^{15}}$$

By assuming a typical value of current density in the copper conductors of 2500 amperes per square inch and using a value of the starting current as being 6 times full load, the value 15,000 $b h$ can be substituted for I, and the deflection or amount of vibration becomes

$$D = \frac{2.3}{10^7} \times \frac{b}{h} \times \frac{L^4}{a}$$

where D is deflection in inches.

h is dimension of conductor in inches in the direction

parallel to direction of applied force, and b is the dimension of conductor in inches in direction at right angles to the direction of the applied force.

L is the length of conductors in inches between supports and a is the space between conductors in inches.

Coil Bracing

The attraction and repulsion of the conductors on each other tends to move the conductors and is opposed by the mechanical fastenings which support the conductors. Many of the conductors are secured by resting against other conductors, which are secured by various means. As all armature conductors pass through the slots, the slots become an effective means of securing a large part of each conductor. Beyond the slots a number of the conductors are bound together in a unit as a coil, and this prevents the conductors from vibrating against each other. Each coil end tends to move under the effect of the force exerted on it by all other coils in the machine but is resisted by the rigidity of the coil as each coil is held by being placed in two different slots and usually at one or more other places on ends of windings by means of rope, bolts, clamps or steel bands to other more or less fixed supports.

The formula for deflection shows that the dominating factor is the length between any two supports, as the deflection varies according to the fourth[2] power of of this length. This distance should, therefore, be kept within proper limits. As the deflection is also proportional to the square of the current, the coil movement will be four times as great for a motor which has a starting current ten times the full load value, as for the same winding with a starting current of five times the full load value. As two-pole and four-pole motors have relatively large coil extensions and also have the highest ratio of starting current to full load current, their windings must be braced much more firmly than others.

In many of the small motors the coils fit closely with each other and the complete winding is reinforced with varnish or impregnating compounds; therefore, their windings are exceptionally well braced to resist the forces exerted when starting the motors.

The vibration and movement of the windings deteriorate the insulation, and if sufficiently severe, will cause an insulation failure. It may also break the coil leads.

The kind and amount of insulation and the method of bracing are the limiting factors which determine how much vibration or coil movement can be permitted. The repetition of these vibrations sometimes has a cumulative effect by loosening the rope which is usually used to secure the coils to a supporting ring.

As the amount of vibration or coil movement is directly proportional to the square of the ratio of the starting current to the full-load current, the starting of squirrel-cage induction motors is much more severe on the windings than it is with wound-rotor induction motors where the current is limited by the resistance in series with the secondary. As the amount of vibration is also directly proportional to the third or fourth power of the length of coil between supports, very thorough bracing is required where the coil extensions are comparatively large. Nevertheless, there seems to be no question but that all induction motor windings can be satisfactorily braced to stand the mechanical effect of full voltage starting.

2 Although theoretical calculations show that the coil movement should vary according to the fourth power of the length between supports, some measurements have been made that indicate that it is more nearly the third power.

Discussion

R. E. Ferris: Mr. Rylander's paper is the result of one of a series of tests being carried on covering the general subject of the effect of vibration on the insulation and windings of rotating electrical apparatus.

Insulating material may be quite highly carbonized and still retain a fairly large percentage of its original dielectric strength, provided actual mechanical breakdown does not occur. In practically all applications, however, some movement will occur. It is, therefore, necessary to keep the operating temperature of electrical apparatus well below the carbonization point of the insulation used, and also to minimize as much as possible the vibration and movement of the winding.

To accomplish the latter, it is desirable to wind all coils as tightly as practicable in the slots and to support the end portions in such a way as to minimize the effect of any possible shrinkage of insulation.

Especially for the larger size induction motors, some form of mica insulation is best, at least for the slot portions of the coils, as this material stands prolonged high temperature with very little shrinkage, thus insuring tight coils over a long period of time. Where induction motors are wound with closely fitting end-windings, *i. e.*, with no ventilation, the problem of bracing becomes simpler, but at the same time the possibilities of higher temperatures are increased, and therefore, with this type of winding, Class "B" insulation would seem to give less chance for shrinkage and consequent movement than with Class "A" insulation; in other words, the type of insulation to be used, especially on the end windings is intimately connected with the type of ventilation and method of bracing.

In the paper under discussion, the author has shown, in a quantitative way, the movements of induction-motor windings under the application of full voltage, and in this way has been able to make an intelligent study of the necessary bracings for the windings of this type of apparatus. With the type of bracing on the motors under test, the author apparently found that the use of an auto-starter did not make a great deal of difference as regards the magnitude of coil movement. The effect of ring-supported coils over those without the support is quite striking.

I might add that as I understand Mr. Rylander, he has not stated that all motors can be started under full voltage regardless of the type of bracing. In other words, he has emphasized the fact that proper and adequate bracing is necessary in order to produce motors which may be started under full voltage or over-voltage, and also that it may not be possible to eliminate the auto-starter unless the windings are properly and adequately braced.

V. Karapetoff: I think we should all welcome this new method of testing actual mechanical stresses in windings, and I am glad, therefore, to see this paper presented. I only regret the appearance of the so-called "working formula" in it.

The "working formula" on the sixth page in Mr. Rylander's paper is entirely misleading in so far as conductors in slots are concerned. The general law is that the mechanical force is equal to $I_1 I_2 d M/d x$, where I_1 and I_2 are the currents in the two circuits, and $d M/d x$ is the rate of change of their mutual inductance with the distance. (See, for example, A. Russell, Alternating Currents, Vol. I, page 40). In a very special case of two infinitely long, straight conductors carrying equal and opposite currents, the mutual inductance happens to be such that its derivative with respect to x gives the expression quoted in the paper. But with rectangular conductors in a slot, with currents flowing in nearly the same direction, and with the magnetic field determined by the iron structure, the coefficient of mutual inductance is expressed by an entirely different formula and gives a different force. For similar reasons, the formula quoted in the paper does not apply to the end connections.

R. E. Doherty: Any one who has ever tried to visualize the leakage flux in the end winding of an induction motor will have sympathy with Mr. Rylander's method of attacking this problem as contrasted with the one proposed by Professor Karapetoff. Any one of us familiar with matters of this kind, can set up the equations which express the force between coils as a function of the rate of change of mutual induction with respect to coil movement; but I would like to see the man who can apply it. Therefore, while I have the greatest respect for the wholesome and healthful effect of Professor Karapetoff's exhortation on us practical engineers toward making our treatment of practical problems a little more rigorous (we can improve it much), I nevertheless wish to express my sympathy with Mr. Rylander's practical point of view. It is necessary in many cases simply to take the larger factors involved (such as, in this case, that the force is proportional to the square of the current) and depend upon tests to determine the proportionality factors.

However, it may be that Mr. Rylander's equations can be improved to this extent: I notice that the formulas written down are for steady-state conditions. He simply balances the force exerted by the current and equates it to the force due to resilience to the coils.

I should like to call attention to the fact that this is a transient state, therefore, the accelerating force for the mass of the coils can not properly be neglected. Possibly if the effect of the mass of the coils were taken into account, it might possibly explain the discrepancy between the variation with the fourth power instead of the third power, as I believe he found in his test.

K. L. Hansen: In a paper entitled "The Starting of Polyphase Squirrel-Cage Motors" (JOURNAL A. I. E. E., Nov. 1923), B. F. Bailey discusses the effects of starting squirrel-cage motors by auto-starter, by resistance type of starter and by throwing the motor directly on the line. He considers the effects from four viewpoints:

1. Effect of starting current upon line voltage.
2. Affect upon connected apparatus.
3. Heating.
4. Power consumption.

Prof. Bailey has shown that in its effect on the voltage regulation the auto-starter offers practically no advantage over the resistance type and little advantage over direct connection to the line. This is especially true when it is necessary to use the higher voltage taps on the auto-transformer to get sufficient starting torque. With reference to possible injury to connected machinery, resulting from too rapid acceleration, there may be cases where throwing the motor directly on the line is less desirable than other methods, but such cases are rare. With reference to heating and power consumption Prof. Bailey showed that throwing the motor directly on the line is superior to both the auto-starter and the resistance type of starter.

To quote directly from Professor Bailey's conclusions:

"In view of the above facts it seems clear that it is entirely practicable to dispense with starters for polyphase squirrel-cage induction motors in a great majority of cases. No harm will come to the motor. The voltage regulation of the system in a majority of cases will be just as good as it was before and will be even better in the case of large installations"........

In his timely and interesting paper Mr. Rylander discusses the effects of various methods of starting from another very important standpoint, namely, the distortion of the windings. As pointed out by Mr. Rylander, the importance of movements and vibrations of the coils lies in the fact that they deteriorate the insulation, and, if sufficiently severe, will cause insulation failure. It, therefore, becomes of interest to observe whether or not throwing the motor directly on the line compared favorably with the auto-starter from this standpoint also.

One decided disadvantage of the auto-starter, clearly set forth in the paper, is that in going from low voltage to line voltage it is necessary to disconnect the motor entirely before reconnecting it to the line. The author states that during the moment of change-over the residual magnetism of the rotor induces a corresponding voltage in the stator, etc. This is somewhat misleading as by residual magnetism is usually understood the magnetism which remains in the magnetic circuit by virtue of hysteresis after the excitation has been completely removed. What he probably means to say is that the flux interlinked with the short-circuited winding of the squirrel cage cannot be instantly reduced to zero, because the decreasing flux induces a current in the squirrel cage tending to maintain the flux.

However, he is right in his conclusion that the voltage induced in the stator winding by the revolving flux of the secondary may be out of phase with the line voltage at the moment when the latter is applied, and that consequently there may be a heavy rush of current at this instant. That these large momentary currents are very undesirable from the standpoint of shocks to the windings is clearly brought out on the sixth page in the paper, where we read—

"Starting motors with full voltage produces a severe strain for a short period, whereas the use of an auto-transformer starter produces a less severe strain for a longer period and *also a momentary strain that may be more severe than when starting with full voltage.* The auto-starter may produce two severe shocks on the winding in opposite directions."

Thus the use of an auto-starter is liable to increase the severity of the shocks as well as the frequency with which they occur. Prof. Bailey's conclusion, that starters can be dispensed with in the great majority of cases, appears, therefore, to hold equally well, or even more so, when the effects of distortions of the windings are considered. The fact that auto-starters were used in the cases, mentioned by the author, where the insulation failed as the result of distortion of the winding, indicates that the starter is more of a liability than an asset.

The conclusions to be drawn from Mr. Rylander's experiments, taken in conjunction with the conclusions reached by Prof. Bailey, inevitably present the question, "Why are auto-starters, or compensators used in connection with starting of squirrel-cage motors, anyway?" No doubt it is desirable to reduce the starting current as well as to improve the starting torque of squirrel-cage motors, but it seems that this can be much more effectively accomplished by other means than by an auto-starter. Quite a number of years ago Boucherot proposed the double squirrel cage as a means of obtaining good starting torque, low starting current and high operating efficiency. One reason for the slow adoption of the double squirrel cage may have been that the older methods did not lend themselves readily to this type of construction. However, a recently developed process of arc welding the rotor bars seems to be readily adapted to the construction of the double squirrel cage, and there are indications that the immediate future developments of squirrel-cage motors may be along this line.

F. C. Hanker: In connection with Mr. Rylander's paper, it is of particular interest to bring out a phase that has not been

discussed. That is the elimination of the control in connection with power-house auxiliaries. This has been one of our most difficult problems because we have been confronted with sources of power far in excess of those usually found in the industrial installations. For that reason it has been very desirable to have a motor that could be thrown on the line at full voltage with satisfactory starting conditions and without control equipment other than the feeder oil circuit breaker.

The bracing of windings in the past has been largely controlled by experience in the field, and it is interesting to see the new point of attack, to observe the effects more accurately. The type of motor with the double squirrel cage gives reduced starting kv-a. and is applicable in cases where we are limited in the capacity available. In power houses we do not have that limitation and on those cases we can use the simple forms of motor with lower cost and just as satisfactory installation.

H. Weichsel: A complete understanding of the forces acting on the windings of an induction motor when the machine is switched on the line is very important in view of the fact that the electrical engineers of many industrial plants are advocating the starting of squirrel-cage motors directly across the line. The investigation carried on by Mr. Rylander reveals many very interesting points, and in some cases apparently contradictory results. In the following an attempt will be made to give a physical conception of the forces acting in a machine during switching operation.

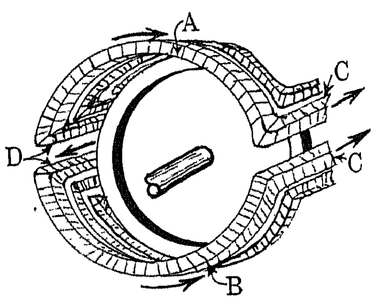

FIG. 1

For simplicity's sake, an induction motor with a so-called chain winding in the primary member will be assumed. A large part of the free ends in such a winding is located parallel to the rotor surface. Another part, the so-called straight part of the free ends, is parallel to the shaft, as diagrammatically shown herewith in Fig. 1 for a two-pole machine. Only one phase of the chain winding is shown.

At any instant, the currents in the circular sections, *A* and *B*, of the free ends flow in the same direction. Therefore, the sections *A* and *B* will attract each other. The straight parts, *C* and *D*, of the coils carry currents of opposite directions. Therefore, a repelling action will take place between *C* and *D*. The forces *C* and *D* try to bend the coils outward, while the forces due to *A* and *B* try to move the coils inward. This assumes that a constant direct current is flowing through the winding. However, if it is a low-frequency current, then the coil will swing periodically, according to the change in the forces acting on the coils. If the frequency of the currents is high, the vibration of the coils will cease and change into a steady deflection. The inertia and spring action of the coils are playing an important part in determining which of the two results will be obtained.

This phenomenon is similar to the well-known fact that the deflection of an a-c. dynamometer-type voltmeter is of a vibrating nature as long as the currents flowing through the instrument are of low frequency and with increasing frequency the swing of the needle becomes smaller and smaller and at a sufficiently high frequency the needle finally shows a steady deflection. Therefore, this example demonstrates a case where either a vibration or a definite deflection can be obtained, depending upon the relative relations of the impressed frequency and the natural periodicity of the deflected member.

It appears to me that this simple experiment gives an explanation of the fact that in Mr. Rylander's tests on the 50-h. p., 60-cycle motor a steady deflection of the coil was observed, while in the tests on the 500-h. p., 25-cycle motor a vibrating deflection was recorded.

In Fig. 1, we had assumed that the overall length of the squirrel-cage winding is considerably less than that of the stator winding and that, therefore, the current in the squirrel-cage endings can not react materially on the free ends of the stator winding.

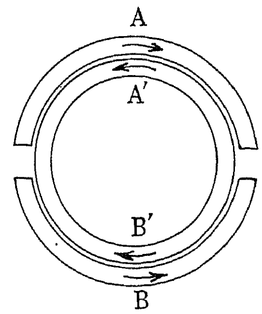

FIG. 2

Fig. 2 represents a condition where the end rings of the squirrel-cage winding are approximately in the same plane with the parts *A* and *B* of the stator free ends. The current distributions in the ring and in the stator free ends are indicated by the direction and shape of the arrows.

The currents in the ring section *A'* and in the stator free ends *A* are in opposite directions and, therefore, a repelling action exists between these members. The straight part of the stator free ends is parallel to the free ends of the rotor bars and the currents in these members are equal but opposed to each other. Therefore, a repulsion exists between these parts also. The net result is that all parts of the stator winding have a tendency to move outwardly, a condition which has been observed in most of the tests shown by Mr. Rylander. This outward movement naturally can either take place in form of a vibrating nature or in a steady deflection.

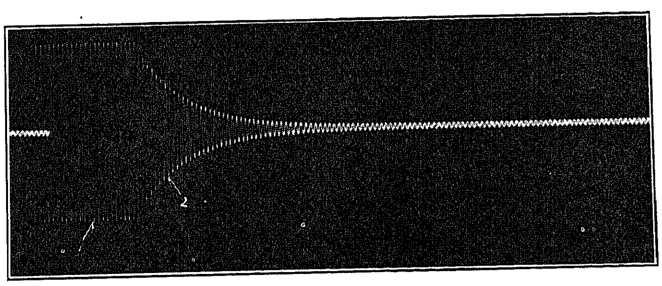

FIG. 3—DYING OUT OF TERMINAL VOLTAGE OF A SQUIRREL-CAGE MOTOR WHEN DISCONNECTED FROM LINE

The forces acting on the windings will not vary in magnitude as long as the current's flow remains unaltered. At any moment the force acting is proportional to the square of the current. During switching operations, transient-current phenomena occur which may produce momentary current flows away above the steady current expected from the constants of the machine. This heavy transient flow may be the result of one of the two following features:

1. When the motor is at rest, the first current inrush depends on the moment at which the motor is connected to the line in respect to the voltage wave on the line.

2. When the motor has been placed in motion by a supply of voltage and is then switched over to a different value of supply voltage, a very increased momentary voltage might act on the motor windings.

The case No. 1 is well understood and simply refers to the phenomena occurring when a choke coil is connected to an a-c. supply. The phenomena No. 2 are not as generally known.

If a squirrel-cage motor is running, let us say at synchronous speed, and the stator winding is suddenly disconnected from the line, then a voltage remains across the stator windings which

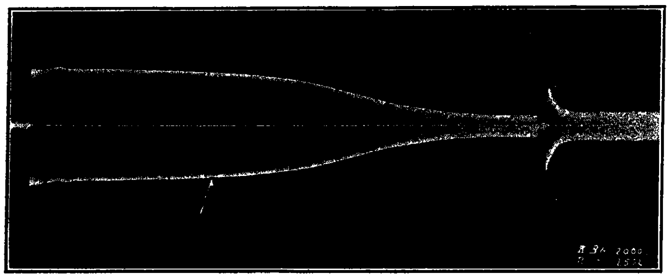

FIG. 4—SQUIRREL-CAGE MOTOR STARTING 22 PER CENT OF FULL LOAD WITH AUTO-STARTER

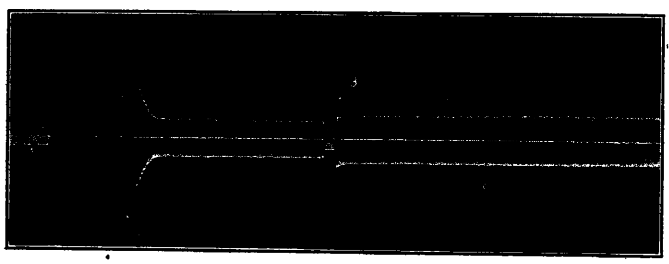

FIG. 5—SQUIRREL-CAGE MOTOR STARTING IDLE WITH AUTO-STARTER

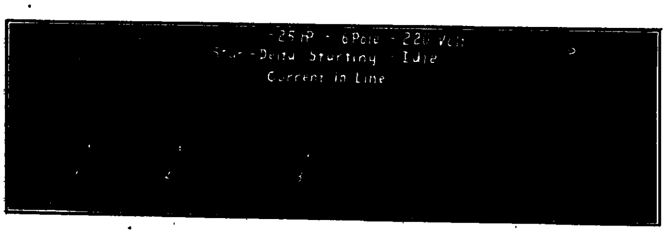

FIG. 6

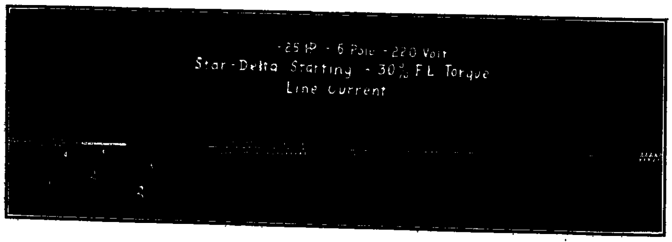

FIG. 7

gradually dies out, as given in the oscillogram Fig. 3. The reason for this remaining voltage is as follows:

According to the Lenz law, the magnetic field in a motor cannot disappear instantly. Therefore, at the moment the line is disconnected from the primary winding, currents will be induced in the rotor winding which try to maintain the original magnetic field of the machine. These are of direct current and gradually die out. The velocity with which they die out depends entirely upon the resistance of the secondary winding and the self induction of the machine. The decrease of the current and, therefore, the decrease of the generating voltage occurs according to the well-known logarithmic law, provided the speed of the armature remains constant.

Naturally the speed of the armature decreases gradually when the supply is disconnected and, therefore, the frequency of the voltage generated in the stator decreases with increasing time.

Therefore, if the line is reconnected to the motor shortly after it has been disconnected, it may occur that at the moment of reconnection the voltage generated in the machine is out of phase with the voltage impressed on the machine, which results in a very heavy current draw at the switching moment.

Oscillograms Figs. 4, 5, 6, and 7 show the heavy current inrushes which may occur during the switching period. As the forces produced by the currents are proportional to the square of the currents, it follows immediately from these oscillograms that the forces at the moment of switching might reach tremendous values and act like hammer blows on the windings.

It may be stated that these forces do not only act on the free ends of the windings but also act to produce torque on the rotor and incidently on the stator. I am familiar with cases where these torques reached such tremendous values that the stator iron shifted in the frame.

There are not only forces acting on the free ends of the stator winding in the manner discussed, but there are also forces acting on the free ends of the squirrel-cage winding itself.

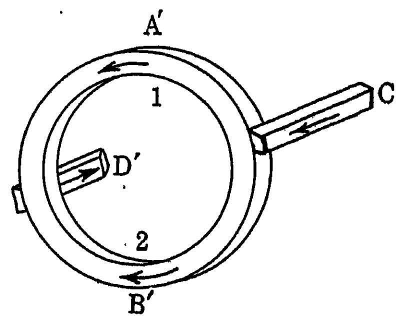

FIG. 8

Fig. 8 represents the current distribution in a squirrel-cage winding at a given moment for a two-pole machine. The ring sections, A'–B', carry a current of equal distribution flowing in the same direction. Therefore, an attraction occurs between these two sections, as indicated by the arrows 1 and 2. The extensions of the rotor bars, C and D, carry equal currents but in opposite directions. Therefore, a repelling force is created between these bars.

If we assume that the currents flowing in the rotor winding are direct currents, then the ring will take an elliptical shape under the influences of the forces just discussed. In a polyphase motor, the relative current distribution in the rotor bars and rings is the same at any moment but the picture of current distribution rotates. The velocity of rotation in respect to a given point of the squirrel cage is proportional to the frequency of the currents flowing in the secondary. Therefore, the end rings on the squirrel cage will successively take shapes as indicated in Figs. 9A to 9E inclusive. This periodic deformation of the rings and bars is quite likely to lead to a fatigue of the materials and a final breakage unless the rings are properly supported to resist effectively the forces acting on it.

In a similar manner, if the stator coils are laced to a circular coil-supporting ring, the forces acting on all the windings have a tendency to deform the ring into an elliptical shape similar to the Figs. 9A to 9E inclusive. In order to counteract this efficiently, it is advisable to brace the coil-supporting rings in twice as many places as there are poles and give these brackets for the

coil-supporting rings equal spacing. A coil-supporting ring with semi-circular cross section and a piece of heavy insulating material on the straight part of the coil-supporting ring has proven to be more effective than a circular ring. The coil would touch the circular ring in only one point and the unavoidable vibration of the coil and ring is likely to wear the insulation through in relatively short time, while with the semi-circular ring the coil makes more of a line contact than a point contact with the supporting ring and, therefore, the possibility of wearing through the insulation is materially reduced.

Mr. Rylander pointed out that the deflection of the stator coils depends to a large extent on the length of the free end coils, but as the length of the free end coils is closely related to the arc

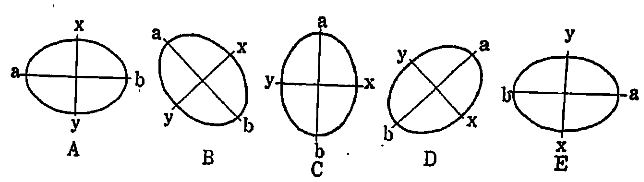

Fig. 9

spanned by the coils, it is possible to obtain simple empirical rules to determine when coil-supporting rings are needed.

My experience has shown that whenever the coil spans more than 8 to 9 in., it is absolutely essential to provide the stator winding with coil-supporting rings. The lower figure refers to 25-cycle and the larger figure to 60-cycle machines. This is explained by the fact that the 25-cycle machines usually have finer wire than the 60-cycle machines and, therefore, the coils have less rigidity.

Returning once more to the forces acting on the squirrel cage, the part of the bar which is located in the slots is subjected to a force due to the leakage lines passing over the bar, as indicated in Fig. 10. These magnetic lines have the tendency to push the bar inward, *i. e.*, in the direction towards the shaft. The force producing this tendency is proportional to the square of the current, *i. e.*, the force will reach a maximum whenever the current is of either positive or negative maximum, as given in Fig. 11. If the bar is not secured tightly in the slots, then these forces are apt to set the bar in vibration, swinging it around its

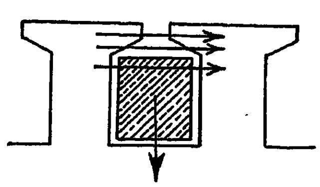

Fig. 10

two points of support on the two end rings of the machine, in the same manner as a violin string. This may result in a fatigue in the bar material at the point where the bar joins the ring with a consequent breakage. It is, therefore, essential to provide means to anchor the bars securely in the slots. Such arrangements can be made, for instance, by driving a wedge between the top of the bars and the lips of the rotor slots.

Mr. Rylander showed in his Fig. 11 that the time decreases rapidly with increasing starting voltage. In case the machine has to accelerate nothing but an inertia load, it can quite readily be proved that the starting time varies inversely to the square of the impressed voltage. If, however, a friction load is to be started in addition to an inertia load, then the starting time decreases still faster than the inverse of the square of the voltage. Therefore, it might quite readily occur that when starting a machine under full voltage the heating of the stator coils is less than when the same load is started with reduced voltage though such starting draws a heavier current than the reduced-voltage starting.

On the other hand, if a motor has sufficient starting torque to handle its load with reduced voltage, then the resistance of the squirrel-cage rotor could be reduced when full-voltage starting is employed. This would result in an increased running efficiency of the machine but also in an increased heating of the stator winding during the starting period.

Full-voltage starting, therefore, might finally lead to machines with somewhat increased running efficiencies by decreasing the rotor resistance. If, however, use is made of a decreased rotor resistance, the designer will have to safeguard against a saddle formation in the speed-torque curve. In other words, the machine will have to be designed more carefully.

J. L. Rylander: In regard to Mr. Hansen's comments about the auto-starter, it is well to mention that the type of auto-starter used was that which opens the circuit momentarily when changing from the low-voltage tap to the full-line voltage, as this is the most severe condition of the various auto-starters; and it was used for the purpose of finding out what happens when the circuit is opened momentarily before applying full voltage.

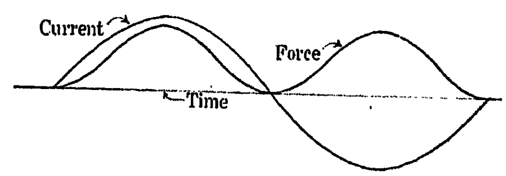

Fig. 11

In regard to Mr. Weichsel's comments about the physical conception, I think the best physical conception is to keep in mind that like currents attract and opposite currents repel. We know the direction of the current and therefore we know the reactions.

In regard to Professor Karapetoff's remarks about the formulas, it should be added that the purpose of the formulas is to show the main factors involved and use them in conjunction with tests, or the known conditions of certain motors to which comparisons can be made. There are four main factors:

1. The shape of the coil.
2. The spacing.
3. The current.
4. The length between supports.

The shape of the coil is fairly constant and the coil movement is directly proportional to it; the spacing is fairly constant and the coil movement is inversely proportional to it. But these two points are not the dominating factors. The coil movement varies according to the square of the current, which varies considerably in the different motors, varying anywhere from four to ten times the full-load current. But the dominating factor is the length, which varies as the third or fourth power. For practical purposes, the main factors are sufficient and the best way is to use them in connection with that which is known.

We can watch any motor that we are acquainted with as it is started on the 50, 65 or 80 per cent voltage tap. Then if we compare that with the formulas, we can about tell what will happen when full voltage is applied. Or if we want to compare windings that are similar except for length, it is a matter of comparing the length of the coil extensions.

Another New Self-Excited Synchronous Induction Motor

BY VAL. A. FYNN*

Fellow, A. I. E. E.

Synopsis.—One form of self-excited synchronous induction motor was described by the same author in a paper presented at the Spring Convention of the A. I. E. E., Birmingham, Ala., the present contribution describes a second form of such a motor. The starting, synchronizing, synchronous load and asynchronous overload periods are analyzed with special reference to the synchronizing torque, the automatic compounding and the weight efficiency, and it is shown that this second form is not only capable of duplicating the performance of the first form but of bettering same.

IN a paper read at Birmingham, Ala., at the 1924 Spring Convention of the A. I. E. E., the writer described the motor diagrammatically shown in Fig. 1, and dealt fully with the theory of this machine during the starting, the synchronizing, the synchronous load and the asynchronous overload periods. It will now be shown how even better results can be achieved in another way. In order to positively and readily differentiate between the two motors, let us refer to that shown in Fig. 1 as "Form No. 1" and to that here dealt with, as "Form No. 2."

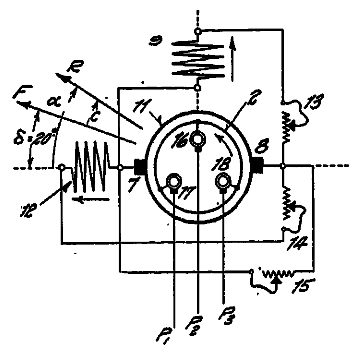

FIG. 1—SELF-EXCITED SYNCHRONOUS INDUCTION MOTOR FYNN FORM No. 1

British Patent No. 3227 of 1913, issued to Crompton & Burge, relates in the main to synchronous motors and indicates among other things, and quite generally, a very interesting arrangement of windings and brushes which by proper modification and proportioning can, as hereinafter described, be used to cause the unidirectional excitation of such machines to increase with increasing motor load in a practically useful manner. The arrangement in question is applicable to single, as well as to polyphase, self-excited synchronous motors and is diagrammatically shown in Fig. 2; its theory, as the writer sees it, can be stated in a few words.

In the two-pole embodiment shown in Fig. 2, the revolving member is the primary, and carries a winding 2, connected to a commutator and capable of being connected to an alternating current supply by means of a suitable number of slip-rings such as 8, 9. In the figure the commutator is not shown and the brushes cooperating with same are supposed to be resting directly on the commuted winding. The same clarifying expedient is used in all the other figures. There are two sets of brushes 4, 5 and 6, 7, located along axes displaced by 90 electrical degrees. The stationary member carries two coaxial windings 11 and 12, located in the axis of the brushes 6, 7. The winding 11, is connected to the brushes 4, 5, the winding 12 to the brushes 6, 7. The British patent states that the voltage at the brushes 6, 7 is dependent on the cross flux which is approximately proportional to the primary armature reaction *A R*. Winding 11 is referred to as the "shunt" and winding 12 as the "compounding" winding. It will be shown that these terms do not correctly describe the functions of the windings 11 and 12, yet, provided this is understood, they will do as well as any others and will be used hereafter.

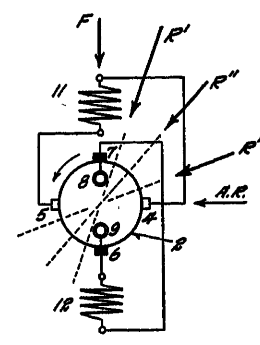

FIG. 2—CROMPTON-BURGE ARRANGEMENT OF EXCITING AND COMPOUNDING CIRCUITS FOR SELF-EXCITED SYNCHRONOUS MOTORS

During the synchronous operation of the machine shown in Fig. 2, the voltages appearing at the brushes 4, 5 and 6, 7 are both unidirectional and their magnitudes depend on the magnitude and space location of the unidirectional resultant motor magnetization *R*. One component of this resultant magnetization is *F* which is due to the arithmetical sum of the unidirectional ampere-turns in 11 and 12, its other component is the unidirectional primary or armature reaction

*Consulting Engineer & Patent Advisor, St. Louis, Mo.

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 9-12, 1925.

A R whose magnitude and space position vary with the load and the power factor of the motor. At no-load R may be made to nearly coincide with F. As the load increases the angular displacement c between R and F increases. In the case of Fig. 2, where the primary is supposed to revolve counterclockwise, F is stationary in space and R moves further and further away from F as the load increases, progressing in a direction opposed to the rotation of the primary and successively occupying the positions R', R'', R''' and so on. When the primary is stationary, both F and R revolve synchronously; with increasing load, F moves away from R in a direction opposed to the rotation of the secondary. At no-load the unidirectional voltage at the brushes 4, 5., is therefore nearly a maximum and it decreases with increasing load. The unidirectional voltage at the brushes 6, 7 is nearly zero at no-load and increases as the load increases. The question arises, can these conditions be utilized in order to secure a satisfactory automatic regulation of the unidirectional excitation of the motor throughout

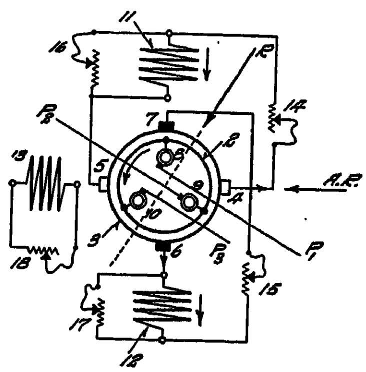

FIG. 3—SELF-EXCITED SYNCHRONOUS INDUCTION MOTOR, FYNN FORM NO. 2

its load range? If so, then can a motor embodying this type of automatic regulation be made to show an acceptable starting, synchronizing and overload performance? What can be done in these respects will be explained in connection with Figs. 3 and 9.

The three-phase, two-pole motor shown in Fig. 3 is a self-excited, synchronous induction motor of Form 2. The primary revolves and carries a winding 2 adapted for connection to the three-phase supply P_1, P_2, P_3 through the slip-rings 8, 9, 10, and a commuted winding 3 with which the brushes 4, 5 and 6, 7 located along axes displaced by 90 electrical degrees cooperate. The stationary member, here the secondary, carries the "shunt" and "compound" windings 11, 12 located in the axis of the brushes 6, 7 and the auxiliary winding 13 located in the axis of the brushes 4, 5. The "shunt" winding is connected to the brushes 4, 5 through the adjustable resistance 14 and can be shunted by the adjustable resistance 16. The "compound" winding is connected to the brushes 6, 7 through the adjustable resistance 15 and can be shunted by the adjustable resistance 17. The circuit of the winding 13 can be closed over the adjustable resistance 18. The windings 11 and 12 are connected to magnetize in the same direction, as shown by the arrows placed alongside these windings. The arrow A R indicates the general direction of the primary armature reaction.

The auxiliary winding 13, together with the exciting windings 11 and 12, form a polyphase, here two-phase, arrangement of windings on the secondary and the machine can, therefore, be very readily and most effectively started, just like a polyphase slip-ring induction motor. In order to facilitate this starting, as well as to gain other advantages, the magnetic circuit is built exactly like that of an ordinary induction motor, without polar projections on rotor or stator and with a very small and uniform air-gap.

In the case of small machines the shunting resistances 16 and 17 can be omitted and one or both of the windings 11 and 12 closed over the commuted winding 2 for use in connection with the winding 13 at starting. The torque is regulated by suitably adjusting the resistances 14, 15 and 18. These resistances are manipulated in exactly the same manner as those in the secondaries of an induction motor. In the case of larger motors, or where small ones have to deal with particularly severe starting conditions, the windings 11 and 12 are closed over the resistances 16 and 17 and the values of the resistances 14 and 15 are kept high during the starting period in order to protect the commutator from the starting currents. When synchronism is nearly reached, the winding 18 is left short-circuited, but if they have been used the resistances 16, 17 are disconnected and the resistances 14, 15 set to their synchronizing or operating values.

The revolving flux F', produced by the polyphase currents in the primary, always revolves at synchronous speed with respect to the primary and, hence, to the commuted winding 3. As the motor starts, the primary moves in a direction opposed to that in which F' revolves. Since F' must continue to revolve synchronously with respect to the primary, its speed in space, for instance with reference to the secondary windings 11, 12, 13, must diminish as the rotor speed increases. Now the revolution of F' with respect to the secondary windings generates voltages therein, the frequency and magnitude of which diminish with increasing rotor speed, both frequency and magnitude becoming zero when the rotor reaches synchronism. These voltages are responsible for the induction motor torque-producing currents in the secondary windings and cannot synchronize the motor because they approach zero as the rotor speed approaches the synchronous. The amplitude of the voltages generated by F' in the commuted winding 3 remains constant as long as F' is constant because F' always revolves synchronously with respect to 3. The voltages generated in 3 are collected by the brushes 4, 5 and 6, 7. The amplitude of the brush voltages is, therefore, constant but their frequency depends on the speed with which F'

moves relatively to said brushes and therefore decreases as the rotor speed increases, becoming zero when the rotor reaches synchronism because F' is then at a standstill.

During the synchronizing period the windings 11 and 12 are not shunted and are connected to the brushes cooperating with the commuted winding. As the induction-motor-torque-producing currents in the secondary windings diminish, the currents due to the slip-frequency brush voltages in the windings 11 and 12 increase, because of the constant amplitude and diminishing frequency of said voltages. These brush currents react with F' and produce a synchronizing torque which brings the rotor into synchronism.

As soon as synchronism is reached the brush currents become unidirectional and provide the unidirectional excitation of the machine through the agency of the windings 11 and 12. As the load changes so does the location of the resultant motor magnetization R change with respect to the axes of the brushes, thus changing the brush voltages. During synchronism, the winding 13 is idle.

When the torque demand is in excess of the maximum synchronous torque of which the motor is capable, the rotor slips out of synchronism and continues to run asynchronously, the windings 11, 12 and 13 again doing duty as polyphase secondaries of an induction motor. Under these conditions the synchronizing torque reappears.

Such in a general way is the mode of operation of the motor, Fig. 3. After what has been said, there can be no difficulty about the conditions to be fulfilled in order to secure a good starting performance. The only question is how are the windings 3, 11 and 12 to be dimensioned in order to secure a sufficiently powerful synchronizing torque and a good compounding characteristic.

To solve the compounding problem it is necessary to divorce one's mind from the idea that 11 is a true shunt and 12 a true compounding winding, and that the voltage at the brushes 6, 7 varies proportionately with the armature reaction. As a matter of fact, increasing load causes the ampere-turns in 11 to diminish and those in 12 to increase. If a compounding action is to be secured the ampere-turns in 12 must increase much faster than those in a true compounding winding would be called upon to increase with increasing load.

Assuming that the motor of Fig. 3 is given the same general design constants as that of Fig. 1, it will be interesting to determine whether or not the performance of the motor of Form 1 can be approached or duplicated by that of the motor of Form 2.

In Fig. 45 of the author's A. I. E. E. paper entitled "A New Self-Excited Synchronous Induction Motor" are given performance curves of a Form 1 motor when designed to produce a certain maximum unidirectional excitation and to operate with its brushes 7, 8 (see Fig. 1 of the present paper), displaced by $\delta = 20$ electrical degrees from the resultant unidirectional magnetization F produced by its secondary windings 9 and 12. With a motor of Form 2 one is able to absolutely duplicate the compounding performance of Form 1. In case the brushes of Form 1 are displaced by δ degrees, this duplication is achieved by so dimensioning the circuits of the windings 11 and 12 of Fig. 3 that when the angular displacement c between F and R is zero the ampere-turns in 11 are proportional to $\sin \delta$, that when $c = 90$ degrees the ampere-turns in 12 are proportional to $\cos \delta$, and that for any value of c the arithmetical sum of the ampere-turns in 11 and 12 of Fig. 3 is equal to the vectorial sum of the unidirectional ampere-turns of Fig. 1. In Fig. 1, when $\alpha = \delta$ then R coincides with F and $c = O$. In Fig. 3 R coincides with F when α is zero. Fig. 4 shows the primary current i_1, the power factor $\cos \phi_1$ and the exciting ampere-turns M of the Form 2 motor shown in Fig. 3,

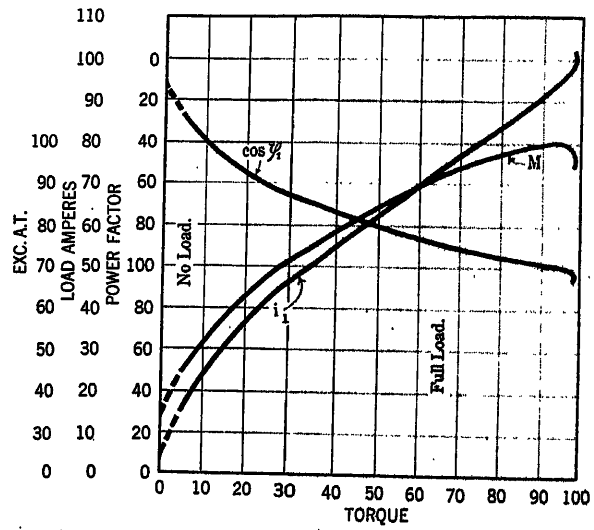

FIG. 4—SYNCHRONOUS PERFORMANCE CURVES OF FYNN FORM No. 2 MOTOR

when the "shunt" and the "compound" windings are dimensioned as just specified. It is seen that the primary current always has a very acceptable value although the power factor is leading almost throughout the synchronous operation of the machine, and that the performance of this Form 2 machine at synchronous speed is indeed identical with that of Form 1.

The commuted winding must be dimensioned with an eye to commutation and to the value of the voltages generated in 11 and 12 at the moment of starting. Both considerations lead to the selection of a low brush voltage. Values of 10 to 30 volts will in most cases answer the purpose. It should be noted that at no-load, practically all of the exciting current is supplied through the brushes 4, 5 which then stand near the neutral in so far as the resultant motor magnetization R is concerned. At full load it is the brushes 6, 7 which carry practically all of the exciting current and

at that time these brushes also stand near the neutral as referred to R.

Turning to the synchronizing possibilities of Form 2, it is seen that at subsynchronous speeds the phase of the brush voltage e_2 appearing at the brushes 6, 7, (see Fig. 5), is the same as that of the voltage generated by the primary revolving flux F' in the winding 12 to which the brushes 6, 7 are connected whereas e_1 appearing at the brushes 4, 5 is in phase quadrature with the voltage generated in 11. For these reasons, the brush current conducted into 12 will react with F' to produce a unidirectional and pulsating torque while the brush

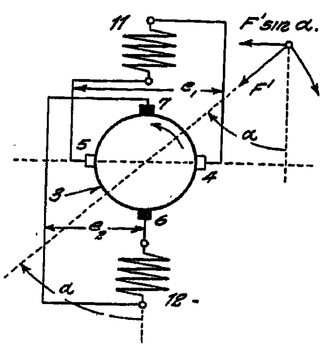

FIG. 5—SHOWING HOW THE SYNCHRONIZING TORQUE IS PRODUCED IN FORM NO. 2 MOTOR

current conducted into 11 is responsible for a double-slip frequency torque with equal positive and negative maxima. How these torques come to be unidirectional and of double frequency can be recognized with the help of Fig. 5.

If the primary member of the motor revolves counterclockwise, it is because the primary flux F' revolves clockwise. The difference between the speeds of F' and of the rotor is equal to the slip of the latter. F' moves synchronously. In Fig. 5, the flux F' has traveled α deg. from its position of coincidence with the axis of the brushes 7, 6, which position is that from which α is measured. For all values of α between zero and 180 deg., the brush voltage e_2 is of the same direction. To be able to speak of this direction as positive or negative, let it be assumed that the direction which e_2 has in normal synchronous operation is the negative one. The normal synchronous conditions are shown in Fig. 6 for both brush voltages and indicate that for values of α between zero and 180 deg. e_2 is negative. Reference to Fig. 5 shows that for values of α between 180 and 360 deg. e_2 must then be positive. This result has been plotted in Fig. 7 on the simplifying assumption adhered to throughout this paper that all voltages, currents and fluxes vary according to the sine or cosine law. The curve e_2 can also represent the current conducted into the winding 12 since at the very low brush voltage frequency existing near synchronism there is practically no phase difference between voltage and current. The current scale may, of course, differ from the voltage scale. The brush voltage e_2 and the corresponding brush current are always proportional to sine α. The other factor determining the magnitude of the synchronizing torque is that component of F' which is at right angles to the axis of the winding 12. This component is $F' \times \sin \alpha$ and the resulting positive torque T_{s-12} is, therefore, proportional to sine^2 α. It is unidirectional and pulsating, becoming zero whenever the axis of F' coincides with the axis of the brushes 6, 7 and remaining positive because the polarity of F' with respect to 12 changes concurrently with that of e_2. The maximum amplitude of this torque is proportional to the maximum conduced ampere-turns in 12. For the conditions yielding the performance curves of Fig. 4, the maximum unidirectional ampere-turns in 12 are proportional to cos 20 deg., which makes the maximum amplitude of T_{s-12} of Fig. 7 proportional to cos 20 deg.

Turning now to the brush voltage e_1 appearing at the brushes 4, 5 and impressed on the secondary 11. By reference to Figs. 5 and 6 it is clear that when $\alpha = 0$ the voltage e_1 is at a negative maximum and becomes zero when $\alpha = 90$ deg. Curve e_1 of Fig. 7 shows its variation throughout a cycle, e_1 is in phase quadrature to e_2 and is always proportional to cos α. Therefore, the brush current due to e_1 is also proportional to cos α and reacts to produce torque with that component $F' \times \sin \alpha$ of F' which is perpendicular

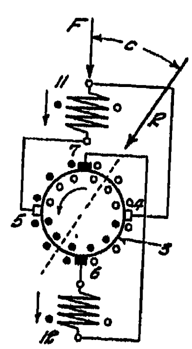

FIG. 6—SHOWING THE SYNCHRONOUS DISTRIBUTION AND DIRECTION OF THE UNIDIRECTIONAL AMPERE-TURNS IN FORM NO. 2 MOTOR

to the axis of 11. The resulting torque T_{s-11} is proportional to $F' \times \sin \alpha \times \cos \alpha$ and is of double slip frequency becoming zero whenever F' coincides with the axis of the brushes 4, 5 or with that of the winding 11. For the conditions yielding the performance curves of Fig. 4 the maximum unidirectional ampere-turns in 11 are proportional to sin 20 deg. which makes the maximum amplitude of T_{s-11} of Fig. 7 proportional to ½ sin 20 deg.

The actually available synchronizing torque is the resultant T_s of T_{s-11} and T_{s-12} of Fig. 7 and it is clear that this resultant is substantially unidirectional and therefore highly desirable. It will produce rapid and positive synchronization without tendency to hunt and will not interfere with the asynchronous overload

stage of the motor's operation to reduce its maximum asynchronous torque.

It is seen that by making the maximum ampere-turns in 12 greater than the maximum ampere-turns in 11 it is possible to secure a desirable compounding characteristic as well as very favorable synchronizing torque conditions. Here again we find no conflicting requirements to embarrass the designer.

Since the winding 11 does not materially contribute to the synchronizing torque when connected to the brushes 4, 5, its circuit need not be closed at that stage and it can also be left open at starting. However,

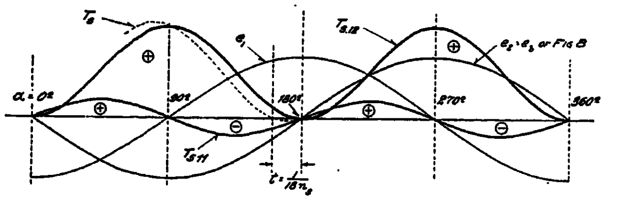

FIG. 7—SYNCHRONIZING VOLTAGES AND TORQUES IN FYNN FORM NO. 2 MOTOR

material increase in synchronizing torque can be secured by temporarily connecting 11 to the brushes 6, 7 and in parallel with 12. To this end, that terminal of 11 which is normally connected to brush 5 is connected to brush 7 and the other to brush 6. This results in a 32 per cent increase in the maximum amplitude of the resultant synchronizing torque. Another way to increase this torque is to dimension 12 for a maximum number of ampere-turns in excess of that required for compounding purposes, reduce these ampere-turns to the desired compounding value by means of the resistance 15 and reduce this resistance to zero during the synchronizing period.

It has already been stated that Form 1 motor of Fig. 1 performs, in synchronous operation, as indicated by the curves of Fig. 4 when the resultant unidirectional magnetization in the motor of Fig. 1 is displaced by 20 electrical degrees with respect to the axis of the brushes 7, 8 of said motor, and its maximum value equals the maximum arithmetical sum of the magnetizations produced by the windings 11 and 12 of Form 2 motor of Fig. 3. To satisfy these conditions, the maximum ampere-turns (disregarding saturation) in windings 9 and 12 of Fig. 1 must be proportional to sine 20 deg. and cos 20 deg. respectively, which means that these ampere-turns are the same as the maximum ampere-turns in windings 11 and 12 of Fig. 3. With this information, the curves in Fig. 8 can at once be plotted. The curve e_b in Fig. 8 must be identical as to phase and magnitude with curve e_2 in Fig. 7, since the machines are identical except for the arrangements and dimensioning of the secondary windings and the number and location of brushes on the commutator. The brush current conducted into the winding 9 of Fig. 1 must yield a double-slip frequency torque T_{s-9} because of the quadrature relation between the axes of its brushes 7, 8 and of its winding 9. The maximum amplitude of this torque is ½ sine 20 deg. and it is therefore identical with T_{s-11} of Fig. 7 except as to sign. The winding 12 of Fig. 1 yields a strictly unidirectional torque proportional to sine^2 α with a maximum amplitude proportional to cos 20 deg. This maximum amplitude corresponds with the maximum of e_b. Torque T_{s-12} of Fig. 8 is, therefore, identical with torque T_{s-12} of Fig. 7 as to direction, magnitude and configuration. Part of the resultant synchronizing torque T_s, is dotted into Fig. 8 and is clearly identical with the resultant synchronizing torque of Fig. 7. In both cases it occurs for the same value of c. The amplitude of the negative wave of T_s is less than 3 per cent of the positive one and the latter lasts eight times as long as the former. It is certainly true to say that T_s is substantially unidirectional.

The very interesting conclusion is thus reached that the synchronizing performance and the synchronous characteristics of a motor of Form 1, see Fig. 1 or any of its modifications, *can be absolutely duplicated* by the motor of Form 2 shown in Fig. 3. No demonstration is necessary to convince anyone that the starting performance of these two machines can be made identical. If the asynchronous characteristics and the synchronizing torques are identical then the asynchronous overload performance of the two machines must also be identical.

But while Form 2, Fig. 3 can do everything that Form 1 Fig. 1 can accomplish, the converse is not true.

It has been pointed out that the synchronizing torque of Form 2 could be materially increased by temporarily connecting winding 11 to the brushes 6, 7. For the compounding characteristic shown in Fig. 4, this change results in an increase of 32 per cent in the resulting

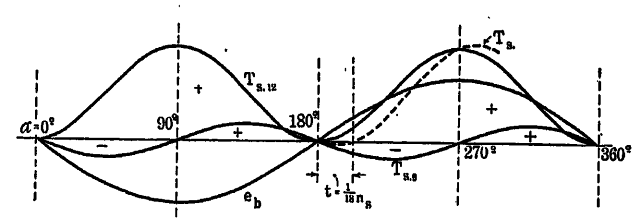

FIG. 8—SYNCHRONIZING VOLTAGES AND TORQUES IN FYNN FORM NO. 1 MOTOR

synchronizing torque. To duplicate this advantage it would be necessary to temporarily displace the brushes of Form 1 so as to bring their axis into coincidence with the resultant magnetization produced by the windings 9 and 12, a proceeding which is not as practical as a simple change of connections.

But Form 2 also permits of a wider range of variation in so far as the compounding characteristic is concerned for the reason that said characteristic can be influenced in at least three ways. The ratio of the maximum ampere-turns in 11 and 12 can be varied as explained or by changing the value of e_1 relatively to that of e_2. This is, for instance, achieved by spacing the brushes

of one set differently from those of the other. A still wider variation can be brought about by disturbing the quadrature relation of the two sets of brushes or displacing both sets from the position shown in Fig. 3 but without disturbing their quadrature relation.

In the arrangement shown in Fig. 9 the brushes 4, 5 are so placed that e_1 is less than the maximum at noload and does not reach zero at full load, while the brushes 7, 6 are so located as to make e_2 negative at no load and positive at full load. The result is that the magnetizations due to 11 and 12 oppose each other at noload and cooperate at full load. No doubt, this example will suffice to indicate the wide range of possibilities afforded by the self-excited synchronous induction motor of Form 2 as illustrated in Figs. 3 and 9. In all cases one secret of success lies in the proper proportioning of the windings 11 and 12 with respect to the limits within which the two brush voltages vary in synchronous and nearly synchronous operation.

The displacement of the brushes from the basic

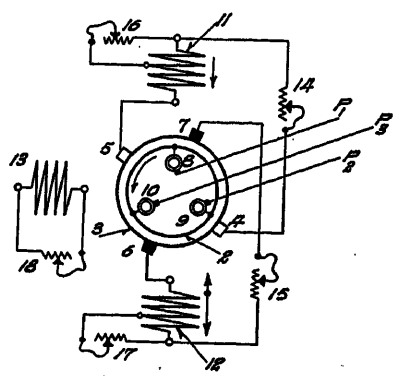

FIG. 9—SELF-EXCITED SYNCHRONOUS INDUCTION MOTOR, FYNN FORM NO. 2

position shown in Fig. 3 also has a bearing on the magnitude and configuration of the synchronizing torque. Just how this torque is affected can readily be stated in general terms. When the axis of the brushes cooperating with the commuted winding on the primary and collecting the synchronizing voltage coincides with the axis of the secondary winding to which said brushes are connected, then the resultant synchronizing torque is unidirectional and pulsating. When said axes are displaced by 90 electrical degrees, in other words, when the phase of the brush voltage conductively impressed on a secondary winding differs by 90 degrees from the phase of the voltage generated in said winding by the synchronously revolving primary flux F', then the resultant synchronizing torque is alternating, of double slip frequency and, all other conditions being equal, of half the amplitude of the pulsating torque. For an intermediate position of the axes under reference the resulting torque has one unidirectional and pulsating and one alternating, double slip frequency component. The nearer the brush and winding axes approach coincidence the larger the unidirectional and the smaller the alternating torque component. It follows that the more the quadrature relation between brush axis and winding axis can be departed from the better for the resulting synchronizing torque. This consideration at once shows one more advantage of the arrangement of brushes shown in Fig. 9.

In so far as the compounding characteristic is concerned, the windings 11 and 12 must be dimensioned with reference to the maximum brush voltages available *within the limits of synchronous operation.* These limits are determined by the travel of R under the influence of increasing load. The measure of this travel is the angle c of Fig. 6. The maximum value of c can usually be made to approach 90 electrical degrees. Reference to Fig. 9 at once shows that, for any value of c up to 90 degrees, the maximum brush voltage available within the limits of synchronous operation can very well be less than the actual maximum. But the *actual maximum* brush voltage *is always* available at subsynchronous speeds when F' travels with reference to the brush axes and it is seen that this condition is also a factor in determining the obtainable amplitude of the synchronizing torque, in this new motor it makes the brush voltage partially effective for compounding and fully effective for synchronizing purposes.

It will be noted in Fig. 9 that only part of each of the windings 11 and 12 is adapted to be shunted or short-circuited during the starting operation. Together with the winding 13, one or both of these shunted parts form a two-phase arrangement of windings. Any other combination of windings which provides a polyphase arrangement of windings on the secondary located in inductive relation to the primary can be used in order to insure the starting and the asynchronous overload operation of this motor, which particular one is chosen largely depends on the conditions under which the machine is to operate.

While the embodiments of this new motor chosen for description all have a revolving primary and a stationary secondary, it will be understood that the functions of stator and rotor may be reversed without in any way changing the underlying principles of operation and design.

In view of misunderstandings which have already occurred, and in order to forestall further questions, it should be stated that the author's inventions relating to synchronous induction motors are held by two entirely independent interests, one of which owns all but that covered by U. S. P. 1,337,648.

Discussion

C. F. Scott: The motor described by Mr. Fynn appears a sort of an extension of the motor described by Mr. Weichsel, probably with improved performance, but with some sacrifice of simplicity in construction.

Both are excellent from the standpoint of the inventor and designer, but after we get through with it all, what is it good for? It is good for improving power factor. And is it worth while to improve power factor? Is it worth while to the customer? Should he pay more for a motor in order to get a higher power factor? What he wants is power output. To make a less simple or more expensive motor attractive to him there must be inducement. That inducement probably must come through better rates for service or other advantages. Then comes the question as to whether this is the best way to improve power factor:—there are condensers of one kind or another and there are other types of synchronous motors and so on. The best way will probably again depend upon the size of motor, and conditions of the particular supply circuit, and the like. So we encounter a large and complicated economic and commercial problem of what is the right and best thing to use in different cases.

But from the standpoint of electrical engineers and of new developments in the art, it seems to me that both of these motor papers can be commended as a splendid move toward overcoming certain difficulties. Their successful application will depend on meeting certain questions in the commercial field and on the inducement given for the raising of power factor by the customer.

L. M. Perkins: If you take the simple Fynn-Weichsel motor, having a single field winding, and a single set of brushes, you may obtain any type of synchronizing torque, as it is called, from the double-frequency torque having equal positive and negative maximums, to the double-frequency torque which has a zero negative with a large positive maximum, and is designated by Mr. Fynn as the continuous positive torque.

If the brushes are shifted off from a 90-deg. position with the field winding, the torque has a so-called constant component added to the double-frequency component, until the brushes reach the point where they are in the same line as the stator winding where the constant torque has such a value that the total torque does not become negative but reaches zero. In between these two limits, there is a large range of ratios between the constant torque and the double-frequency torque. The addition of another set of brushes and another winding increases, of course, the constant torque and adds the double-frequency torque at some angle vectorally, which will increase the double-frequency torque over what it was before. The net result, however, is simply constant torque plus the double-frequency torque, which is what was secured with the simple winding. If it is desired to increase the total amount, that is easily done by changing the resistance of the field winding.

As long as the field windings, which are connected to brushes, are all in one axis it is impossible to vary the ratio between the constant torque and the double-frequency torque beyond the range of ratios that may be secured with the single set of brushes and single winding. This is true regardless of how the angle of the brushes with each other or with the field windings is varied.

V. A. Fynn: The suggestion that the theory of this machine be gone into more thoroughly will, I think, be fully met by the addition of a couple of circle diagrams. The synchronous operation of my Form 2 motor is fully discussed in paragraph four of my paper, but the circle diagrams will, no doubt, add to the value of the record. The starting and synchronizing periods are exhaustively dealt with in my paper, the former in paragraphs 5, 6 and 7, the latter in paragraphs 8 to 24 inclusive.

The presence of the two pairs of brushes shown in Figs. 3 and 9 gives the designer possibilities of varying the compounding and the synchronizing characteristics of motors of this type not available in my Form 1 motor, which is that described by Mr. Weichsel in his paper "A New A-C. General-Purpose Motor" and commercially known as the Fynn-Weichsel.

In my Form 1, there is but one set of brushes and the compounding as well as the synchronizing characteristics depend first, on the angular displacement of the axis of this one set of brushes from the axis of the conduced ampere-turns on the secondary and second, on the conduced ampere-turns per volt, in other words on the number of turns and on the resistance of the secondary winding or windings which are connected to the brushes. There are but two ways of varying the compounding or the synchronizing characteristics, one is to change the aforesaid angular relation, the other is to change the ampere-turns per volt of the secondary windings.

In my Form 2 motor, the characteristics in question can be

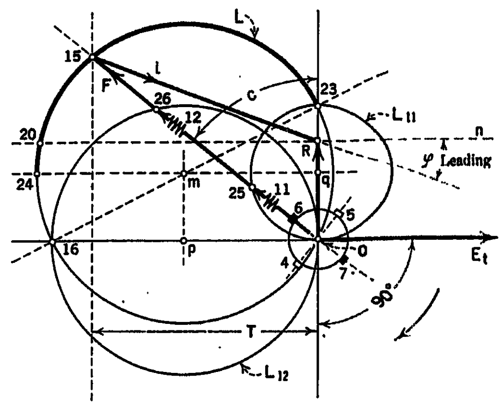

FIG. 1

varied by changing the angular relation between either brush set and the axis of the secondary ampere-turns, by changing the angular relation between both brush sets and the secondary ampere-turns and by changing the ampere-turns per volt of one or of both windings on the secondary. In addition, the maximum brush voltage can be made available for synchronizing without being available in synchronous operation.

Referring to the synchronous operation, let it be supposed that the brushes are located as shown in Fig. 3 and that the maximum ampere-turns in winding 12 are greater than the maximum

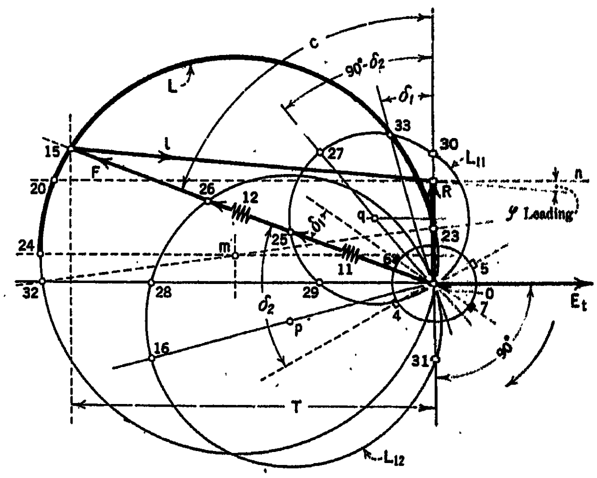

FIG. 2

ampere-turns in winding 11. To construct a circle diagram for these conditions, refer to Fig. 1 herewith and assume that R is the resultant motor magnetization in synchronous operation and that it lags 90 deg. behind the terminal voltage E_t. Further assume that R is stationary and that all the brushes, together with the windings 11 and 12 to which they are connected, are moved through 180 deg. while retaining their correct relative positions. Knowing that the magnitude of the voltage at any pair of brushes, and therefore the magnitude of the ampere-turns in the secondary winding to which they are connected, depend on the angular displacement between R and the axis of said brushes, we

can at once determine the positions for which the ampere-turns in 11 and 12 reach a maximum. When the axis of the brushes 6, 7 is at right angles to R the ampere-turns in 11 are zero and those in 12 a maximum. The vector 0–16 of Fig. 1 herewith shows location and magnitude of the maximum ampere-turns in 12. As the angular displacement between 6, 7 and R changes the end of the vector measuring the ampere-turns in 12 describes a circle, the center p of which is located half way along 0–16. The circle L_{12} is the locus for the ampere-turns in 12. Similarly, when the brushes 4, 5 are at right angles to R, which occurs when the

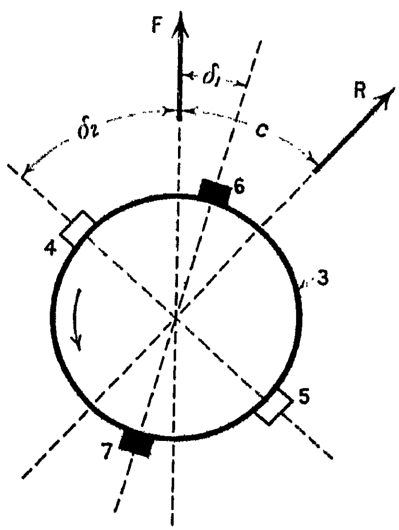

FIG. 3

brushes have moved 90 deg. from their first position, the ampere-turns in the winding 12 are zero and those in 11 become a maximum and are represented by the vector 0–23 at right angles to 0–16. The locus for the ampere-turns in 11 is the circle L_{11} about the middle point q of 0–23 as center. But we are, at each instant, interested in the arithmetical sum of the ampere-turns in 11 and 12, this sum must always be coaxial with the windings 11 and 12 and must, therefore, be measured by a vector coinciding with the axis of the brushes 6, 7. For the angular displacement of R and the brush axes specifically illustrated in Fig. 1, the vector 0–25 measures the ampere-turns in 11, the vector 0–26 those in 12 and 0–15 is the sum of the two. The vector 0–15 represents the secondary unidirectional magnetization F. The locus for F is the circle L with center at m, which center is found as the intersection of the perpendiculars on 0–16 and 0–23 at p and q respectively. The synchronous torque T is always the projection of F on the perpendicular to R. Zero torque occurs at point 23, maximum torque is reached at point 24. The primary current i is measured by R–15 and the primary phase angle by the angular displacement of i from n which is a parallel to E_t through the end of the vector R.

Fig. 2, herewith, shows the corresponding circle diagram for a case such as that illustrated by Fig. 9 of the paper. The selected brush displacements are those shown in Fig. 3 herewith and the ampere-turns per volt in the winding 11 differ from those in the winding 12. Again assuming R and E_t to be stationary and moving brushes and windings counterclockwise, when the latter have moved through δ_1 deg. from the position in which F coincides with R, the ampere-turns in 12 are zero. After a movement through $(90 + \delta_1)$ deg. the ampere-turns in 12 are a maximum and measured by the vector 0–16. The locus for the end of the vector measuring these ampere-turns is the circle L_{12} with center at p, midway on 0–16. After a movement through only $(90 - \delta_2)$ deg. the ampere-turns in 11 are a maximum and measured by the vector 0–27. The locus for the end of the vector measuring these ampere-turns is the circle L_{11}, with center at q midway on 0–27. To find the locus for F, which is the sum of the ampere-turns in 11 and 12, consider any two quadrature positions of the system of brushes. When F coincides with R the resultant secondary ampere-turns are the arithmetical sum of the vectors 0–30 and 0–31 of which the latter is negative. In this case F is represented by the vector 0–23. After the brushes have been moved through 90 deg. the ampere-turns in 11 are 0–29 and those in 12 are 0–28, their arithmetical sum F is 0–32. The locus for the end of the vector F is a circle L passing through the points 23, 0 and 32, which makes it easy to find the center m of this circle. For the rest this diagram is the same as that shown in Fig. 1.

My self-excited synchronous induction motor Form 2 is interesting from two points of view. It is quite independent of my Form 1, known under the trade name Fynn-Weichsel motor, and is not only capable of duplicating the performance of my Form 1 but of excelling same, for it has very useful characteristics not possessed by the latter.

Artificial Representation of Power Systems

BY H. H. SPENCER[1]
Associate, A. I. E. E.

and

H. L. HAZEN[1]
Non-member

Synopsis.—The size and complexity of present-day power systems have increased to the point where the prediction of the behavior of the system by analytical methods is more and more difficult. The solution of commercial networks by Kirchhoff's Laws or by cut and try methods, even with the help of star-delta transformations, leads to such involved equations that the need for simpler methods is keenly felt. Increasing attention has been given to various methods of representing power systems in miniature so that an experimental solution may be substituted for an algebraic one.

The d-c. short circuit calculating table is a satisfactory and relatively simple means of determining short circuit currents in networks, but is too inaccurate to give satisfactory solution under normal operating conditions.

An a-c. artificial representation of power networks in miniature has been developed by O. R. Schurig of the General Electric Company who used 3.75-kw. 110-volt three-phase generators as power stations. Actual transformers are used, while lines and loads are made up of conveniently arranged lumped units of inductance, capacity, and resistance. This apparatus has been in satisfactory operation for several years.

Evans and Bergvall of the Westinghouse Electric and Manufacturing Company used a test floor set-up to check experimentally the theory of long line stability. Powers of about 500 kv-a. were used.

The present paper presents a method of artificial representation on a laboratory scale, decreasing the size of the apparatus and increasing the precision of the results.

All rotating apparatus has been eliminated. Generators are represented by phase shifting transformers; transformers by their equivalent circuits, and lines by lumped constants. A description of the apparatus used by the writers is presented, together with the results which were obtained by its use in the solution of several typical problems. An analytical check on one of the examples is given, showing a precision of better than 1 per cent.

Purpose and Summary

The purpose of this paper is to describe briefly the work done by the authors under the direction of Dr. V. Bush, in the Research Laboratory of the Masschusetts Institute of Technology in designing, building, and testing apparatus for setting up miniature networks, using generating station powers of 100 watts or less. Complete voltage, current, and power solutions were made on several arbitrary networks. The representation was single-phase, using phase-shifting transformers for generating stations, and a vacuum tube voltmeter drawing absolutely negligible current for measuring potentials.

Introduction

Present power systems, comprising one to many generating stations, widely scattered loads, and the connecting lines, form complex electrical circuits. The problem of the power company is to supply its loads with dependable power at constant voltage in the most efficient way through these networks. To adequately solve this problem for an existing and constantly growing system requires thorough knowledge of its electrical characteristics. Lines and cables should be of proper size to carry present and reasonably anticipated future loads, and so placed that the minimum loss and interruption of service will occur. Future additions to lines and generating equipment should be so placed as to give the best system electrically, other conditions being equal.

What cable or line in the present system limits the load which may be added at a given point and what will be the voltage there with the new load? Where can a new feeder be placed to relieve the overload on a substation? How much may the load be shifted between stations within the system without overloading any feeder or causing excessive voltage drop? With a given load on the system, what distribution among the various generating stations gives the best voltage regulation, the minimum losses and best distribution of load over the various feeders? If a new tie line be put in, will it relieve or add to existing overload on the other lines under some conditions? The answer to these questions is found in numerous solutions of the network under normal steady state operation.

Another group of problems is presented when unusual conditions, such as short circuits, occur. Knowledge of what happens with short circuit at various points in a system is important. The proper size of current-limiting reactors must be determined to limit short-circuit currents to safe values. The magnitude of the currents again determines how much time may be allowed for relays to act without causing serious damage, and what size oil circuit breakers are required. As bus bars and other structural parts of the system have the severest mechanical stresses set up under short circuit, knowledge of short-circuit currents gives data needed in their design. Another factor is the voltage at critical points on the system, such as between generating stations, which has direct effect upon the ability of these stations to stay in synchronism. The current and voltage solution of the network under short-circuit conditions gives data from which the answer to the above problems may be obtained.

Methods of Solution

In general, the solution of a network under either normal operating or short-circuit conditions may be done analytically or by one of several experimental methods.

An analytical solution may be accomplished by using Kirchhoff's Laws, or, commonly easier on any but the simplest systems, the cut and try method. Using the former, equating the sum of all the currents entering a junction, and the sum of all voltages around any closed

1. Of Massachusetts Institute of Technology, Cambridge, Mass.

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 9-12, 1925.

loop, each to zero, gives simultaneous equations, the solution of which solves the network. The method becomes so tedious and complicated in a network of any complexity that the cut and try solution is quicker and simpler. By this method, a voltage is assumed at the load most remote from a generating station. Knowing the kv-a. and power-factor drawn, the current is calculated, and the drop due to it, over the line to the next load, added to the assumed voltage. This load current may then be found, the drop due to both currents in the next section of line added to obtain the next junction voltage, and so on until the generating station is reached. The discrepancy between this voltage, and that known to exist at the generating station, is used in making a new trial voltage assumption at the first load, and the problem worked through again. This procedure is continued until a sufficiently close check is obtained for the work in hand. Even the cut and try procedure is very laborious for other than comparatively simple networks and attention has been turned toward experimental solutions.

The most extensively used of these methods is the d-c. short-circuit table,[1] which serves a very useful purpose in giving approximate short-circuit currents. Its results are sufficiently accurate to be used in designing current-limiting reactors, oil circuit breakers, bus bars, and in setting relays. Two methods of representing the a-c. constants on the d-c. miniature are used; the resistance of the arms may be set equal to the reactance or impedance of the corresponding arm in the actual circuit. The former, or reactance method, is most frequently used and gives results less than 20 per cent and usually under 10 per cent in error when the generator reactance forms a large fraction of the total circuit impedance, and the power factor angle of the external circuit is roughly over 45 deg. Here the experimental currents are too large. The impedance method gives approximately the same error when used on circuits having a smaller power-factor angle, but the currents found are below the true values.

This accuracy is good enough for abnormal conditions on a network where other factors, such as generator voltage, are so uncertain. For steady state solution, where results within 1 per cent or less are desirable, the d-c. solution is powerless, and alternating currents with true impedances must be used.

In a-c. representation, the metering of the circuit determines the scale of representation, which should, for convenience and economy, be as small as is consistent with the desired accuracy. Mr. Schurig finds that with standard portable instruments, the current must be 5 or 10 amperes with 200 or 100 volts respectively to keep errors safely below 10 per cent.[2] These errors are a result of the relatively large current taken by standard dynamometer instruments. The voltmeter and wattmeter potential coils together introduce about 1.6 per cent error in the current on the 5-ampere representation. With a line drop of 10 per cent the current coils of ammeter and wattmeter cause an error of slightly over 10 per cent in this drop at 5 amperes if uncorrected. The series impedances of these instruments may, of course, be substituted for an equivalent amount of line impedance, eliminating this error entirely. Error due to potential coil admittances cannot be thus eliminated.

Mr. Schurig's apparatus, in use since 1919, gives results which are usually within 5 per cent of the true value. The error is due to unsteadiness of such small machines and to the difficulty of making the large number of simultaneous readings required, with greater accuracy.

This apparatus may be used for obtaining normal steady state solutions, usually made single-phase; or for short circuits, either three-phase, one wire to ground, or between two wires, in which case unbalance due to unsymmetrical short circuit can be studied.

This, with the work of Evans and Bergvall[3], represents practically all the work done up to the present time. It was in the attempt to get a simple, compact, accurate, easily manipulated laboratory scale means of solving networks that the present method was worked out. Since the factor limiting the reduction of scale was metering equipment, principally the voltmeters, a currentless voltmeter would largely solve the problem. In Appendix I is described the vacuum-tube instrument developed to fulfill this requirement. As constructed, it has the accuracy of the standard portable a-c. voltmeter.

With this instrument available, it was found practicable to reduce generating station capacities to a maximum of about 100 watts.

The apparatus used consisted of phase-shifting transformers representing generating stations, smooth artificial lines, resistance loads and metering equipment.

The phase shifters have the same external characteristics as generating stations, which will later be demonstrated. They alter their load by changing the phase of their terminal voltage relative to the system, the phase shift being manually adjusted in the miniature, and by the torque supplied to the generator in the actual machine.

Sections of the smooth single-phase artificial line in the research laboratory, representing No. 00 B & S solid copper at 8 ft. 9 in. spacing were used for all the lines. In some cases, two parallel circuits were used to give additional capacity. Slide wires, giving adjustable unity power-factor impedance, in series with the ammeter impedance or its equivalent, served as loads.

Voltage as high as 200 r. m. s. could be used and a maximum current of one ampere. Since the ratio of voltage to current is usually of this order of magnitude on the high-tension lines, actual line constants can be used, making current and voltage scales equal. The power scale will then be the product of the current and voltage scales.

1. For references see Bibliography

The vacuum-tube voltmeter was used to measure all voltages, both in phase and magnitude, by the three-voltmeter method. Load ammeters were made a part of the load impedance. At the generating station, the terminal voltage was held constant on the line side of the wattmeter and ammeter current coils. Correcting the wattmeter reading for the small $I^2 r$ loss in the current coils, amounting to one per cent maximum, compensates for all meter errors in the circuit.

ADVANTAGES

a. *Apparatus.* All the component parts of this network, including generating stations, are portable, *i. e.*, one man can carry a phase shifter, the heaviest, piece of apparatus. No particular set-up is required before running the apparatus.

But little space is required, the total set-up of three generating stations, some 200 mi. of line, 6 loads and metering equipment requiring only 40 or 50 sq. ft. of table space.

Since the maximum current is an ampere, very small capacity of lines and loads is required, the smooth artificial lines having ample current capacity. Lamp cord is ample for leads. While the scale is small, ½ and 1 ampere ammeters work well and 1.5-amperes, 150-volt wattmeters give satisfactory deflection. These are standard instruments.

Power requirements may not be of primary interest, still it is an advantage to have low energy consumption. The total input for three stations at full load is less than half a kilowatt.

b. *Operation.* The phase shifters can be set at phase angles unstable for synchronous apparatus and conditions will remain entirely steady. That is, any voltage at any phase within the range of the machines can be held indefinitely. The operator has far more control over the variables than in motor-generator sets.

With the absence of moving parts comes the steadiness of operation of a transformer. With steady supply voltage, the whole network remains free from current and voltage swings, which are somewhat bothersome in small rotating apparatus. Because of this steadiness and completeness of control, adjustments can be made easily, rapidly, and accurately. A network can be quickly solved. The time required for various tests, as will be shown, is surprisingly small.

Relative phases of all voltages are determined by the three-voltmeter method described later, and knowing the power factor of loads and generators, the phase of all currents can be found.

Since this system, as built, is all single-phase, unbalance cannot be studied either under normal operating conditions or in case of short circuit. It is limited to balanced polyphase or single-phase representation. A three-phase set-up can, of course, be used to analyze unbalanced conditions. For steady state solutions this method combines laboratory precision with the simplicity of test floor procedure.

ARTIFICIAL GENERATING STATION

A power network consists essentially of generators, transformers, reactors, transmission lines of one sort or another, and loads. For a representation of power generation it is not necessary to duplicate all generators, for to an observer on the line outside a generating station, completely equipped with instruments, the number of units is undeterminable at any particular time. Also, if there is a Tirrill regulator on the high-tension side of sending end transformers, the presence of the transformers cannot be detected in normal operation. One requirement of an artificial generating station is that it must be able to maintain constant voltage at its terminals or some other point.

Let us see what happens when a generating station takes on or drops load, as viewed by this outside observer. Assume two identical power stations are supplying one load jointly over separate identical lines. Let the load voltage be the vector V_L and the current

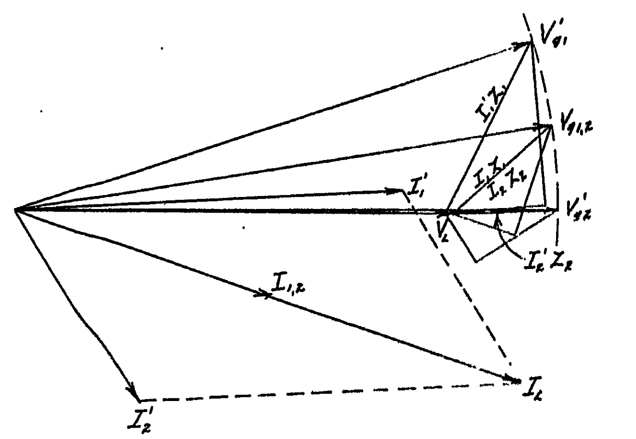

FIG. 1—VETCOR DIAGRAM SHOWING THE EFFECT OF SHIFTING LOAD BETWEEN TWO GENERATORS

taken by the load be I_L. See Fig. 1. The stations have identical governor settings so the load is divided equally. Adding the drops $I_1 Z_1$ and $I_2 Z_2$, where subscripts 1 and 2 refer to line and station 1 and 2 respectively, gives the station voltages, V_{g1} and V_{g2}, which are coincident and slightly advanced in phase from V_L, the load voltage.

Now let station 1 add 50 per cent to the load it is carrying and station 2 drop 50 per cent, the load current remaining constant in phase and magnitude and the station voltages being held constant in magnitude by the regulators. To get the new current I_1' over line 1 requires the drop $I_1' Z_1$. While the load component of I_1' is fixed by the power furnished the station by its prime mover, the reactive component is determined by holding the V_g constant. Imposing the above conditions requires that V_L be slightly decreased in the new condition. Neglecting this in its effect on load power, the vector diagram for the second condition becomes that shown by the primes in Fig. 1.

All that appears to the observer at the high-tension side of transformers at station 1 is a phase advance of V_{g1} when more steam was supplied to this station. The

normal action of a station, then, is shifting the phase of a constant voltage according to the power furnished the generators. A phase shifter therefore fulfills the entire requirements, provided sufficient power can be transformed to hold the voltage constant at the angles at which it is required. Output is a function of terminal-voltage phase relative to the system and a phase shifter output can be adjusted by varying the voltage phase and watching the wattmeter. By having taps at

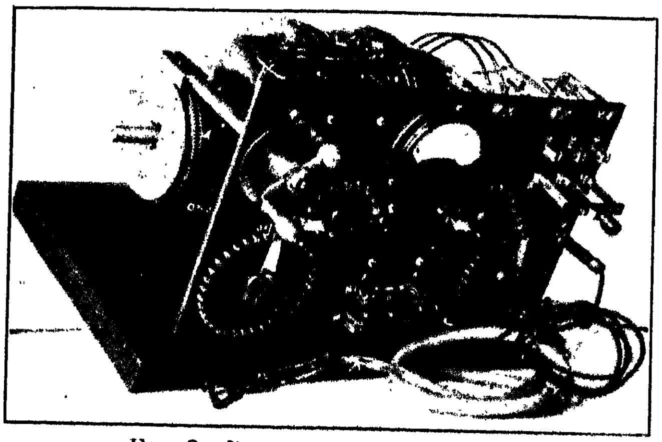

FIG. 2—PHASE SHIFTER COMPLETE

The input is through the three-phase cable in the foreground. Terminal voltage is adjusted by means of the switches on the panel. Voltage phase is adjusted by the crank on the upper left hand corner

different points on the secondary, the magnitude of the voltage can be altered independently of the phase.

To operate these artificial stations, one must, of course, know the voltage regulator settings and turbine governor speed-load curve of the machines represented and this information is necessary for the operation of any artificial station.

The above discussion of generators applies to any

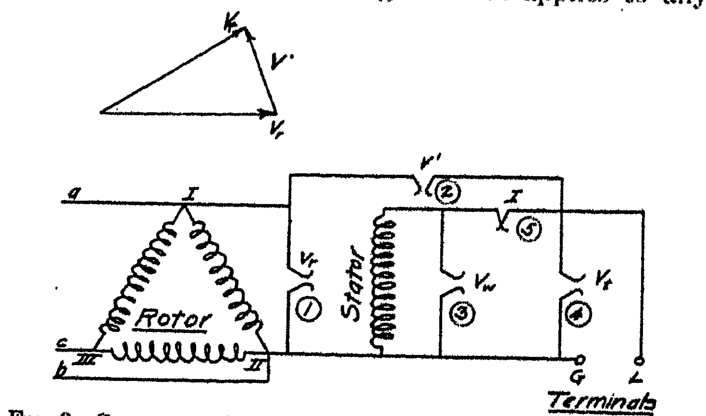

FIG. 3—SCHEMATIC DIAGRAM OF PHASE SHIFTER CONNECTIONS SHOWING METERING JACKS

The vector diagram illustrates the three-voltmeter method of determining voltage phase.

synchronous apparatus so the phase shifter may be equally well used for synchronous condensers or loads at any power factor desired.

PHASE SHIFTERS

On the basis of the above reasoning, a phase shifter, of suitable capacity to fit well with the artificial lines, was designed and two machines have been built. They are three-phase rotor, single-phase stator machines wound on half h. p. induction-motor frames. The details are very similar to an induction regulator, adapted to the voltage and current used.

Fig. 2 is a picture of the complete artificial generating station while Fig. 3 gives a schematic diagram of connections including the metering system. V_r is a voltage jack connected across one phase of the supply voltage, which is used as a phase reference. V_t gives the voltage at the machine terminals G and L. V_w supplies the wattmeter potential coils and at I the ammeter and wattmeter current coils are connected in series. Since one connection of rotor and stator is common, V' will give the third side of the voltage triangle as indicated in the vector diagram. This gives the terminal voltage phase and magnitude. By carrying the common connection throughout the entire set-up, the phase of all voltages can be determined.

STEADY STATE PROBLEMS OF THE POWER SYSTEM AND THEIR SOLUTION ON THE ARTIFICIAL NETWORK

The division of load among alternators operating in parallel is determined, in the steady state, by the governor settings of the prime movers to which they are coupled. Thus if two turbines have the characteristics shown in Fig. 4, the division of load between them would be completely determined in advance. It is not cus-

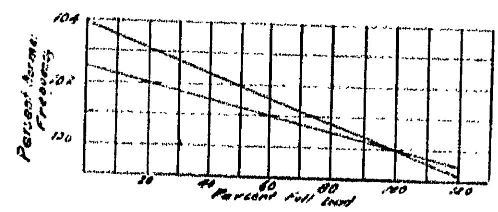

FIG. 4

tomary, however, to regard the governor setting as fixed, but to alter the spring tension so as to make the units pick up or drop load at the will of the load dispatcher. The effect of so increasing the spring tension is to translate the characteristic of the unit upward so that the load carried at any given frequency is increased. On the basis of these considerations, the apparatus described in the preceding section was used to attack some of the problems which arise in the steady state operation of power systems. Several networks were set up on the artificial system, five of which are described. The first is made simple so that an analytical solution is practicable; the others are more complex and approach more closely the problems which are continually encountered in operation practise.

Example 1. The first system set up for study in miniature consisted of two generating stations connected by 96 mi. of line. It was assumed that the generators were subject to the control of Tirrill regulators connected through potential transformers to the high-tension bus of the station, or so compounded as to compensate for the drop in the power transformers.

It was also assumed that one station was clock governed so that the frequency was held constant by that station at all loads, the other station delivering full load constantly to the system.

In solving the problem on the artificial network, the magnitude of the nominal system voltage, reduced by the scale of 1 to 707, was set at the phase shifter terminals and the phase adjusted until the stations were

TABLE I
LOADS ARE IN KW. × 10^3

Load	P_A Meas.	P_A Calc.	Error	P_B Meas.	P_B Calc.	Error
65	74.9	73.4	2.04 per cent	− 3	0	....
85	74.9	75.2	0.39 per cent	20.4	20.0	0 per cent
103	74.9	74.9	0 per cent	38.3	38.4	0.26 per cent
118.9	74.9	75.0	0.13 per cent	58.6	59.5	0.11 per cent

together. Conductance was then added at the point of load until the power absorbed corresponded to the desired value. Finally, the relative position of the phase-shifter rotors was adjusted until the stations delivered load in accordance with the original assumptions. That is, one station should deliver full load and the

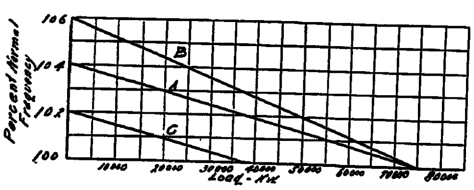

FIG. 5

other station take the balance. The results of this solution are shown in Table I and the experimental results are compared with results obtained by standard cut and try methods.

The entire time required for the solution of this problem on the artificial network was less than two

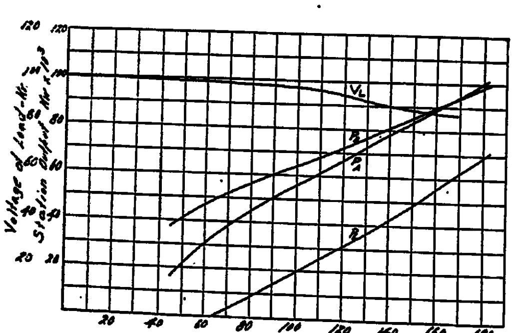

FIG. 6

hours including the time required for setting up the apparatus and applying the instrument calibrations. When the results were checked analytically, it was found that an hour was required for each point checked, although the writers knew in advance about what the answers should be.

Example 2. The second system studied on the artificial network consisted of three generating stations connected by lines, each 48 mi. long, to a load at the common junction. In this problem, as in the preceding one, it was assumed that the voltage was held constant at the high-tension side of the generating station transformer bank. The assumption in regard to governing, however, was considerably changed, the characteristics of the stations being assumed to be as shown in Fig. 5. The method of solution is identical with that used in the first example and about two hours and a half were required to obtain the results which are plotted in Fig. 6.

The characteristics which were assumed for the stations in this example must be based on the assumption

TABLE II

Station	Unit	Governor Sensitivity

C	22,500	2.0 per cent
C	22,500	2.0 per cent
C	45,000	5.0 per cent

that each station consists of one unit and one only, or else that all of the units of the stations operate all of the time. The addition of a unit in a station would have the effect of raising the frequency and would produce a discontinuous characteristic instead of the smooth curves of Fig. 5. The third example contains the added assumptions, in regard to the equipment of the stations and the order of putting the units into service, that are necessary to make the problem complete.

Example 3. The configuration of the system of this example was taken as identical with that of Example 2, but with the additional assumption that the stations

were to have the equipment shown in Table II and that the various units of the stations would be put into service in the sequence shown in Table III. In Table II the quantitative measure of governor sensitivity is the per cent regulation in frequency as the alternator goes from no load to full load. From these tables the station load-frequency curves shown in Fig. 7 were plotted.

The load voltages and outputs of the stations were measured for various values of load, but the results have not been plotted, since the discontinuity of the variables would render the curves meaningless. The results,

which were obtained in approximately two hours, are presented in Table IV.

Example 4. The purpose of this problem was to discover what time would be required to set up and solve the sort of problem which arises in determining the expansion policy of a power system. A certain power company was assumed to sell large blocks of power from

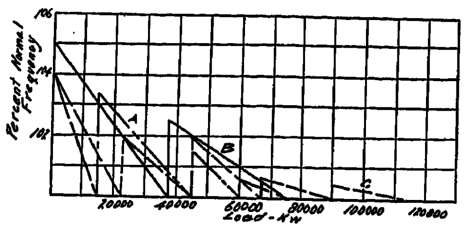

Fig. 7

its two stations A and B of Fig. 8 to the public utility corporations of two cities, L_1 and L_2. It is proposed to extend the system by building a line from J, to carry the load of L_3, a third city. The lines are all of No. 00 solid copper spaced at the corners of an 8-ft. 9-in.-equilateral triangle. L_1 and L_2 draw 93,500 kw. and 96,500 kw. respectively. The nominal system voltage is 100

TABLE IV

LOADS ARE IN KW. × 10^3. VOLTAGES IN KV.

Load	V	P_A	P_B	P_C
42.9	98.6	10.9	24.1	13.5
83.4	97.5	47.5	57.6	32.5

kv. and is maintained constant at the stations. The supplying company wishes to know what load can be supplied to L_3 without causing the voltage at any point on the system to drop more than 15 per cent from the nominal value. The division of the total load between the stations is also desired.

The solution of this problem by cut and try methods

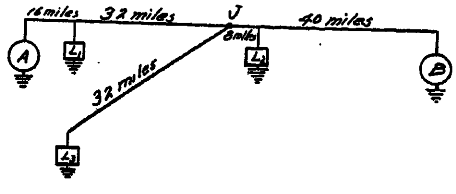

Fig. 8

is quite possible but it would require a considerable amount of time to get the correct answer. The solution of the artificial network required 45 min. of experimental work including the time required for making the set-up, and half an hour to apply the instrument calibrations and work up the data. The results show that 22,750 kw. can be delivered to L_3 and that when this load is being drawn, the other loads being as specified, stations A and B will supply 112,500 kw. and 96,500 kw. respectively.

None of the four problems which have so far been described has approached in complexity the problems which are constantly arising in commercial power networks. In such systems the problem of load dispatching, as well as the problems of voltage distribution which have been considered for the simpler cases, becomes increasingly important and difficult. The example which follows was laid out to determine whether the artificial

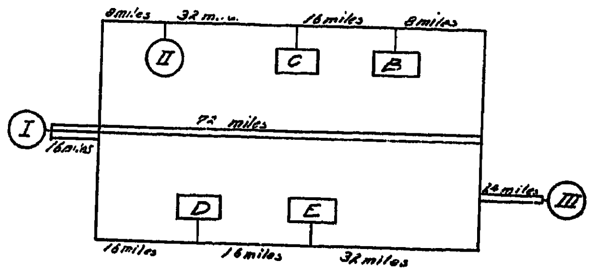

Fig. 9

network could be used as a source of information to aid the load dispatcher in the operation of the system.

Example 5. The circuit of Fig. 9 represents the high-tension network of a typical power system. Generating stations are located at I, II, and III; A, B, C, D, and E represent substations located at load centers which were assumed to have the characteristics which follow. A supplies a large steel mill, a portion of which operates on a 24-hr. day; B carries the load of several large industrial plants; C an industrial load with a small lighting load in addition; E the industrial load of a small

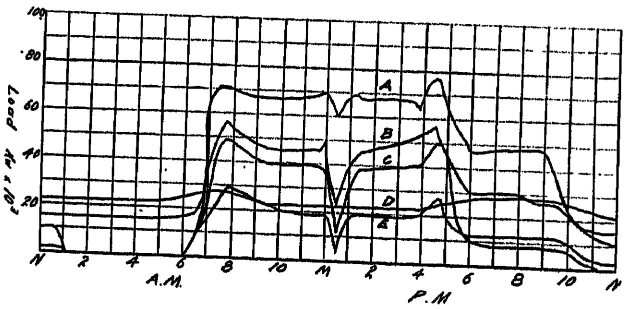

Fig. 10

town together with its lighting requirements; and D was assumed to supply a very large paper mill in a relatively small community where a small lighting load would be superimposed on the constant power demands of paper manufacture. The load cycles of these substations are plotted in Fig. 10. The problem is to determine the load distribution, during the four-thirty afternoon peak, which will give the minimum departure from the nominal system voltage at the various load centers; to determine the divisions of load at ten-thirty in the forenoon which will be satisfactory from the point of view of voltage regulation; and finally, to determine the distribution of load, as dictated by voltage maintenance, which can be used during the noon valley.

The illustration, Fig. 11, gives a general idea of the apparatus as set up for this problem, and shows the two phase shifters representing Stations I and II; between them is the vacuum-tube voltmeter.

For convenience, but one ammeter was used to measure the load currents, the equivalent impedance of the ammeter being inserted in series with the conductance, except when a reading was being taken. This made it possible to insert the instrument at will without disturbing the system. The solution of the problem, which required three hours, is given in Table V.

The A-C. Calculating Table

The work described in the foregoing section was done on smooth lines. There is no reason, however, why lines with lumped constants cannot be used in an artificial network and this network set up as an a-c. calculating table. There are two uses to which such a table might be put; it might be used by a power company in obtaining information to aid the load dispatcher, or it might be used by the consulting engineer in the solution of difficult steady state problems for his client.

In the first application the lines should be represented by lumped constant circuits. The nominal π method of representation[1] leads to an error of only 0.7 per cent with lines up to 200 mi. long, which makes this method entirely satisfactory. Transformers should be represented by their equivalent circuits; and if the assumption is made that the charging current of the line and the exciting current of the transformer produce a negligible drop in the transformer windings, it is possible to add the equivalent impedance of the transformer directly to the architrave impedance of the line or cable and the no-load admittance of the transformer to the pillar admittance. This will make the network much more compact without appreciably sacrificing the accuracy of representation.

The artificial lines and the equivalent circuits of transformers in a calculating table for the consulting engineer's use would be better designed with adjustable constants. In designing coils to represent the impedance of lines in a table of this sort, it would be well to make them up in units of five loop-miles with taps taken out of the coils to take care of the shorter sections. The resistance of the coil would be determined by the largest conductor of the lines to be represented, the inductance by the largest spacing. Thus two coils wound with 235 turns of No. 14 wire on an inside diameter of one and three-fourths inches (4.45 cm.) and one inch (2.54 cm.) thick, axially, would represent five loop-miles (8.04 loop-km.) of any line with a conductor not larger than No. 0000 and a spacing of less than 25 ft. (7.65 m.); an adjustable resistor in series with the coil takes care of the higher resistance of the smaller conductor sizes.

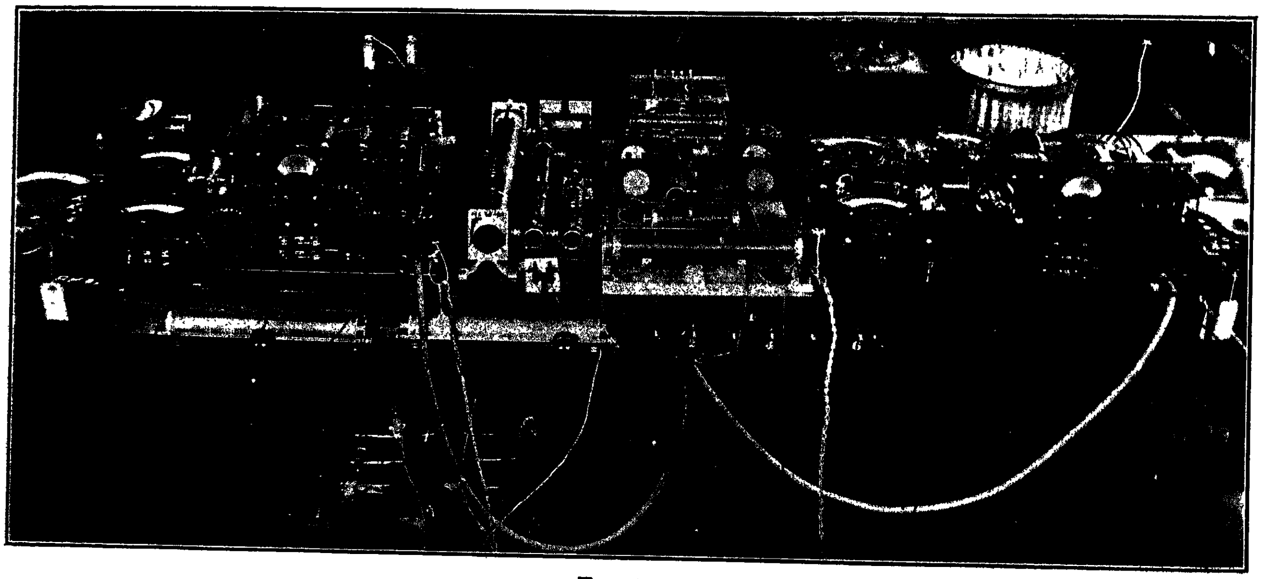

Fig. 11

Loads on the calculating table would be represented by admittances. They should be made up in boxes with point switches calibrated directly in real and quadrature mhos. Then from the voltage it would be possible to set at once the admittance to give the desired power at any power factor without the aid of any meter except the vacuum-tube voltmeter which would not draw power to introduce an error.

In conclusion, the writers wish to express their appreciation of the kindness of C. R. Oliver, of the New England Power Company, in supplying data on an actual power system.

Appendix I

The Thermionic-Tube Voltmeter

The problem of making measurements on artificial lines does not find its solution in the use of ordinary instruments. This is especially true in the case of the voltmeter as a consideration of the scale adopted will show. For example, in the work described in this paper

1. A. E. Kennelly, "Artificial Electric Lines."

the voltage scale was such that 100 volts on the miniature system corresponded to 70,700 volts on the system represented and, since there is no change in the impedances, one watt on the miniature represents 500 kw. single-phase or 1500 kw. three-phase on the actual system.

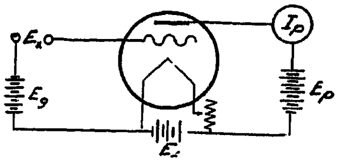

FIG. 12

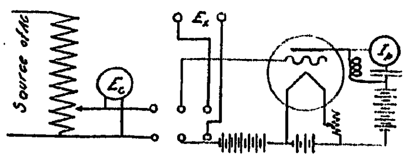

FIG. 13

The ordinary dynamometer type voltmeter takes approximately 0.660 amperes at full scale. This means, for a 150-volt meter, 9 volt-amperes at full scale; or at 141.4 volts, corresponding to 100 kv. in the above scale, 7.96 volt-amperes which is equivalent to 11,920 kv-a. three-phase. The remedy is an instrument which, like the electrostatic voltmeter, will draw no current, but stant filament temperature as the resistance of the filament of the tube increases with age.

In order to obviate these difficulties, a double throw switch was placed in the grid circuit so that the grid could be thrown over to a calibrating voltage immediately after each reading. The drawing, Fig. 13, shows how this was done. The voltages were impressed across the ends of a high resistance drop wire (2.12 megohms) and the filament and grid were placed across a portion of this wire, thus increasing the range of the instrument. The plate current of the vacuum tube consists of an alternating current superimposed on a direct current. The use of a d-c. milliammeter in this part of the circuit is impossible as it would read only the average current, the d-c. component. An a-c. milliammeter or thermo-couple instrument would be satisfactory, except that the change in alternating current is small compared to the steady d-c. component, so that the accuracy would be poor. To eliminate this trouble a 2 μf condenser was placed in series with the meter to

P_A	P_B	P_C	P_D	P_E	Hour
76.0	56.6	49.2	22.9	23.0	4:30 P. M.
67.2	45.7	38.1	18.5	22.5	10:30 A. M.
67.5	45.7	38.0	18.5	22.5	10:30 A. M.
67.1	45.7	38.1	18.5	22.5	10:30 A. M.
61.2	22.5	9.9	2.1	22.5	12:30 P. M.
61.2	22.4	9.9	2.1	22.0	12:30 P. M.

which will have the accuracy of a meter of the galvanometer type.

The vacuum tube operating as a repeater will draw no current from the input circuit so long as the grid is maintained at a negative potential with respect to the filament. This makes it possible to vary the plate current of the tube by impressing a voltage between the filament and the grid without disturbing the circuit impressing the voltage. The simplest way of doing this is shown in Fig. 12. The plate milliameter is calibrated in volts impressed.

In a circuit of this kind there are several difficulties. The alternating voltage must not reach a maximum value greater than the value of the grid bias; the grid bias must not be so great as to approach the cut-off point of the tube; and all the parameters of the circuit, as filament temperature, grid bias, and plate voltage, must be held absolutely constant. The most difficult of these problems is the maintenance of constant filament temperature. It is even difficult to hold the filament voltage sufficiently constant for work of this sort, and constant filament voltage does not mean con- block out the direct current and an inductance of 39 henries was connected across the instrument and condenser to by-pass this component.

The circuit of Fig. 13 was mounted together and made self-contained, with the exception of the batteries and some of the rheostats. The method of continuous calibration makes the precision of the vacuum-tube instrument the same as that of the voltmeter which was used in calibration. No difficulty was encountered in manipulation after the circuit was set up; as many as 120 readings being taken in an hour with ease.

Power System Transients

BY V. BUSH[1]
Fellow, A. I. E. E.

and

R. D. BOOTH[1]
Associate, A. I. E. E.

Synopsis.—The steady state load limits of a power network may be examined by familiar methods of analysis. However, the instability of a system with one or more elements working close to these limits sets lower values of power at which the system can be expected to give satisfactory operation under the sudden changes in load or connections which it must successfully sustain in operation. This paper presents methods for the analysis of power systems under transient conditions.

A qualitative discussion of the problem is given, followed by an outline of a point-by-point scheme of analysis which takes into account the inertia of machines, field transients, etc. The value of this scheme depends upon having available rapid methods of analysis applicable to conditions prevailing at a given instant during the transient. Therefore, there is also included a description of the methods which have been found advantageous, notable among which is a superposition method of solving systems by means of charts. This is a powerful means of attacking complicated systems. The method of point-to-point analysis is applied to specific types of networks as examples. There is also given an extension of approximate methods of analysis presented previously.

The paper is confined to the exposition of the methods of analysis which we have found convenient and powerful.

Introduction

With electrically long transmission lines, the ultimate carrying capacity of the line and the economic loading are of the same order of magnitude. Hence it becomes imperative to examine carefully and in detail the maximum power limit of such lines from technical considerations.

The problem is far from simple. If there were no system disturbances to be considered, no voltage fluctuations, no load variations, and so on, then a steady state analysis, using, of course, long line formulas, would readily give the load limits. It is when we attempt to consider disturbances that matters become complicated. Yet analysis is necessary, for while the margin to be allowed between operating load and ultimate steady-state load limit will always be a matter of judgment, there must be available definite facts in regard to the behavior of typical systems under the application of definite assumed disturbances on which such judgment can be based.

There are only three ways in which the knowledge necessary for a proper judgment can be gained:

1. Mathematical analysis.
2. Test of laboratory models.
3. Experience.

We shall not, for some time, accumulate sufficient experience with long lines operating close to their theoretical power limits to enable proper engineering margins of safety to be determined. So we must rely upon analysis and test.

Each of these should be made as nearly a complete treatment of the actual problem as possible, but neither can absolutely reproduce the conditions of the actual network. Test is limited because small machines cannot have the same relations between their electrical and mechanical constants as do large machines. Analysis is limited by the complexity of the problem. As in the analysis of all physical problems, something must be approximated or assumed to make a solution possible Yet each mode of attack should be pushed as far as possible in completeness. The economic importance of the problem warrants taking great pains to omit nothing from consideration that may be important. Analysis and test are complementary. The final check of theory is by test, and the final attack on the actual problems of system design must be by analysis.

In general the problem before us is this: Given a system of power stations connected by transmission lines, and operating close to the steady state power limits of some of its elements, how susceptible is such a system to disturbances of the sort which it will encounter and which it should sustain without rupture? In other words, what is the degree of stability of such a network when subjected to disturbances of the types likely to be encountered in practise? This problem is best solved at present by showing in detail how the system will react to certain definite assumed disturbances of a nature like those to be encountered in practise. For example, how will the system perform if a certain section of line is suddenly tripped out, or if a generating unit is suddenly dropped off? The answer to such questions is the definite guide needed to compare different system designs, and give the basis of judgment as to whether a given layout is satisfactory for the service for which it is intended.

The factors entering the problem are very numerous. The electrical constants of lines and machines are involved as in a steady state solution. In addition, during disturbances, the behavior of exciters, governors, and regulators comes into play, and the mechanical constants of machines as well as their electrical behavior must be considered. In other words, we are concerned not only with the distribution and time variation of voltage and current in the network, but also with the time variation of the air-gap flux of machines, and their mechanical phase relations.

Basis of Analysis

During a power-system transient we have a succession of instantaneous states which occur in sequence,

1 Both of Jackson & Moreland, Engineers, Boston, Mass.

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 9-12, 1925.

each of which changes into that which follows. Actually there are an infinite number of such states and the transition is entirely gradual. However, as done in many mathematical devices, we may consider only a finite number of such states occurring at finite intervals of time. If the time interval is short, we may approach the actual process in this manner as closely as is necessary for accuracy. We practically choose a time interval sufficiently short to avoid undue error, and as long as is consistent with this condition, in order to shorten the necessary computation. Hence analysis of the transient behavior involves, first, the solution of the network under the conditions prevailing at each of these chosen instants, and second, a computation of the manner in which the conditions determining these instantaneous solutions vary with the elapsed time.

When a system passes from one instantaneous state to another, the transition, so far as the transmission lines are concerned, is accomplished by means of traveling waves. These die out within a cycle or two. If the chosen time intervals are large compared with the time constant of the traveling waves, then the conditions prevailing at each instant for given terminal conditions on the line will be substantially the same as though these terminal conditions were sustained. In other words, the instantaneous solution for the transmission line will be given by formulas applying to the steady performance of the line as represented most conveniently in circle diagrams.

In machines the case is somewhat different. When the terminal voltage on a synchronous machine is suddenly altered in phase or magnitude, there is an armature transient which lasts a few cycles only. This armature transient may be neglected since it lasts for a brief interval, and its effect, if taken into consideration, would amount only to a minor correction to be applied to the field current. After this has died out, conditions in the machine are those given by curves giving the machine performance for steady conditions, provided they are entered with the actual values of field current and angle which prevail at the instant under consideration. The field current and angle change slowly, due to the large time constant of the field circuit, and the inertia of the machine; and, as we pass from one instantaneous state to another these slow changes must be allowed for and computed.

Therefore, if for any given instant we state the connections and electrical constants of any network, the flux of any connected synchronous machines, the relative phase angles between them, the characteristics of any connected load, and the voltage and current distribution in phase and magnitude, we specify to a sufficient degree of accuracy, the condition of the system at that instant. If sufficient of these data are given for a certain instant, we can solve the remainder from the circle diagrams of lines and connected machines, using these latter at the values of field current and angle actually existing at the instant considered.

Outline of Method of Analysis

Before going into the detail of computation of the complete solution, let us consider qualitatively what happens to a typical system during sudden load changes.

Consider a system consisting of a load supplied in parallel from a local steam station and a hydro station transmitting power over a long line which has synchronous condensers at the receiver end. When a load is suddenly applied at the receiver end of such a system, the increment is shared in the first instant between (1) the steam stations, (2) the synchronous condensers, and (3) the line and hydro station. Each begins to drop back in phase at a rate depending upon the load increment applied and the moment of inertia of its rotor. The field fluxes remain substantially unchanged during the first instant, and then start to alter at a rate depending upon the constants of the field windings and upon the rate at which armature currents are simultaneously changing. After an interval the regulators act and the variations of field current are, thereafter, influenced by this new factor. The governors on the various units also come into action after an interval, and the rate of phase change of each machine is thereafter correspondingly influenced by the increment shaft torque applied by the prime mover as the throttle is changed in position.

Preliminary consideration of the sequence of these events show that at first all of the rotating equipment on the system will start to change speed, and that the apparatus which supplies the larger increment of load in proportion to its kinetic energy of rotation, probably the synchronous equipment nearest to the load, will slow down most rapidly. In slowing down this equipment so changes the phase position of its field structure with respect to the terminal voltage that it delivers a smaller and smaller load increment which eventually passes through zero. It then takes power until the excess changes the direction of swing. Meanwhile the other machines must deliver the deficit in power created by the swing of the first machine, thus in turn carrying a load which makes their rate of phase change greater, so that they follow the first machine through a similar cycle. In this manner synchronous apparatus on the system oscillates about some power point. The condensers, of course, oscillate about the zero power axis and the generators tend to oscillate about their respective governor characteristic curves plotted against the time.

While this discussion relates primarily to sudden load application, there is a similar sequence of events when a generating unit is dropped at the receiver end of the line, or when a transmission circuit is suddenly tripped out. The methods of analysis presented are applicable to any of these cases, or to three-phase short circuits in any part of the system considered.

Given a power system operating under known steady conditions, and given a disturbance such as a change of load or connections suddenly impressed on this system,

it is desired to compute in detail the time variations of all factors in the system in which we are interested.

There is an immediate change, first to be computed, which follows directly after the start of the disturbance and after the lapse of a very small interval of time. This small time interval, a cycle or two, is sufficient for the subsidence of traveling waves, and for the armature transients in machines to have disappeared; but it is insufficient for appreciable change in the relative mechanical phase angles of machines, or appreciable change in the magnitude of the flux in machines.

This immediate change can hence be computed by a solution based on the characteristics of lines and machines in which the given quantities are all the mechanical phase angles and values of flux. These are sufficient to fix the system, and a solution then gives the phase and magnitude of voltage and current everywhere, and hence the new values of power and reactive volt amperes in each machine. We will assume for the present that this solution is made, and later we will return to specific examples, and show how such a solution can be obtained in a manner conveniently adapted for the transient analysis.

We now have the solution for the first instant after the beginning of the disturbance, and hence the values of power which appear immediately after the disturbance in each machine involved. The difference between these values and the initial values of power give the power increments, plus or minus, on each machine. In the first instant these increments are applied entirely to produce positive or negative acceleration of the rotors, and these accelerations may be computed, when the speeds and moments of inertia of machines are known, by well-known formulas.

If now this power increment remained constant, that is if the flux in the machine and its terminal voltage suffered no further change in either phase or magnitude, and if there were no additional power supply to the unit from governor action, we could compute its position for subsequent times from

$$\theta = \frac{\alpha t^2}{2}$$

Where α is the acceleration and θ is the mechanical change in angle. In making this computation, we may, as noted below, make as a refinement a correction for the power consumed by damper windings. Of course, quantities do not remain constant in the manner indicated above, yet, if we choose a sufficiently small time interval, the error in assuming them constant may be made as small as we please. In fact, even although a small variation in the factors involved occurs during the time interval, we may estimate the variation and allow for it. The accuracy in the estimate could be checked presently, and in case of serious discrepancy, corrected by a recomputation. It is possible though to avoid the cut and try process involved in this estimate of power increment and this is in fact necessary if the analysis is not to become unduly laborious. The superposition methods of analysis which are described below enable this to be done by a correction applied to a characteristic curve.

In the first instant after the occurrence of a disturbance, each machine will also have an increment of armature current. Due to the fact that the magnetic linkages with the field winding cannot be changed instantly the field current will also undergo a sudden change. The amount of this change can be obtained from the increment of armature reaction, since the total magnetomotive force on the magnetic circuit of the field remains constant. In this computation allowance is, of course, made for the incompleteness of coupling between armature and field circuits. It is sufficient to use the increment of armature current in quadrature to the induced voltage.

We thus obtain the value of field current in each machine at the instant after the beginning of the disturbance. If there were no further change in armature current and in the absence of regulator action, we could then compute the field current, and hence the flux, in each machine for subsequent times. The field current would return exponentially to its original value, the decrement of the exponential being given by the time constant of the alternator field circuit. In the first short interval of time the regulators will not have acted, so we can compute in this manner the flux in each machine at the end of a chosen short time interval, except for one effect. This is the result of further armature current change during the interval. Such change produces a field current increment in exactly the same manner as the initial change. This may be termed for convenience the subsidiary field transient. It could be allowed for as follows: Estimate the terminal voltage at the end of the chosen interval, from the machine characteristic determine the corresponding armature current and armature reaction, and from this the subsidiary field transient. Apply to this the field decrement corresponding to half the time interval to allow for the fact that the effect is produced continuously throughout the interval at approximately constant rate, and add the result, with proper sign, to the field current obtained from the previous computation. Upon obtaining the next solution the estimate of voltage could be checked. While this method of allowing for subsidiary field transients would work, it is laborious in that it involves a cut and try method. Again the superposition method of obtaining instantaneous solutions which we use in this transient analysis enable us to allow for this subsidiary transient without using cut and try methods. This will appear in the examples which follow.

From the above we now have at the end of a chosen time interval the values of flux in all machines and their relative mechanical phase positions. It is hence possible, by just the same methods employed for the previous solution, to solve for the voltage and current

everywhere in the system at the end of this interval. We may then compute new power increments, and new values of field current.

We then proceed with a second time interval. The procedure is exactly as before with two exceptions. First, in computing the angular space travel of machines in the second and subsequent intervals, we must not only, as before compute, that due to their angular accelerations in the interval, but must add the travel due to the velocity which existed at the beginning of the second interval with respect to a constant speed base. The angle for the second interval is given from

$$\theta = V_1 t + \frac{\alpha_2 t^2}{2}$$

where V_1 is the angular speed at the end of the first interval, obtained from

$$V_1 = \alpha_1 t,$$

except for the effect of power increment during the interval, allowed for as before. Second, it is necessary in computing the field current change in the second interval, to apply the decrement for the interval to the total field current increment at the end of the first interval due to both initial and subsidiary field transients, and to add on the curves the effect of the subsidiary transient in the second interval.

Proceeding in this manner, we can compute the variation point by point with the time, of the voltages, currents, powers, and angles in the system. This is continued until sufficient data is obtained to make evident the behavior of the system subsequent to the beginning of the disturbance. During this process we will shortly arrive at a lapse of time sufficient for the voltage regulator to begin action. When this occurs we shall need to add a new term in our computation of field currents, namely the increment produced by the regulator action on the exciter. This is obtained from a curve of main field current against time after closing of regulator contacts, drawn for the particular exciter system involved. Mr. R. E. Doherty has developed the form of these exciter transients in much detail[1], and we have checked many of his derivations. It is accurate for small increments with shunt wound exciter and brushes on neutral to add the separate effects of field decrement and exciter action. In other words, the effect of exciter field built-up occurs, as far as small increments are concerned, as though the field current were otherwise stationary in value. The consideration of compounded exciters requires that the two effects be considered in combination by a cut and try process.

It may even occur in the course of the analysis that the terminal voltage of a machine will rise to a point where the regulator contacts will again open. This is taken into account by a curve very similar to the above, again allowing a definite interval of time after arriving at the new voltage for the delay in opening of contacts due to time lag of the relays. This is one or two-tenths of a second, depending on the regulator design.

Another effect which occurs after an interval where prime movers are involved is governor action. This is readily taken into account, provided we know the governor characteristics, by including with the power increment used in calculations of angular swing a new increment, of the same or opposite sign, as the case may be, due to governor action. For this we need simply a curve for the governor giving additional power supply to the unit against the time. It is in fact best to construct this as we proceed, as the rate of response of a governor depends upon the increment in speed, or the total response depends upon the integral of the speed change. This again is a matter requiring detailed analysis of its own, and unfortunately complete information in regard to the behavior of all types of governors is not yet available in the form necessary. We have been assisted in arriving at reasonable curves for governor action by certain studies carried out by the General Electric Company. The action of steam governors is especially important. The lag of hydraulic governors is so much greater that the power transient is usually past its critical stage before they get into action.

From the above it is evident that point by point analysis of this sort depends principally upon a proper adaptation of methods of obtaining instantaneous solutions under the conditions set up by the transient analysis. Especially is it possible to proceed with facility when the charts are so modified that cut and try processes, both on power variation and on subsidiary field transients, are avoided. We will, therefore, devote much of this paper to the treatment of rapid solutions under the peculiar terminal conditions which obtain where such solutions are a part of a transient analysis. We will follow this by examples employing the methods developed.

Experimental methods of studying transients, using alternating current artificial lines, and small machines to represent the various generating and condenser stations, have been used by Evans and Bergvall to give a means of checking theory. This is a valuable procedure which will undoubtedly be extended. When it is attempted, however, to obtain from such an artificial system transient data which will apply directly to an actual system, we encounter a difficulty in that the relations between electrical and mechanical constants and the relation between armature and field constants cannot be made the same in a small machine as in a large one. One way of avoiding this difficulty is to replace the small rotating machines by stationary phase modifiers, and to then manually make the phase adjustments and generated voltage changes indicated by the point by point analysis. The artificial network then becomes simply a convenient means of arriving rapidly at the steady state solutions necessary for the complete analysis. This method of representing gener-

1. R. E. Doherty, Trans. A. I. E. E., 1922.

ating stations in an artificial network has been developed by Messrs. H. H. Spencer and H. L. Hazen at the Massachusetts Institute of Technology, and their paper (see page 72 of this volume) describes the apparatus and its use, so that it need not be further discussed here. The advantage of the method, of course, is that the solutions for points in a transient analysis may be obtained more rapidly when complicated systems are considered.

The refinements to be introduced in the transient analysis are a matter of judgment, and experience with the method soon shows the relative importance of various factors. One point of this sort deserves particular mention. During the progress of a transient the speed of a machine will change slightly, and strictly its characteristic as used in the solutions for instantaneous points should then be altered so as to apply to its actual speed. We have found, however, that in cases in which the disturbance was such as to approximately produce loss of synchronism the speed change during the portion of the transient which must be computed in order to predict results was usually well below 1 per cent, so that we have not considered this particular refinement necessary when treating transients due to sudden disturbances.

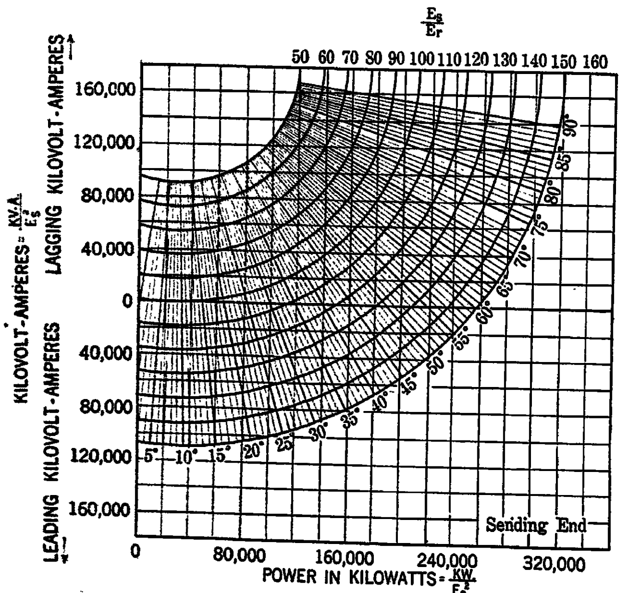

Fig. 1—Simplified Circle Diagram of Transmission Line, Sending End

Aids to Rapid Calculations

In the course of this work, a type of circle diagram has been developed which, while it does not incorporate all the features of some of the diagrams, is much simpler to construct and use, and is particularly convenient for the type of solutions we need in this transient study.[1]

1. This same form of diagram has been presented, since this paper was written, by Mr. C. A. Nicklein a discussion in Transactions A. I. E. E., 1924, Page 85. The numerical example which he gives will be found especially useful.

Hence, although it is a digression, we shall briefly describe it. This simplified diagram, shown in Figs. 1 and 2, is a modification of the Evans and Sels diagram, except that we have included the voltage, power, volt-amperes and angle relations at variable voltages at both ends, instead of at a single end of the line as has been done by previous writers. The advantages of this chart are simplicity of construction, accuracy, and the ability to depict line conditions with variable sending and receiving-end voltages on two charts only, instead

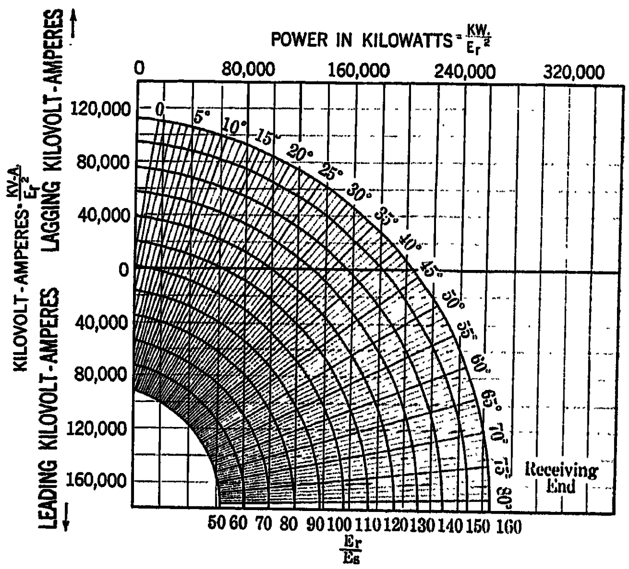

Fig. 2—Simplified Circle Diagram of Transmission Line, Receiving End

of the large number required by the ordinary diagrams to cover a range of voltage conditions. Interpolation on this diagram is rendered more accurate and easy by the uniform scale of voltages at either end of the line and by the fact that the circles are concentric. The diagram is not an approximation: it may be based upon hyperbolic formulas for a long line, and will then represent the action of the line in accordance with these formulas.

The derivation of this chart and the computations of the requisite constants for construction, are similar to those which have been presented for other circle diagrams.

The equation

$$\check{E}_s = (a + j\,b)\,\check{E}_r + (c + j\,d)\,\check{I}_r$$

is a vector equation expressing the relation between the sending voltage $\check{E}_s$, the receiving voltage $\check{E}_r$, and the receiving current $\check{I}_r$, for a given line in terms of the constants $(a + j\,b)$ and $(c + j\,d)$. This equation may be written for a simple line, a line with transformers, a pair of parallel lines, etc.[2]

Take $\check{E}_r$ at standard phase, denote the horizontal and vertical components of $\check{I}_r$ by $\bar{I}_r$ and $\dot{I}_r$, and similarly for other vectors. The scalar equation corresponding to this is then

2. Evans and Sels, *Electric Journal*, August 1921, p. 358.

$$\bar{E}_s + j\,\dot{E}_s = (a + j\,b)\,\bar{E}_r + (c + j\,d)\,(\bar{I}_r + j\,\dot{I}_r),$$

which may be written in two parts:

$$\begin{cases} \bar{E}_s = a\,\bar{E}_r + c\,\bar{I}_r - d\,\dot{I}_r \\ \dot{E}_r = b\,\bar{E}_s + d\,\bar{I}_r + c\,\dot{I}_r \end{cases}$$

Square and add these equations, and we have

$$E_s^2 = (a^2 + b^2)\,E_r^2 + (c^2 + d^2)\,\bar{I}_r^2 + (c^2 + d^2)\,\dot{I}_r^2 + 2\,(a\,c + b\,d)\,E_r\,\bar{I}_r + 2\,(b\,c - a\,d)\,E_r\,\dot{I}_r$$

Now if P_r and Q_r are the total receiving-end power and quadrature volt-amperes respectively, and if E_s and E_r are phase voltages, then

$$\bar{I}_r = \frac{P_r}{3\,E_r}$$

$$\dot{I}_r = \frac{Q_r}{3\,E_r}$$

for a balanced three-phase system. We also use the abbreviations:

$$A = a^2 + b^2$$

$$B = \frac{c^2 + d^2}{9}$$

$$C = \frac{2}{3}\,(a\,c + b\,d)$$

$$D = \frac{2}{3}\,(b\,c - a\,d)$$

Insert these above and obtain:

$$\left(\frac{P_r}{E_r^2} + \frac{C}{2\,B}\right)^2 + \left(\frac{Q_r}{E_r^2} + \frac{D}{2\,B}\right)^2 = \frac{1}{B}\left(\frac{E_s}{E_r}\right)^2$$

If $\frac{P_r}{E_r^2}$ and $\frac{Q_r}{E_r^2}$ are used as coordinates, this is the equation of a circle, and the coordinates of the center of the circle and the radii are then given by

$$\begin{cases} h_r' = \dfrac{C}{2\,B} \\[2ex] k_r' = \dfrac{D}{2\,B} \\[2ex] r' = \dfrac{1}{\sqrt{B}}\,\dfrac{E_r}{E_s} \end{cases}$$

Similar reasoning applies to charts in terms of sending-end conditions giving

$$\begin{cases} h_s' = \dfrac{J}{2\,B} \\[2ex] k_s' = \dfrac{K}{2\,B} \\[2ex] r_s' = \dfrac{1}{\sqrt{B}}\,\dfrac{E_s}{E_r} \end{cases}$$

where $J = -\,2/3\,(e\,c + f\,d)$

and $K = 2/3\,(d\,e - c\,f)$

The position of the center of the circles is now fixed independent of voltage. For any given value of $\frac{E_r}{E_s}$ we have the same radius, and hence the same circle. Therefore circles may be labelled with the ratio of the two voltages, and these circles will be concentric and evenly spaced. The angle between terminal voltages will be given by a series of evenly spaced radial lines. The diagram is thus simpler to draw and use, and more accurate when it is necessary to interpolate. Also a single chart, instead of a series of charts, is sufficient to cover the line behavior with variable voltage at both ends.

The charts shown in Figs. 1 and 2 give a graphic description of the operation of the line, but even they are not necessary, for the ideas involved in this sort of chart may be readily incorporated in a simple link motion which will avoid altogether the necessity of line charts in the usual computations.

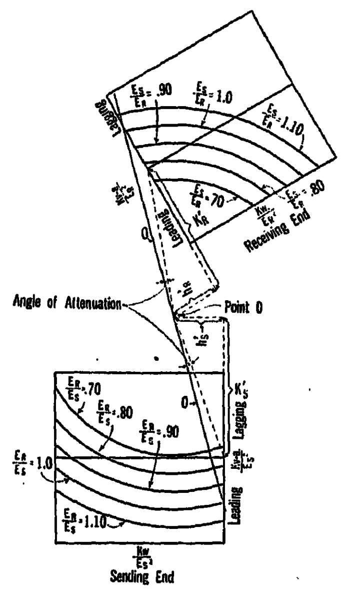

Fig. 3—Layout of Transmission Charts for Use With Link Motion

Place two pieces of rectangular coordinate paper, with axes marked in termes of the ratio of power and quadrature volt-amperes to the square of voltage, as shown in Fig. 3. It is unnecessary to add further loci to the diagram, but some of these are shown on the figure for convenience in explanation.

An examination of this figure shows that a bar pivoted at the point O will intersect the charts at equal angle values. If this bar is graduated to read values of $\left(\frac{E_s}{E_r}\right)$ and $\left(\frac{E_r}{E_s}\right)$ and equipped with a mechanism such when a rider on one end of the bar is adjusted to a certain value of $\frac{E_s}{E_r}$ or $\frac{E_r}{E_s}$ the rider on

the other end will be set at the inverse ratio, we will then have a device with which we can predict conditions at either end of the line when sufficient data are given. The inverse motion can be accomplished by the simple linkage in Fig. 4.

The analysis of the linkage is as follows: (See Fig. 5)

$$a^2 = b^2 + x^2 - 2\,bx \cos\theta_1$$
$$a^2 = b^2 + y^2 + 2\,by \cos\theta_1$$

From which

$$a^2 (x + y) = b^2 (x + y) + (x + y)\,x\,y$$
$$x\,y = a^2 - b^2 = \text{constant.}$$

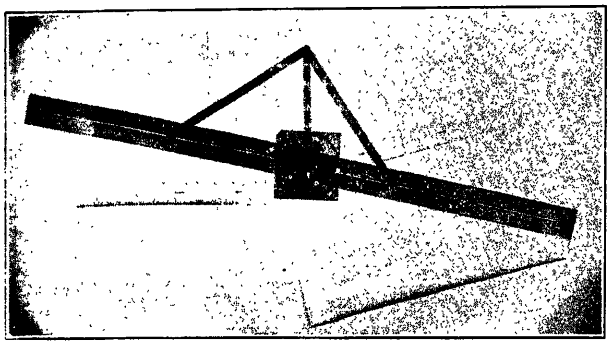

Fig. 4—Linkage and Charts for Predicting Transmission Line Performance

Let us now consider x and y for ratios of $\frac{E_s}{E_r}$ and $\frac{E_r}{E_s}$ of unity, to be themselves unity.

Then $b = 1$ and $a = \sqrt{2}$ are convenient lengths of arms. Choose convenient scales for the coordinate axes used for the sending and receiving end charts, making the length unity equal to the length unity employed on the bar, and mount these upon a board in

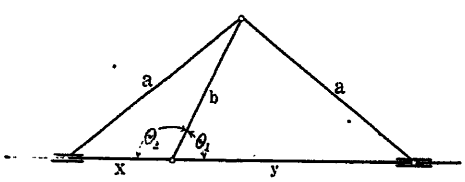

Fig. 5—Diagram of Linkage Used with Transmission Line Charts

such a manner that the angle and the distances between the axes may be varied in accordance with any line constants.

It will then only be necessary, in solving for conditions on any line, after fixing the position of the rectangular scales, to multiply the scalar value of power or volt-amperes read from the chart by the value in volt-amperes of the radius of either chart for $\frac{E_s}{E_r}$ = unity; which is a constant for any line, and by the proper value of E_s^2 or E_r^2. If the bar $x\,y$ is calibrated with a linear scale so that unity occurs at the distance unity from point O, these latter values may be obtained directly from the readings at the two ends of the bar.

The link motion with the two pieces of coordinate paper may thus be set for any given line, and will then give all the necessary relations between power, quadrature volt-amperes, voltage, and angle at both ends of the line. The angular relation between, and the relative positions of the two charts are determined by the values of h and k defined for the sending end and receiving end on a preceding page.

Machine Characteristics

Much more information in regard to the behavior of synchronous machines than is usually given is necessary for the solutions we have in hand. It is necessary to specify the complete relations between field current, generated voltage, terminal voltage, and armature

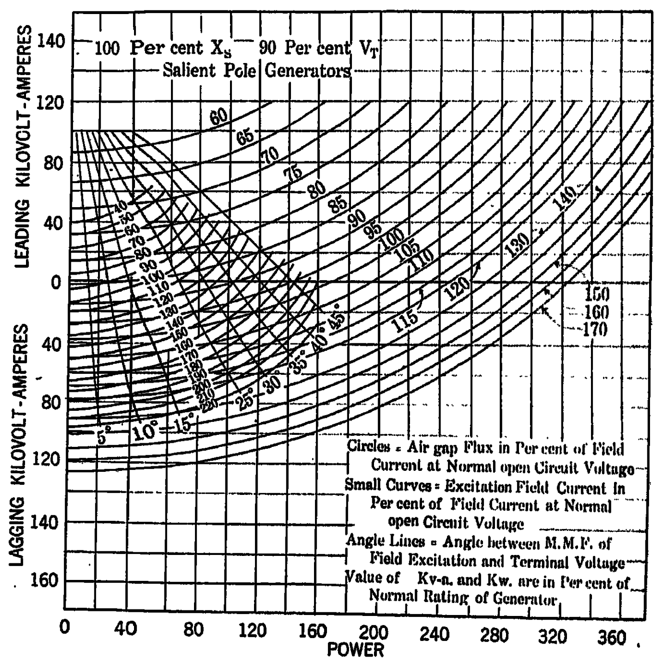

Fig. 6—Chart of Salient Pole Generator Performance

current, both in phase and magnitude. This is most readily done by a series of charts, similar to circle diagrams, constructed for various values of terminal voltage, having power and reactive volt-amperes as coordinates, and showing the loci of constant field current and constant flux in the air gap. Such a chart is shown in Fig. 6. From these may be rapidly derived the necessary curves for graphical system solutions.

Since the stability of power systems operating close to their load limits depends intimately upon the characteristics of the connected machines, it is necessary that these charts be constructed as faithfully as possible. The assumption of a constant synchronous impedance is here unallowable, since under the conditions of operation, it varies widely. Also the usual treatment of a salient pole machine by non-salient pole methods appears too loose an approximation.

We shall usually have available the excitation curve, and the full-load current, zero power-factor characteristic of the machine, together with its short-circuit curve, and the leakage reactance which may be assumed constant without serious error. We can also obtain from design data the factors which apply for armature reaction, for a salient pole machine, to the components of armature current in quadrature to and in phase with the generated voltage; that is, the cross magnetizing and demagnetizing components of armature reaction. Let us call these respectively K_c and K_d.

We can now construct a vector diagram, Fig. 7, for any assumed value of armature current as follows:

Lay off the known current I_a and the terminal voltage V_t. Compute the leakage reactance drop, and by adding this to V_t, obtain the generated or air-gap voltage, E_a'. Perpendicular to this, and of a length obtained by reference to the magnetization curve, lay off the resultant field current R. Through the end of R draw $R\,A$ opposite in phase to the current, and of a length equal to the armature reaction in terms of field current. Divide this line at B so that

$$\frac{R\,B}{R\,A} = \frac{K_c}{K_d}$$

Draw $O\,B$, and project A on this line at C. Perpendicular to $O\,C$, and of a length corresponding in voltage scale to $O\,C$ as a field current on the magnetization curve, draw E_a, the nominal or field current voltage. The length $O\,C$ gives the field current corresponding to the assumed voltage and current. The angle $I\,O\,E_a$ gives the angle of current with respect to the field structure.

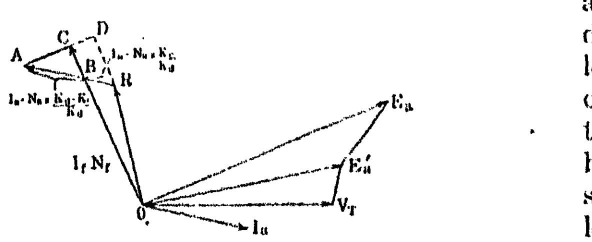

FIG. 7—VECTOR DIAGRAM OF A SALIENT POLE ALTERNATOR

The basis of this construction is as follows: Armature reaction $R\,A$ is split into components $R\,D$ and $D\,A$, in phase with and in quadrature to the center line of field structure given by the direction $O\,C$. The former is added, complete, to vector R, but the latter or cross magnetizing portion is only partially added. The portion used, $D\,C$, is that part of the total, $D\,A$, given by multiplying by the factor K_c. This follows from similar triangles. This method assumes that the reluctances of the magnetic circuits of the leakage flux and the main flux are equally affected by saturation of the iron core.[2]

2. A more complete treatment of the vector diagram of the salient pole machine will be found in *Harmonic Analysis*, by W. V. Lyon, TRANSACTIONS A. I. E. E., 1918, Page 1477.

From the above diagram, we obtain power, quadrature volt-amperes, current and power factor as usual. These are then entered on a chart, and the loci of constant field current, etc., mapped out.

REPRESENTATION OF SYSTEM CHARACTERISTICS

When a system consists of transmission lines interconnecting existing systems, some method is necessary for representing the behavior of each formerly independent system which is tied in. This representation should include the behavior of the loads in that system as well as the generating stations, and the characteristic should be reduced to the point where the system is tied into the transmission line. The generating stations on the system are considered independently as outlined in a preceding section. The load, which may include many small synchronous motors and a large percentage of induction motors, cannot, of course, be treated as so many independent rotating machines. An examination of the relative time constants of these machines and the natural period of oscillation of the rotors shows that the duration of the transients will be very short as compared with those obtaining in the large alternators. Hence, we have used the steady state characteristics of these machines in our analyses.

Actually, each system consists of distributed loads and one or several generating stations feeding into the distribution network. The action of the distributed load may be represented as a single concentrated load of proper characteristics at the load center of the system. In computing these characteristics there are to be included the constants of the lines connecting the several loads with the load center. Thus an individual load which is connected to the load center through a given line may be represented by an impedance at a particular value of voltage at the load center. This impedance includes the impedance of the load and connecting distribution lines in series. Adding the admittances of individual loads at the load center in parallel gives a resulting load admittance for the particular value of voltage assumed. Repeating this process at different voltages gives the load characteristic at the load center. This characteristic is then to be transferred to the point of connection of the system to the transmission line, which is accomplished by adding the impedance of the lines between the load center and the point of connection to the resulting load impedance at the particular value of voltage, thus constructing a new characteristic of the load as determined against voltage at the point of connection.

The above outlines the method of representing the characteristics of a system which is connected to the primary transmission system at a single point only. In case the system is connected to the primary network at two points, a modification of the method is necessary. This consists, in general, of splitting the system into two parts to be concentrated at the two points of connection. The tie, within the secondary system, be-

tween the two points, is then included as a parallel connection to the primary transmission system between the two points. In other words, instead of reducing the load to a single equivalent load, it is reduced to an equivalent load in two parts at the two points of connections. The load at the load center, which is determined as before, instead of being transferred to a single point of connection by including the impedance between the load center and that point, is divided into two parts which are transferred to the two points of connection. The general principle of this method of transfer is that the system with its loads is reduced to an artificial network with two concentrated loads, which is equivalent to the actual system in so far as its behavior at the two points of connection is concerned, in terms of the variation of both power and volt-amperes with voltage.

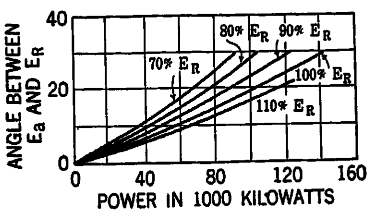

Fig. 8—Derived Power Chart of Condenser Performance Output

Derived Curves

For the solutions incident to this transient analysis, the primary tools, or reference charts, are the characteristics, preferably in the form of circle diagrams as shown above, of generators, connecting lines and transformers, condensers, and loads. From these are taken off as needed in the course of the study of a particular transient problem, special curve sheets for rapid use in obtaining solutions for a given point of time. These are, for reasons which will appear below, most conveniently put in the form of plots of kilowatts or reactive kilovolt-amperes against electrical angle with respect to some base angle as reference, for lines, generators and condensers. The vector used as a base may be the terminal voltage at some chosen point for steady state normal load conditions. On each sheet is a nest of curves for various terminal voltages. For a machine it is also necessary to prepare a separate sheet for each value of field current. Curve sheets of this sort are shown in Figs. 8 and 9 for a 20,000 kv-a. synchronous condenser. Similar charts for a line are shown in Figs. 10 and 11.

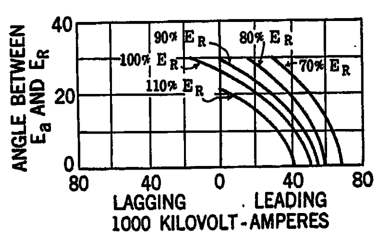

Fig. 9—Derived Quadrature Kv-a. Chart of Condenser Performance Input

These curve sheets are used by superposition methods for obtaining solutions for a network where angles and flux values are the known parameters. It has been found desirable to put kilowatt and quadrature kilovolt-ampere relations on separate sheets, and treat them separately rather than to attempt to superpose circle diagrams themselves. The reason for this is that these solutions are made as a part of a transient solution and because when done it is possible to avoid laborious cut and try processes by a single alteration in the curve sheets used in superposition. Upon superposing these curves a resultant diagram is obtained satisfying all power relations for the network, as well as a second diagram which satisfies all quadrature relations. A final superposition of these two gives a set of conditions which is common to both, and hence is a solution of the network under given conditions.

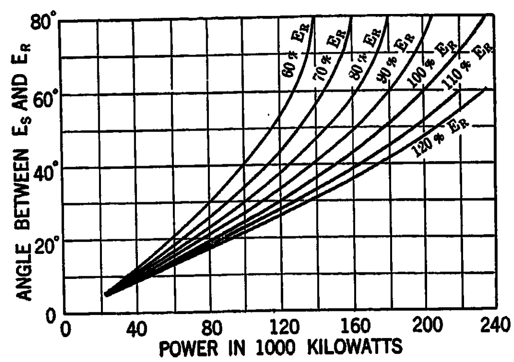

Fig. 10—Derived Power Chart of Transmission Line Performance

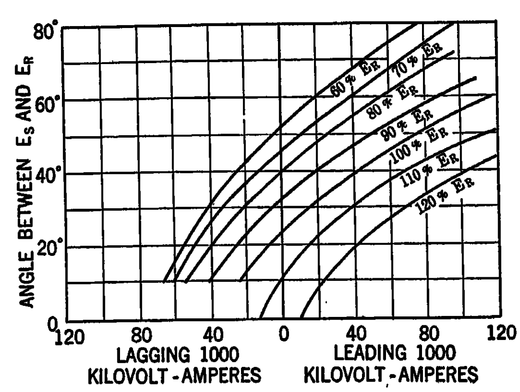

Fig. 11—Derived Quadrature Kv-a. Chart of Transmission Line Performance

This, in brief, is the scheme of the superposition method. It is difficult to explain clearly in general terms, but specific examples will be presented in some detail, and in the course of this, it will appear why these particular superposition methods, avoiding the necessity of cut and try processes, have been adopted for the solutions incident to this transient analysis.

Examples

The underlying theory of this analysis has been presented in foregoing sections and it has been noted that characteristics of machinery, and lines are most readily introduced into the calculations in the form of kilowatt vs. angle charts and reactive kilovolt-amperes vs. angle charts. This modification of the ordinary solution has been found desirable for two main reasons: first, that the intersections obtained by use of the ordinary charts were obscure, and second, that refinements to introduce mechanical movement and subsidiary transients in the fields were readily applicable to the new charts in such a manner as to eliminate the cut and try processes otherwise incident to the consideration of these factors.

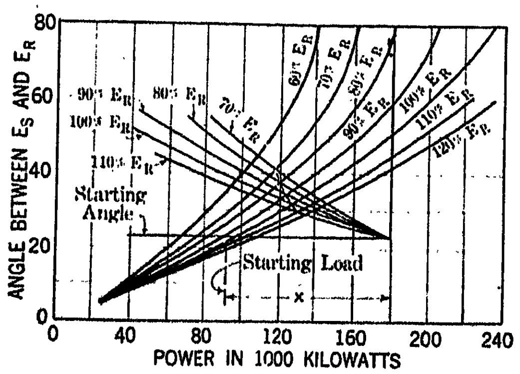

FIG. 12—SUPERPOSED CHARTS FOR DETERMINATION OF POWER CONDITION LOCUS

The method of using these new tools will be illustrated in examples. The first case will be very simple for the purpose of presenting the general method, and because of its simplicity will not involve all of the refinements necessary for solutions of more nearly representative systems. The other cases will consider more extensive systems and will, we hope, present the method and refinements in sufficient detail making the extension to more complex systems apparent.

Consider first a system consisting of a generating station of such dimensions that the high tension voltage at the sending end of a transmission line is substantially fixed in phase and magnitude, with a line transmitting power from this station to a receiver point where a condenser is operating to regulate voltage. Let us determine the operation of the system upon the sudden application of a block of load of constant kw. and kv-a. at the receiver end of the line.

The characteristics used for the solution of the first point are, Fig. 10, the receiver-end power characteristic of the line plotted vs. angle between the sending and receiving end voltages, E_s and E_r, Fig. 11, the receiver-end kv-a. characteristic plotted also vs. angle between E_s and E_r, Fig. 8, the power characteristic of the condenser for the known initial field excitation plotted against electrical angle between the voltage of the impressed field or the center line of field structure and the terminal voltage E_r, and Fig. 9, the corresponding quadrature kv-a. characteristic for the condenser.

Locate upon Fig. 10 the operating point of the line before the application of the additional load x; then place Fig. 8 upon Fig. 10 so that its 0° line coincides with this point of operation. If the zero power point of the condenser is also located at this point, the graph indicates steady state power conditions. However, since we are considering the application of an additional load of x kw., place the zero power line of the condenser on the load line equal to the total load as shown in Fig. 12. Initially, the power in the condenser is zero, so that the angle between terminal voltage and field structure is zero. Thus, the vertical distance between the displaced axes gives the angle between the voltage at the sending end of the line and the field structure of the condenser, which remains unchanged in the first instant after the application of additional load.

It is apparent from Fig. 12 that the power requirements of the system independent of the reactive kv-a. could be satisfied at any point on a locus indicated by the intersection of characteristics of the line and the condenser, for corresponding terminal voltages, shown on the dotted curve. This fixed superposition applies when the kw. of the load is independent of terminal voltage E_r. In case of a load characteristic showing a variation of kw. with E_r, it is sufficient to simply slide the two superposed curves horizontally with respect to one another, as the intersections are spotted in succession, keeping the total horizontal displacement equal to the power in the load corresponding to the particular voltage curves being considered. This same process applies to the consideration of quadrature kv-a. below.

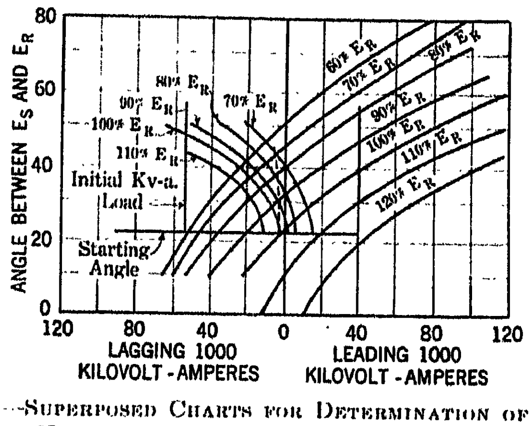

FIG. 13—SUPERPOSED CHARTS FOR DETERMINATION OF QUADRATURE KV-A.-CONDITION LOCUS FOR INITIAL CONDITIONS

We can, in very similar manner, satisfy the kv-a. requirements independent of the power. In Fig. 13, we have made a solution for kv-a. under the initial conditions.

The conditions obtaining upon the addition of a load of y kv-a. are as indicated in Fig. 14.

The dotted curve indicates the possible operating range without regard to power requirements. It now remains to simultaneously satisfy the power and kv-a.

relations. This we can do by superposition of the two resultant characteristics when plotted upon a common base. We have chosen condenser angle and E_r as the determining characteristics, but in this example line angle and E_r could be used equally conveniently.

When the two preceding loci are thus plotted, we obtain Fig. 15, the intersection indicating the operating point for the instant immediately following the application of load. Now knowing the receiver voltage and the angle of the condenser, we can readily determine line angle, line power and the other information desired.

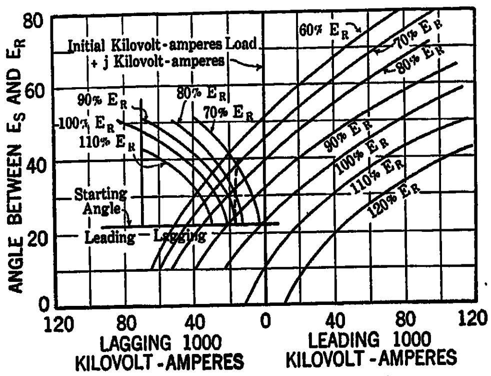

Fig. 14—Superposed Charts for Determination of Quadrature Kv-a.-Condition Locus for Conditions After Adding Load

The above indicates the approach to the problem but certain factors have as yet been omitted from the solution. The first is the transient that occurs in the condenser field as the current in the condenser armature becomes altered. The condenser characteristic used above was made for a fixed value of field current. The field transient may be taken into account by showing this characteristic on a somewhat different basis. Let

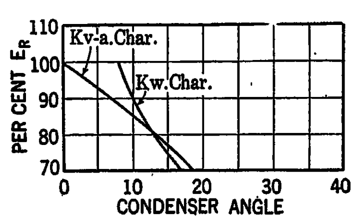

Fig. 15—Superposition of Power and Kv-a.-Loci to Obtain Common Point

us compute, in advance, the change in condenser field current due to transformer action per ampere change of each component of armature current. Now construct the condenser characteristic in such a manner that for a constant terminal voltage the curve is not drawn for constant field current, but at each point for the field current which would obtain, in accordance with the change of armature current in arriving at this point. Since this change of armature current for a given change in electrical angle is definite both in power and kilovolt-amperes for any particular terminal voltage, the resultant change in exciting current which would have obtained, is likewise definite. When in computing later points, the conditions to be determined are for an instant at an interval of time after some preceding known conditions, the increment of field current is computed as a current generated equally throughout the interval considered and is then attenuated in a corresponding manner before being applied. For convenience the time interval chosen between computed points is taken equal, in order to facilitate the computations and make curves useful for more than one point. When the condenser curves are thus constructed the solution will automatically be corrected to allow for the field transient in the machine.

It may be noted that the above method of introducing the field transient involves the assumption of field currents in the condenser, which differ at each point of the chart and do not correspond on the two characteristics. However, since the operating point obtained as a solution is that point at which the condenser angle and terminal voltages are identical on the two characteristics, the field currents involved on each characteristic at the intersection will be identical and correct for the

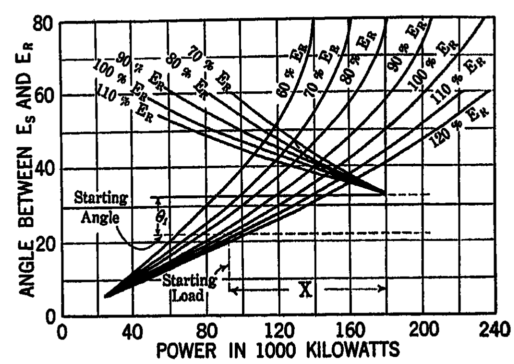

Fig. 16—Superposed Charts for Power Locus Showing Shift for Angular Travel

conditions obtained as a solution. At no other points on the curves would this obtain.

Let us now determine the conditions obtaining after a short interval of time t. The rotor of the condenser has now made an angular movement of θ deg. given by,

$$\theta_1° = \omega t + \tfrac{1}{2} \alpha_1 t^2$$

where α_1 is the acceleration due to power increment at the preceding point, and ω is the relative angular velocity at the beginning of the interval; zero in this case, but to be included for later points. Also the field current increment at the preceding point will have attenuated to a new value, even if the armature current has remained unchanged during this time t.

First construct condenser characteristics for the new attenuated value of field current, correcting the curves as before to the field current that would obtain at any point that involves an armature current other than found for the last-known condition of flux.

This curve will now be used in conjunction with the line characteristic in a manner similar to computations for the initial conditions; except that since the rotor has

been slowing down and has moved the distance θ behind synchronous speed position, the pole pieces of the condenser have now assumed an angle equal to the angle of the preceding point plus the angle of travel. This is shown in Fig. 16. It will be apparent that the condenser may be delivering or receiving power at the end of this interval different from that at the starting time, and that the movement due to this additional accelerating force during the interval considered, has not been incorporated in the calculations. This is done by moving each point of the characteristic curves by an angle θ_2. Since the difference in power between that delivered at the preceding point and the new is variable during the time interval, we must consider a resultant acceleration. If we assume the variation of power to be linear with time during the short interval, we find that

$$\theta_2 = \frac{1}{6}\,\alpha_2\,t^3$$

where α_2 is the maximum acceleration due to an additional power increment during the period, and corresponds to the difference in power delivered from the condenser at the successive time intervals. Hence, after choosing a given time interval, we can compute what additional movement the rotor would complete during the interval by considering the power at the preceding point as a base and computing the maximum acceleration which would obtain at any other power as that created by the difference between that power and the power at the preceding point. The additional movement due to this is then added to the electrical angle of the condenser for each point on the characteristic. This may be most readily done by merely rotating the axis of the power characteristics by the proper amount about the power point of the preceding interval, and then replotting the characteristic by measuring ordinates from this displaced axis. The same change in ordinate for each electrical angle of the condenser and terminal voltage is added to the kv-a. characteristic of the condenser.

Where damper winding effects are important they can be introduced into the calculations at this point. Since these effects are induction motor action which is a function of the difference between the angular velocities of the rotor and the impressed voltage, we have the data for computation of this action. This will be facilitated if we consider this action to be the resultant of a constant slip velocity equal to the velocity $\omega + \frac{1}{2}\,\alpha_1\,t$, plus a variable velocity equal to $\frac{1}{4}\,\alpha_2\,t^2$. Since this variable element can be expressed as a function of power at the end of the interval in a manner similar to space travel we can predict the damper winding effects that would obtain from operation at any point and add these effects to the characteristic of the synchronous machine in the manner indicated for power change in the interval. The field windings of the machine will give us similar effects, but in computations made for typical cases we have found these negligible.

Succeeding points are now computed in similar manner and the progress of the transient mapped out point by point. After sufficient time has elapsed for regulator action to begin, the field current increment due to this cause is also added in at each point, taken from a curve for the regulator used on the condenser. The process is continued until sufficient information is obtained to determine whether the system will or will not lose synchronism, and how much voltage fluctuation is involved.

From the above the method undoubtedly appears more laborious than it really is, although it is admittedly not simple, the problem being inherently complex. Yet in applying the superposition method, many short cuts will be seen; the necessary portion of characteristics only need be plotted, etc. For a system such as above considered, after the circle diagrams and first angle charts are prepared, two practised computers may readily determine the effect of a given disturbance in a day. Of course, more complicated cases take much more time.

Let us now apply these tools to more complex systems. Consider the system shown in Fig. 17. For

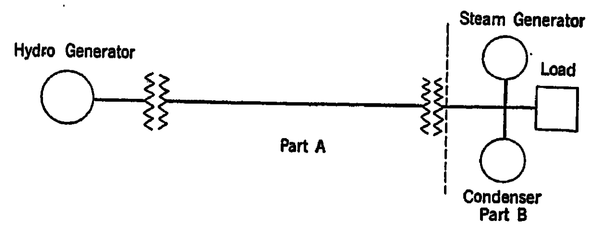

FIG. 17—SYSTEM LAYOUT FOR EXAMPLE

simplicity consider the system broken into two portions as indicated by parts A and B. We can prepare characteristics for the part indicated as A which will show independently the power and kv-a. characteristics of the line and generator at the receiver end vs. the angle between the voltage at the receiver end of this system and the voltage of the impressed field of the generators. This can be prepared quite easily in the manner outlined below for computations of the approximate analysis. These curves, in the form of constant field current characteristics, can readily be applied to any case by choosing points from curves of proper values of field current to make up the characteristics which include the subsidiary transients. These subsidiary effects of changing armature currents can be applied to the characteristics in a similar manner to that used for condensers in the previous example. It will be noted here that the curves are plotted in terms of receiver values whereas the factors which enter into the computation of the field changes are sending-end values. These sending-end values are quite easily obtained when the equation for sending-end current is noted.

$$I_s = C_o\,E_r + D_o\,I_r$$

For any characteristic at constant receiver voltage, we may compute the change in sending-end current by multiplying the change in receiver-end current by D_o. Hence the constant D_o may be incorporated with the transformation ratio of armature to field of the generator to make it a vector ratio of receiver-end current to

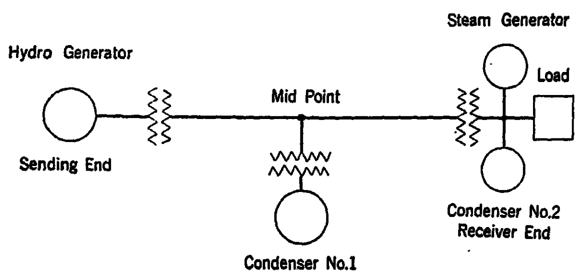

FIG. 18—SYSTEM WIRING DIAGRAM

field current. In this case we must compute and include the angular swing of the hydro generators as well as of the condensers. This is handled in the same manner for each, computing with respect to a constant speed base. With these modifications the portion of the consideration. The rate of swing of condensers and generators will not be the same, so each is computed separately, and this shift changed accordingly at each point. In this example the movement of the rotor of the turbo generator due to governor action, must also be considered. The unbalanced force to produce acceleration is the difference between electric and mechanical shaft torques. The details of this computation of the variation of mechanical shaft torque need not be discussed further at this point.

With these slight modifications we have now reduced our data for this system to a form similar to that used in the first example and no difficulties of solution should be found.

Let us now consider a system that involves transmission lines sectionalized by condensers as indicated in Fig. 18. The treatment of this case, if modified slightly, will also apply when the mid-condenser is replaced by a generator, or generator and load.

The method of attack on this problem is similar to that used for previous cases, but is more involved as the present example has one additional degree of complexity.

FIG. 19

a. Receiver Power Characteristic of Generator and First Section of Line
b. Power Characteristic of Condenser No. 1
c. Power Characteristic of Second Section of Line
d. Power Characteristic of Condenser No. 2 and Steam Generating Station

system shown in A can be readily handled in a manner similar to that of the preceding case.

The portion B of the system can be reduced to an equivalent single electric machine plus a load by adding together, as we compute each point, the characteristics of the steam generator and the condenser for equal angle displacements at the same terminal voltages. This is accomplished by superposing the individual characteristics with a shift in the direction of the axis of angles of an amount given by the angular displacement of the machines as computed for the instant under

The necessary tools for this solution are characteristics similar to those previously used. The power characteristics are shown in Fig. 19. It will be understood that these are to be modified as in previous cases, to take care of increment power and subsidiary field transients in the interval under consideration.

Fig. 19A is the receiver power characteristic of the hydro-generator and the first section plotted against angle between the voltage of the impressed field and the voltage at the mid-point E_m. This is similar to one of the characteristics used in the preceding example.

Fig. 19B is the power characteristic of the condenser installation No. 1, plotted against the angle between the voltage of the impressed field and the terminal voltage E_m.

Fig. 19C is a plot of both the sending and receiving power characteristics of the second section of the line against angle between E_m and E_r. This figure, for simplicity, shows but one set of terminal voltage conditions.

Fig. 19D is a summary plot similar to 19B for both the condenser No. 2 and the steam generator.

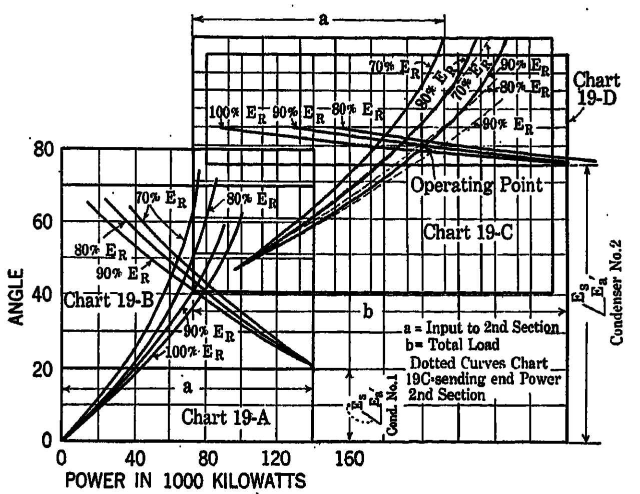

Fig. 20—Superposed Charts for Determination of Power Locus

When the various angles between the field structures of machines are known, it will be sufficient to show the manner of obtaining the solution at a given instant. From an examination of Fig. 20, it will be apparent that the power conditions will be everywhere satisfied for any set of terminal conditions given by an arrangement of the charts as shown. The kv-a. conditions could be similarly treated, but in order to obtain good intersections in this particular type of system it has been found advantageous to adopt a slightly different method than used in previous examples, although it will be apparent that a similar group of charts could have been set up for solutions for reactive kilovolt-amperes.

The power charts are moved in position, keeping the relations shown in Fig. 20 always satisfied, and from each grouping of the power charts we record the power and angle of each of the component charts together with the terminal voltages assumed. We now tabulate with this material the kilovolt-ampere wattless component which would be required in each of the two condensers, as determined from line charts, in order to make conditions fixed by these power relations an actual operating condition. This then provides us with a tabulation of required wattless component of each of the condensers against terminal voltage. We also have a tabulation of terminal voltages, fluxes and internal angles of these same machines as specified by the power components of the condenser output. Since each of these sets of data specify the condenser conditions, we now have a means of determining the operating point by finding the point at which the specifications of operating conditions from power and wattless components of load are identical. Since condensers one and two must simultaneously satisfy these requirements the solution may not be immediately apparent and will be briefly outlined.

Plot the required condenser actions as in Figs. 21A and 21B. Fig. 21A shows the required input to the mid-point condenser for various receiver voltages E_r plotted vs. E_m and 21B in a similar plot for the condenser at the receiver end. We have also shown on these plots the kv-a. characteristic of the corresponding condensers for various angles between the pole pieces and the terminal voltages. The above figures show graphically what condenser angle will be required at each station for various combinations of mid-point and receiver voltages as specified by reactive kv-a. relations. Since the power relations, first satisfied, have also specified the angles on the condensers for similar combinations of

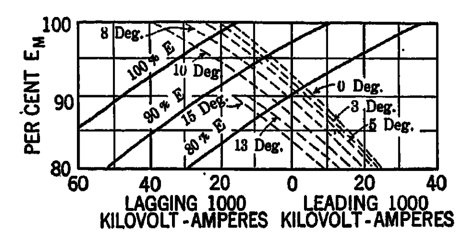

Fig. 21A—Mid-Condenser Requirements

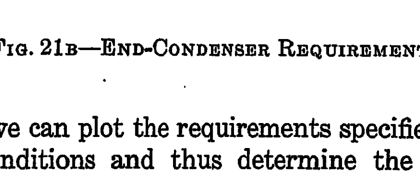

Fig. 21B—End-Condenser Requirements

voltage, we can plot the requirements specified by each set of conditions and thus determine the operating point. From superficial consideration of the above, it might appear that a plot of requisite condenser angle at each point as determined from power and reactive requirements would be sufficient to determine independently each of the condenser angles. However, since we have an additional requirement that the power and kv-a. relations for both condensers shall be satisfied simultaneously—*i. e.*, when all other determining conditions of the circuit are identical—we find it desirable to

express the angle of each condenser in terms of some function common to both.

We find that the angle of the mid-point condenser can be expressed in terms of the first section line angle, since the condenser field structure will maintain a posi-

tion with respect to the sending voltage in accordance with the computed angle θ, plus the angular movement due to acceleration during the interval which is later incorporated in the condenser characteristic. Where

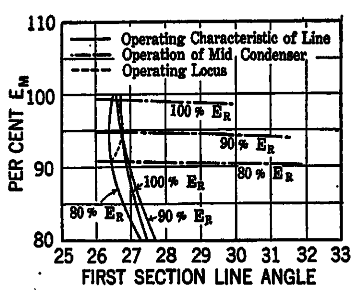

FIG. 23A—DETERMINATION OF OPERATING LOCUS OF MID-POINT CONDENSER

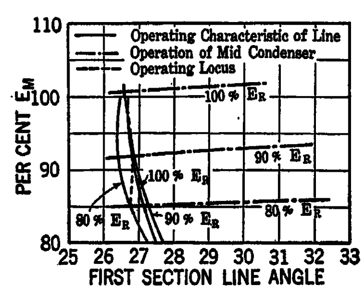

FIG. 23B—DETERMINATION OF OPERATING LOCUS OF RECEIVER APPARATUS

we have referred to the angle between the pole pieces of a machine and the terminal voltage, we mean the angle between the space position of the voltage of the impressed field at the start of the interval and the terminal voltage at the end of the interval. Hence we know that the line angle of the first section, at any time, must equal the line angle at the start of the interval, minus the electrical angle of the condenser at the start of the interval, plus the angle θ, plus the angular movement of the rotor during the interval, plus the electrical angle of the condenser. This for computations for conditions at any given time reduces to a constant plus the angle of the condenser. These relations are shown in the vector diagram, Fig. 22.

In a similar manner we can express the action of the receiver-end condenser in terms of the angle of the first section of the line by knowing the total angle of the system at the preceding point and deducting from this

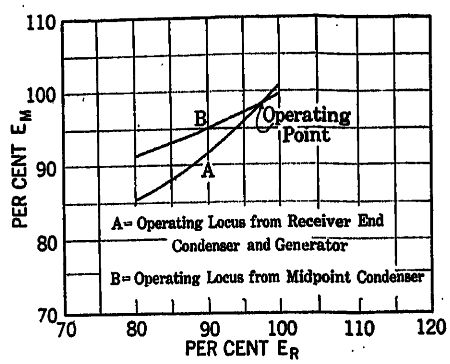

FIG. 24—SUPERPOSITION OF CONDENSER OPERATING LOCI

the angle necessary in the second section to transmit the reactive kv-a. specified for any condenser position with the values of E_m' and E_r also specified, and adding the change in receiver-end condenser angle shown on graphs. By this construction we obtain graphs which depict the requisite angle of the first section of line as specified by the mid-point condenser and by the receiver-end condenser which we can superimpose on the line angle specified by the power relations as shown in Figs. 23A and 23B. These two charts give loci of

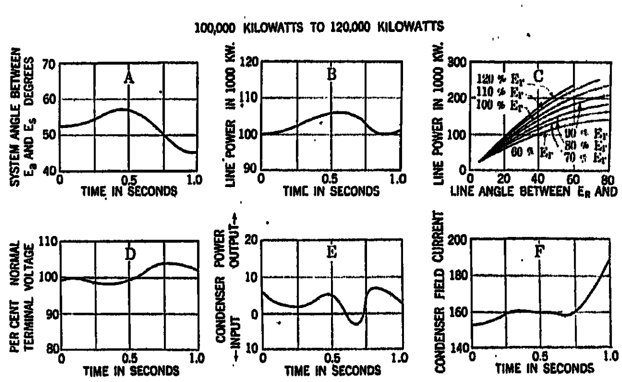

FIG. 25

operation which would be possible as specified by each of the condenser characteristics. Now, by superimposing these two loci as shown in Fig. 24, we obtain the operating point.

It may be remarked that the power characteristics shown in Figs. 23A and 23B are identical but the operating point determined from plotting both condenser characteristics on one chart is obscure. This results from attempting to determine the intersection of two lines in space, *i. e.* three dimensions—from one pro-

jection. However, by transferring the operating lines to the above Fig. 24, we obviate this difficulty.

We have found that the results of the foregoing analysis may most readily be presented in the form of plots similar to those in Fig. 25, which depict results of calculations for a system similar to that used in the second example. Fig. 25c, which is a plot of line power vs. line angle, is found especially useful. If the points are plotted upon this characteristic, it will be possible to predict whether the system will stay in synchronism or go out by the movement of the operating points. It can be demonstrated analytically that when the power over a section of line decreases as the angle increases, that element of the system has entered upon a cycle of cumulative unstability. There are many interesting features indicated in these curves, but the space available is so limited that this discussion must be omitted.

Approximate Methods

In the preceding we have presented a scheme of analysis which, while undoubtedly complicated, has at least been simplified and shortened to a considerable extent; and in this analysis we have provided for the inclusion, we believe, of all the principal factors affecting the behavior of a power system in the transient condition. If some of these factors are left out of consideration the solution becomes much easier, and, of course, a less faithful treatment of actual conditions. However, having available complete methods, which can be used on important cases as a check, it is very desirable to also have available more rapid approximate schemes for common use, testing the conclusions arrived at by their use either by test or by complete analysis.

In the discussion of the transmission papers presented at the Midwinter Convention last year, as published on pages 72-77 of the 1924 Transactions the writers presented an approximate method for determining system stability for a two section line with mid-condensers and a generating station of such size that variations in its terminal voltage could be considered negligible. This method was based upon the assumption that the field structure of the condenser followed the terminal voltage instantly and that rate of build-up of the Tirrill was so slow that the field transients, due to the change of load, were completed before any benefit of Tirrill action was experienced. Hence the characteristics of equipment considered were those of synchronous reactance. The application of the same method to leakage reactance characteristics was outlined at the same time.

This approximate method of analysis may be extended to include the action of systems involving more than one generating system feeding into a network, together with load action, also at various points. Consider, for example, a system consisting of a long transmission line with two generating stations, one at either end, and load systems connected at the mid-point through another line. Assume condensers, also, to be used here, and a transmission line from this to other power systems. The characteristics of the main generating system, together with the first section of line can in a manner similar to that previously outlined be determined from known starting conditions for various values of voltage at the junction at this point, but also upon the two lines connecting the other systems. However, since the condensers operate not only on the long line we must obtain the characteristics of the interconnected systems as generators delivering load to this junction. As previously outlined we can first determine the characteristics of the load at the point of connection to their local generating stations. This load characteristic must now be used in parallel with the generating stations, the combined effects of which, for varying system voltages, can be computed quite

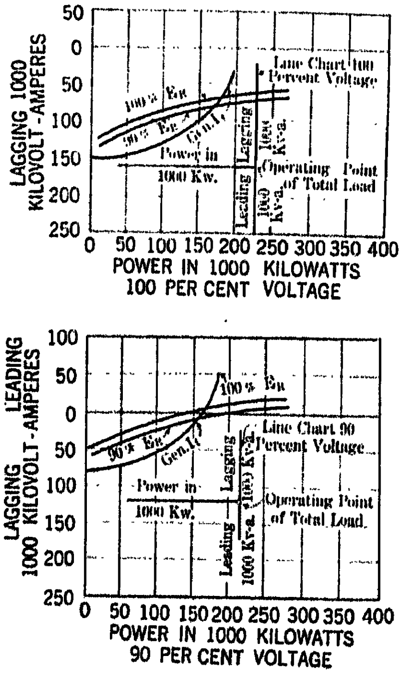

Fig. 26—Method of Obtaining Operating Point of a Line for Various Terminal Voltages When Generator, Load and Line Characteristics, are Introduced into the Calculation

readily as indicated in Figs. 26A and 26B. These figures are plotted characteristics of the generator and line power vs. reactive kilovolt-ampere for a given terminal voltage at the generating station. The generator characteristic given is one of constant field current corresponding to initial conditions and the line characteristic indicates conditions for various voltages at the junction with the main transmission system. A group of figures for various generator terminal voltages is used in the computations. The method of constructing these superimposed charts is to locate upon the generator chart a point corresponding to the total kilovolt-ampere and kilowatt of the load at the particular terminal voltage to be considered. Place upon this point the origin of the kilowatt and kilovolt-ampere axes of the line chart with proper attention to orientation

ot axes of chart. When the charts are thus arranged it will be noted that the given load has been divided between the lines and the station as indicated by the intersection of the field current line of the generator and the line characteristic corresponding to the voltage being considered at the junction with the main transmission system. The determination of the line characteristics for varying junction voltages is thus

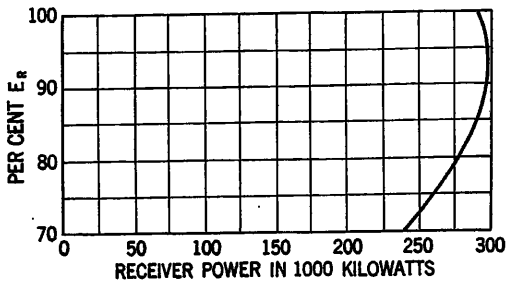

FIG. 27—OPERATING CHARACTERISTIC OF GENERATOR AND TRANSMISSION LINE ONE SECTION OUT IN INITIAL CONDITION

rendered simple and the load characteristics are properly introduced. In locating the center of the line chart for voltages other than normal, we determine the power and reactive components from the load characteristics.

Hence we can build characteristics for the several lines and stations connecting at the junction, at which point the characteristics may be combined. We can combine for common junction point voltages, but some other determining condition is also necessary, since voltage alone does not completely fix the system. We take this condition to be equal increment angle changes in all the interconnecting lines. That is, when the voltage at the junction falls back to a certain angle on the main line, we assume it to experience an equal change when viewed from any other line. This involves the assumption that the rotors of all generators in the network drop back in phase together, or that the rotors of all generating equipment remain fixed relatively during the switching disturbance.

Having obtained a combined characteristic for power at the junction, which for convenience we have plotted in the same form as a generator or line chart, it remains to superimpose the combined characteristic of the condenser and the sending-end of the next section. In previous analyses, we have superimposed the kilovolt-ampere of condenser and load on the receiver-end charts of a line to determine the stability curve, but here this would be inconvenient, since the various lines to the junction have varying sending voltages. Therefore, we determine the kilovolt-ampere at the receiving end of each of the lines for corresponding junction-point voltages and equal increment angles for various transmitted powers, from which we deduct the kilovolt-ampere taken by the condenser at any given terminal voltage. The resulting kilovolt-ampere are summarized and plotted against the transmitted kilowatt. These values are then plotted in the same manner, as are the kilowatt and kilovolt-ampere of a generator, to obtain a characteristic which depicts the equivalent generator action of the system combined at the junction.

From here on, this is used as a single generator of characteristics as found above, making combinations where necessary, and with the analysis completed as for the compound line.

From this example it will be evident that an approximate solution of this sort may be readily extended by similar methods to those here described, to give results for quite complicated networks.

These approximate methods are, of course, more easily applied than the more complete method. However, the neglecting of the effects of inertia and field transients is so loose an approximation that it may render misleading results obtained by the short method. One purpose of the point-by-point method is to determine, by the examination of specific cases, whether the approximations made in shorter analysis are justified. An example of this use was given in the discussion mentioned above and need not be repeated.

The advantage of the shorter method is that it may be applied rapidly to complicated systems. The results obtained, while they must until examined by complete analysis or test be regarded simply as indications of the probable behavior of the system, are often of much interest.

With this reservation, we present in Fig. 27 and Fig. 28, the results of such approximate analysis of a system consisting of a two-circuit long line supplied by hydro generators, and with an intermediate condenser station, as well as a condenser at the receiving end of the line. One curve sheet, Fig. 27, gives the stability for condi-

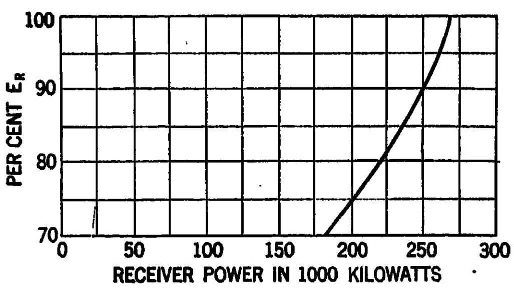

FIG. 28—OPERATING CHARACTERISTIC OF GENERATOR AND TRANSMISSION UPON SUDDENLY DROPPING ONE SECTION OF LINE WHEN DELIVERING 291,000 KILLOWATTS INITIALLY

tions obtaining with one section of one transmission circuit out of operation, field conditions of alternators being adjusted for full load operation under this condition. The other, Fig. 28, gives the curve obtaining when the section is suddenly dropped at time of full load. These curves, in terms of power against percentage of normal receiver-end voltage, give an indication of the stability of operation, since they show the way in which voltage will vary for a sudden load change.

The fact that the second curve shows the load to decrease with decrease of voltage, even at the full voltage point, indicates that this system upon suddenly dropping a section, becomes unstable. In this case the line was 240 miles long, 220-kv., 60-cycles per second, and the characteristics of apparatus were taken typical of standard apparatus, and therefore not specially designed for this service. With condensers and generating equipment more suitable for the service, a similar analysis upon dropping the section indicated stability.

The approximate analysis is valuable as an indication of performance, especially when backed by complete analysis of typical cases for comparison. Our experience, thus far, has been that results obtained by the two methods correspond satisfactorily when synchronous impedance charts are used in the approximate method. This is not, however, a general conclusion, and each system configuration is a separate problem in itself.

Conclusion and Comments

We have outlined in this paper certain methods of analysis of the behavior of power systems during transient conditions. We have confined the paper to an exposition of methods. As a result of our experience in using these methods, we have several suggestions which we believe will assist others in their application to specific problems.

The stability of systems is greatly influenced by the characteristics of the connected machines. Hence it becomes desirable to obtain comparisons between machines of different designs from the standpoint of their relative effects in the maintenance of stability in a system. We find this can be most readily accomplished by analyzing their performance when connected to a typical simple system, using approximate analyses. However, the process should be checked by occasional complete analyses in order to make sure that the result of introducing approximations is to affect each machine studied to substantially the same extent. For example, the use of an exciter system of more rapid response will undoubtedly influence the comparison between alternators, and may even render a different approximation more nearly applicable. That is, it may become advisable to use the assumption of constant air-gap flux in the approximate methods of comparison when such an exciter system is used rather than the assumption of a complete subsidence of field transient such as appears to give more dependable results when the exciter system responds slowly. A complete analysis will determine the matter. It is also advisable to analyze the effect of the machine studied in different networks in order to be sure that the simple one adopted as a basis for comparison will give results which are not misleading.

It appears, from approximate analyses we have made of complicated networks, that a disturbance may often produce instability in a single element of the networks, and that when this occurs the network as a whole will become unstable provided the element is of a magnitude comparable with the remainder of the system. Whether approximate analysis indicates correct conclusions in such a case can of course be determined by a point by point analysis. Even when the network is so complex that a complete analysis would be very laborious, the question may often be settled by the computation of two points only to give the direction in which operating characteristics begin to vary after the first instant. The approximate analysis based on transient reactance gives the solution for the first of those points applying to the instant after the application of the disturbance. The second point, if refinements are considered unnecessary may even be computed in the same manner after introducing computed angular differences.

We have found in examining the behavior during disturbances of a portion of a system, such as a trunk transmission line, that widely different results are obtained according to whether this element is treated as a separate unit or in connection with the network to which it connects. Hence, in examining the design of such an element of a system, it is advisable to make at least some complete analyses of the entire system. The influence of a connecting line depends not only upon its line constants but also upon those of any generating stations and load to which it ties the main transmission unit.

Discussion

V. Karapetoff. The method of solution of the problem of power surges, developed by the authors, may be called that of solution of differential equations by finite increments. While in the paper the differential equations themselves are not written down explicitly, they are understood to hold true. These equations express the condition that an excess of mechanical energy, applied to a synchronous machine, partly accelerates (or retards) its revolving masses, partly is delivered to the bus through a change in the torque angle, and the rest is delivered to the bus through the asynchronous action of the damper winding[1]. This is expressed analytically as

$$(J/p)\,\Omega_m\, d\,\omega/d\,t + W_s\,(\theta - \theta_m) + W_D\, d\,\theta/d\,t = \Delta\,P \qquad (1)$$

where the first term represents the rate of change in the stored kinetic energy in a rotating mass of moment of inertia, J, the second term represents synchronous power due to a change in the torque angle from its mean value θ_m to an instantaneous value θ, and the third term represents the power transmitted through the damper winding. The term Δ, P on the right-hand side, is the applied excess power which causes the surge. Such an equation may be written for every synchronous generator, motor, or condenser in the system. In addition, we have relationships of the form

$$d\,\theta/d\,t = \omega - \omega_k \qquad (2)$$

where ω_k is the angular velocity of the vector of the bus vector and ω is that of the machine, both at the instant under consideration. For each bus, the value of ω_k is different because of the properties of the transmission line. For a section of such a line we may write

$$N\,(\omega_k - \omega_k') = \Sigma\,\Delta\,P \qquad (3)$$

1. E. Arnold, *Wechselstromtechnik*, Vol. 4, p. 384.

where ω_k' corresponds to ω_k at the other end of the line and N is the slope of a power curve, such as are shown for example in Fig. 10 of the paper. In other words, N is the rate of increase in power transmitted, per degree in the change of the angle between the receiver and the generator voltages.

All the equations of the types (1), (2), (3), form together a system of simultaneous differential equations which expresses the complex phenomenon of hunting within the limits of the assumptions made. Further equations may be added to take into account centrifugal governors, voltage regulators, machine transients, etc. While the foregoing equations are linear with constant coefficients, so that their solutions may be written down directly without much trouble, the purely algebraic complexity of these solutions makes them almost useless in all but the simplest cases.

The method of finite increments consists in taking small finite values, Δt, of time and computing the values of θ and $d\,\theta/d\,t$ at the end of each interval Δt. For example, at the first instant of application of ΔP, we must put in eq. (1): $\theta = \theta_m$ and $d\,\theta/d\,t = 0$. Hence $d\,\omega/d\,t$ may be computed directly. Assuming this value of $d\,\omega/d\,t$ to remain constant over a small interval of time Δt, will give directly the values of θ and $d\,\theta/d\,t$ at the end of the interval. Substituting these values in eq. (1), a new value of $d\,\omega/d\,t$ can be computed, etc. Of course, the method is quite tedious, but is apparently the only one feasible if the results are to be derived by computation, and not experimentally.

Sometime ago the present writer proposed a similar method of solution for high-frequency transients on transmission lines and constructed a computing device to facilitate the actual obtaining of numerical results.[3]

F. C. Hanker: The problem of stability in power systems has become one of increasing importance as a result of the rapid increase of electric supply systems. In the early days, a great many of the troubles were caused by the variation in angular velocity due to use of reciprocating prime movers. It was found, however, that difficulty was experienced, even with turbine-driven units, in operating synchronous apparatus on transmission lines of high impedance values, and field tests made some twenty years ago at the suggestion of Mr. Lamme developed empirical data that were sufficiently accurate to meet conditions existing prior to a few years ago.

During the power survey made in 1920-1921 in the North East Atlantic States, studies of transmission of large blocks of power from the St. Lawrence indicated instability. Mr. Baum had been working on the same problem, and the analytical studies suggested the use of intermediate regulating stations. It was recognized that systems were operating satisfactorily under similar conditions when prime movers with drooping speed characteristics were driving the machines used for regulating purposes. There was some discussion, however, as to the stability of synchronous condensers operating in this way, and it was for the purpose of studying this and other important phases of the problem that the tests made in 1923 were conducted.

These tests were reported to the Institute in a group of papers presented at the 1924 Midwinter Convention. Since that time, we have continued our analysis of the problem, supplementing it with tests to develop data on specific phases. It is very reassuring to find that there is a very general interest in the problem, and that the importance of it is recognized. In addition to the studies that are being made from the standpoint of bulk transmission, the operating companies are making careful analysis of the conditions that exist in power systems. This will give us a great deal of fundamental data that will be extremely valuable as supporting the analytical work.

The authors state "There are only three ways in which knowledge necessary for proper judgment can be gained." It appears that they have overlooked one of the most important sources of information, and one in which the variables are considered in their proper relation. I refer to tests made on actual operating systems where the layout corresponds to the condition to be analyzed. A number of tests of this character have been made, more are now under way, and it is to be hoped that further tests will be carried on. The very active interest of the operating engineers in this problem, and their cooperation in carrying on these tests, give us the assurance that data necessary for supporting analytical studies will be available.

As the authors have pointed out, it is necessary in the theoretical studies, to make assumptions as to the characteristics of a number of the variables involved. It is this necessity in connection with analytical studies that makes it important that supporting data be made available.

The investigations that we have made have indicated that the single-phase short circuit with its subsequent switching is the most severe practical condition to be met in operation. Obviously, a system cannot be economically designed to insure continuity of parallel operation under a three-phase short circuit that would reduce the voltage on the interconnecting lines to zero. On extremely high-voltage lines, the construction is such that the occurrence of a short circuit involving all conductors is extremely rare and can be practically eliminated from consideration as the final criterion. In the present state of the art, single-phase faults from one conductor to ground are to be expected, and for such condition, we consider it reasonable that the system be designed to maintain continuity of service.

A short circuit to ground may involve a considerable increase in the true power demand on the generators, depending upon the location of the fault, and the ohmic resistance of the ground circuit. In our study of this problem, we find that under certain conditions, the usual method of governing by speed only increases the tendency to instability. It is desirable to reduce the amount of power transmitted during a disturbance, and with the relation between generator inertia and line impedances found on long lines, sufficient time is available to effect this by closure of the water-wheel gates, provided the actuating impulse is started at nearly the same time the short circuit occurs. The control device to do this would probably be a relay operating on ground current, negative-sequence current, reactive power, or increment of true power.

Tests have been made on a large power system, which show that the oscillation produced by disturbances are damped out very rapidly, hence after the control point has been passed, the gate may be opened again, the whole operation lasting perhaps 15 seconds. The deficiency in energy at the receiver end of the line, due to thes hort circuit and partial closure of water-wheel gates, can be readily supplied from the kinetic energy of the rotating apparatus there, and by temporary overload of the steam plants.

We are making a study of the normal action of steam-turbine and water-wheel governors to determine their effect on stability, when they are grouped together at the receiver end of a line. Due to the large number of stations, it is impracticable to attempt to use any auxiliary control on the governors, and only their normal operating characteristics can be considered.

C. L. Fortescue: The authors of this paper have undertaken the difficult task of presenting in detail a step-by-step method of computing the effects of power transients in transmission systems. On starting to read this paper I was quickly conscious of the inherent difficulty of presenting a subject of this nature in a paper, and I can fully sympathize with them in these difficulties.

I have gone over this paper several times with some care and believe I am safe in saying that it would require fully a week of careful study before anyone not thoroughly familiar with the authors own particular methods could apply them to the solution of transient problems. There are so-called short cuts that in

2. V. Karapetoff. Double Integraph for Electric Line Transients; *Sibley Journal of Engineering*, 1925, Vol. 39, p. 243; also the Bulletin No. 4 of the Engineering Experiment Station of the College of Engineering, Cornell University.

my estimation save little time and are confusing to use, as for example the arrangement illustrated by Figs. 3, 4 and 5. In my opinion the circle diagram without the other attachments would be much more understandable and just as easy to use.

We have made analyses similar to those described by the authors. However, our methods are, I think, more direct and simple although they take into consideration all the factors which the authors have considered. I cannot help feeling that they have made a difficult problem still more difficult. Some of the statements in the paper are very obscure, as for example the statement regarding computations for condenser angle at the bottom of the first column on the eleventh page. My understanding of this statement is that the field current is determined on the basis that during the initial transient the magnetomotive force acting on the main field remains practically constant.

The proper way of presenting a subject of this kind is of course by direct example, that is to say, carrying out the computations step-by-step with the pupil and showing the method of superimposition actually. It may be as the authors state that in a description these methods appear to be more complicated than they really are.

I believe, however, that graphical superimposition methods, however appropriate they may be for illustrating the behavior of a system under certain abnormal conditions, do not lend themselves to accurate point-by-point analysis. In point-by-point analysis, the accuracy of each succeeding computation depends upon that of the previous one, consequently small errors become cumulative resulting in quite large errors in the final results and after all, the point-by-point computations are only steps leading up to the final result which determines whether the set up under the conditions assumed is stable or not.

I would like to point out that the circle diagram which the authors use is a simple modification of the circle diagram which we have used in the past. I am quoting verbatim from our paper of last winter's convention.[3]

"Proof of the Circle Diagram

"From this point a proof of the circle diagram is readily derived. The conjugate equations of (2) may be written:

$$\hat{I}_s = (\alpha - j B)\,\hat{E}_s - (\gamma - j \delta)\,\hat{E}_r$$
$$\hat{I}_r = (\gamma - j \delta)\,\hat{E}_s - (\alpha - j B)\,\hat{E}_r$$

"Multiplying I_s by E_s and I_r by E_r we obtain the power at generator and receiver respectively.

$$P_s + j\,Q_s = E_s\,I_s = (\alpha - j B)\,E_s\,E_s - (\gamma - j \delta)\,E_r\,E_s$$
$$P_r + j\,Q_r = E_r\,I_r = (\gamma - j \delta)\,E_s\,E_r - (\alpha - j B)\,E_r\,E_r$$

but $E_s\,E_s = E_s^2$ and $E_r\,E_r = E_r^2$

If we let E_r be the datum line and $E_s = E_s\,\epsilon^{j\theta}$ then $\hat{E}_r\,\check{E}_s = E_r\,E_s\,\epsilon^{j\theta}$ and $\check{E}_r\,\hat{E}_s = E_r\,E_s\,\epsilon^{-j\theta}$. Substituting in above,

$$P_s + j\,Q_s = (\alpha - j B)\,E_s^2 - (\gamma - j \delta)\,E_s\,E_r\,\epsilon^{j\theta} \qquad (4)$$
$$P_r + j\,Q_r = (\gamma - j \delta)\,E_s\,E_r\,\epsilon^{-j\theta} - (\alpha - j B)\,E_s^2 \qquad (5)"$$

Dividing (4) by E_s^2 and (5) by E_r^2

$$\frac{P_s}{E_s^2} + \frac{j\,Q_s}{E_s^2} = (\alpha - j B) - (\gamma - j \delta)\,\frac{E_r}{E_s}\,\epsilon^{j\theta}$$

$$\frac{P_r}{E_r^2} + \frac{j\,Q_r}{E_r^2} = (\gamma - j \delta)\,\frac{E_s}{E_r}\epsilon^{-j\theta} - (\alpha - j B)$$

A circle diagram which has many advantages is obtained by dividing both equations (4) and (5) by $E_s\,E_r$ giving

$$\frac{P_s}{E_s\,E_r} + j\,\frac{Q_s}{E_s\,E_r} = (\alpha - j B)\,\frac{E_s}{E_r} - (\gamma - j \delta)\,\epsilon^{j\theta}$$

$$\frac{P_r}{E_s\,E_r} + j\,\frac{Q_s}{E_s\,E_r} = (\gamma - j \delta)\,\epsilon^{-j\theta} - (\alpha - j B)\,\frac{E_r}{E_s}$$

Divide equation (4) by E_s^2 and equation (5) by E_r^2 and we have the two systems of concentric circles which the authors used. Moreover the angular relation between sending and receiving voltage is not lost, thus equation (4) says that the locus of $P_s + j\,Q_s$ is given by $\alpha - j\,B$ and the radius vector drawn from this point $-(\gamma - j\,\delta)\dfrac{E_r}{E_s}\,\epsilon^{j\theta}$. The angle θ being the lag of $\dfrac{E_r}{E_s}$ over E_s, the data from which to measure being obtained by equating θ to zero.

I wish to say that when plain vectors are under consideration there is no excuse for using Cartesian analysis since an appropriate algebra for such vectors already exists, being merely the algebra of complex numbers. The only precaution necessary in dealing with electrical quantities represented by vectors is to remember that the vectors are not the actual quantities but merely represent them; the actual quantities are scalar and may be represented actually by the sum of two conjugate vectors. The advantage of the above method of analyzing the transmission power problem is that the angular relation between sending and receiving voltage is preserved and its relation to the power sent over this circuit is plainly seen.

While the authors have taken a great deal of pains to present a method of computing the behavior of transmission systems they have said very little in regard to methods of improving the behavior of such systems. While the Company with which I am connected has been quite busy in making extensive computations in connection with the stability of transmission systems they have been still busier in attempting to find means to improve the stability. The following is a brief résumé of some of the most promising means of accomplishing this.

(a) *High-Speed Excitation and Special Machine Characteristics.* When a sudden load is thrown on a system there is an instantaneous drop in voltage at the load point. If a regulator can be obtained sufficiently sensitive with a high-speed exciter the field of the condenser or generator at this point may be kept from decreasing and actually increased. As an actual fact during the field transient the field circuit has no effective inductance and the only resistance the electromotive force of the exciter has to overcome is the resistance of the field itself, so that there is a decided advantage in quick action outside of the effect on stability. The same exciter if it were to operate after the field transient had died out would take very much longer to build up a field to the same value.

Special machines can be designed having characteristics which lend themselves to stability. The theoretical basis of this may easily be obtained by the consideration that generators, synchronous motors, condensers, etc., are merely extensions of the transmission line; their internal characteristics will therefore have considerable bearing on stability.

(b) *Intermediate Condenser Stations.* Intermediate condenser stations having condensers of suitable characteristics are essential for economic transmission over long distances. There are other advantages which cannot be measured in dollars but which may be more important. Properly chosen characteristics for the condensers may result in considerable increase in the stability of the system.

(c) *High-Speed Circuit Breakers.* In case of short circuit in any section of the transmission system it is advantageous to cut out the faulty section as quickly as possible. Where the fault occurs near the generating station due to the sluggishness of hydraulic governors the generators may fall in speed quite considerably before the circuit breaker opens. After the circuit breaker opens on regaining equilibrium there is a tendency to overshoot due to gathered inertia to such a point that the machine gets out of step. A sufficiently quick acting circuit breaker takes care of this condition very effectively and also will take care of most conditions of trouble arising in transmission systems.

(d) *Governors.* A complete paper could be written on steam

3. *Some Theoretical Considerations of Power Transmission,* C. L. Fortescue and C. F. Wagner, A. I. E. E. Journal, February 1924, page 106.

and hydraulic governors and such a paper would I regret to say deal chiefly with their shortcomings. I feel that there is room for a great deal of improvement and such improvement will come by studying their characteristics in connection with the problem of stability.

(e) *Increasing the Number of Sectionalizing Points.* The shorter the sections of transmission line that are cut out due to a fault, the less effect the cutting out will have on stability. Therefore, increasing the number of sectionalizing stations will improve the stability of the system. There is, however, an economic limit to this method determined by the number of circuit breakers required for each additional sectionalizing station.

(f) *Neutral Impedances; Selective Impedances.* Since most of the troubles connected with transmission lines are due to grounds, power stability may be preserved by the introduction of neutral impedances or resistances. The objection to this method of preserving stability is the tendency to produce voltage transients in the transmission system endangering insulation and apparatus. Since most short circuits are single-phase or unsymmetrical therefore an impedance which will impede the negative-sequence component of current without offering impedance to the positive-phase component of current will help secure stability.

In our study of the problem of stability we have attempted to steer a course between analytical methods and practical experiment. Since the analytical solution at its best is very involved, one can hardly expect engineers of utilities or technical advisers of syndicates to accept the results without some practical backing. We are preparing papers to be presented shortly before this Institute showing our method of analyzing these problems but we prefer to hold back this information until we can get actual data in the field, substantiating our results. Tests are under way now to procure this data and so far results appear to be very promising. I may say that the results indicate that all the investigators of stability under transient conditions including ourselves have been too pessimistic. I am glad to say that we have been the least pessimistic and are therefore more nearly right.

I wish to emphasize that in a problem so involved as in the one that the authors treat of, analytical solutions alone carry very little weight and they must be backed by actual practical demonstrations on existing circuits. Demonstrations without artificial transmission lines and models are not satisfactory. The method of point-by-point analysis using an artificial transmission line described by Messrs. Spencer and Hazen offers a great deal of promise. There is also a possibility of working out kinematical models which will embrace all the essential elements of the problem. I think that work along these lines should be encouraged. I think a machine is much more adaptable in working out problems of the character than a human being.

F. G. Baum: The problem of stability is one that has been with us for more than twenty years. If you will examine the TRANSACTIONS of the Institute of twenty odd years ago you will find a great deal of space taken up by discussions of the question of hunting of synchronous motors, and the hunting between parallel stations.

The problem as presented by Professor Karapetoff was covered, I think, as early as twenty odd years ago, and for those of you who haven't followed the transmission work particularly and who wish to study it, and to begin in an elementary way, I suggest you look at a paper published in the *Electrical World*, March 29, 1902 on "Synchronous Motor Stability and Overload Capacity Curves." You will find there many of the curves given by Messrs. Booth and Bush. They are curves given in pecentage of voltage, percentage of current, and so forth, so they are applicable for any scale that you wish to take, whether it is 110,000, 150,000 or 220,000 volts or something beyond that.

It has been my pleasure and privilege to be connected with transmission work for nearly thirty years, and I have found the subject so interesting and so broad that I haven't done much of anything else. But the transmission has been rather a disappointing part of the system, I may say, until within the last few years. It seems as though transmission was always lagging behind the power-station work. The power stations and the transformers were always ahead of the transmission lines. We never could get the capacity over the transmission lines that it would appear to be necessary, from the demands of the power stations and the power-consuming loads.

About five or six years ago, realizing that that condition confronted us, I made a study of the 220-kv-a. system. And I must say that the first time I ever got a real kick out of making transmission calculation was when I calculated a 220-kv-a. system; for it appears that for the first time we have a transmission system that is commensurate with the generators, and the large-size generators, water-wheels, transformers, and loads required at the present time.

As I say, realizing that five or six years ago, I recommended that we build a 220-kv-a. system to bring power from the northern part of California down to San Francisco, as I felt that without a high-voltage system of this kind it could not be economically done.

In a large system like the Pacific Gas and Electric Company, many problems of stability are solved by Nature. For example, on our system for about twenty years we have not operated with all the governors on the system trying to take hold of the load. You can not do that, but you eliminate and block the governors, and one or two stations at the most become the clearing house for kilowatt-hours. That simplifies your governor operation very materially and resolves it, then, to an infinite bus practically and a smaller unit with a fluctuating load.

With the 220-kv-a. system, it is necessary to operate with condensers on the system. You cannot do it without them. That makes it possible to simplify the operation to a very much greater extent, for just as we have one or two stations furnishing a clearing house, so to speak, for the kilowatt-hours, we have one or two stations furnishing a clearing house for the kv-a.

It is the lagging kv-a. that pulls the power system, and if you can prevent that lagging kv-a. from pulling the voltage out of the system, and if you can keep the actual kv-a. necessary to maintain the reaction pressure tangent to the voltage circle, you are not going to have instability. It is impossible to have instability with the current and pressure in phase. It is only when they get out of phase, at cross-purposes, that you get instability.

Finally, I may say this: It appears, that now for the first time we have a transmission system which is commensurate with the needs of the industry, but apparently we also have a transmission system that is inherently suited to outdoor operation. It seems, that we can never defy the lightning or the weather conditions in other respects.

C. F. Wagner: The authors of the paper mentioned the subject of high-speed excitation but have not stressed its importance sufficiently. I wish to emphasize high-speed excitation as a means of improving the stability of long-distance power transmission systems.

Introducing the effect of generators and condensers reduces the ability of the system to withstand disturbances as compared with the line alone. Suddenly increasing the lagging current drawn from an alternator or condenser increases the demagnetizing effect. The flux, however, cannot change instantly. At the first instant current is induced in the field windings and eddies in the pole pieces of such magnitude as to overcome this demagnetizing effect. The eddy currents in machines without damper windings are relatively small and to simplify the discussion will be neglected. The voltage required to circulate the additional field current is supplied by the change in flux through the field windings and is equal to the increment of IR drop in the field circuit. With hand regulation the flux will decrease until the total IR drop in the field winding is again equal to the exciter

voltage. In effect, a hand-regulated machine introduces an artificial internal series reactance although it is in part compensated by the larger artificial internal voltage.

The voltage coils of automatic voltage regulators of the Tirrill type are connected across the terminals of the generator. On sudden application of lagging load the internal-drop reduces the terminal voltage which in turn closes the regulator contacts and increases the exciter voltage. If the exciter voltage could be built up instantly to such value corresponding to the new IR drop of the field currents the flux would remain constant. Actually, however, the exciter voltage builds up along a very definite curve. During the interval while the drop in the field winding

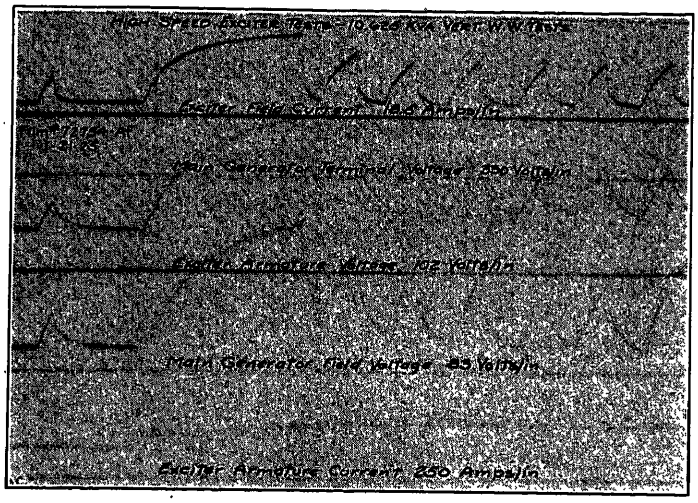

Fig. 1

is greater than the exciter voltage, the flux in the main machine decreases in a manner similar to that discussed for hand regulation. The flux will continue to decrease until the exciter voltage is equal to the drop in the field windings. An excess of exciter voltage over IR drop increases the flux.

From the foregoing it can be seen that the faster the exciter voltage increases the smaller will be the decrease in flux. This is what the high-speed exciter attempts to accomplish. Note particularly that the high-speed exciter relies not upon changing the flux in the main machine but rather upon annulling the effect of the armature demagnetizing current. Of course, the slower the field of the machine the smaller will be the flux change, but if the increase in exciter voltage is always of such value as to annul very quickly the effect of any reactive current that might reasonably occur then it would be more desirable to have a fast field and a high short-circuit ratio.

Fig. 1 is an oscillogram taken during some tests on a 10,625-kv-a. 100 rev. per min. alternator in which 4350 kv-a. leading load was thrown off. This simulates the condition of suddenly increasing the lagging load as would be the case during short circuits. Dropping leading load simultaneously decreased the terminal voltage. After an interval due to the lag in the regulator and relays the exciter voltage begins to increase as shown. This lag can be made practically zero by arranging an extra pair of contacts in parallel with those of the regulator and operating them from the fault ground current or from reactive kv-a.

The rest of the story is self-evident. The loss of magnetizing armature current induces an equivalent current in the field winding. This current decreases for an interval but the rapidly increasing exciter voltage soon annuls this action and increases the field current. In the meantime the terminal voltage is increasing with the field current until a voltage is reached which causes the regulator contacts to separate. The exciter voltage decreases and after a series of oscillations settles down to normal no-load conditions.

The effect of high-speed excitation upon the flux is better illustrated in Fig. 2. These curves were prepared from test data and indicate the change in exciter terminal voltage and flux of main machine as the armature current is increased from zero to rated-value zero power factor. Curves marked a represent the conditions for hand operation, curves marked b for standard exciters and curves marked c for high-speed exciters. The load was applied at an instant when the exciter voltage had reached a minimum value to represent approximately the worst condition. For hand operation the flux decreased enormously; with the standard exciter the decrease was still quite considerable; but with the high-speed exciter the decrease was negligible. With this type of excitation transient conditions may be calculated using the assumption of constant flux through the field windings, *i. e.*, that component of flux in phase with the rotor. It should be noted that high-speed exciters do not control the cross flux, this being a function of armature current only.

While it is true that the stability of a high-voltage transmission system can be increased by the application of high-speed exciters with fast regulators of the Tirrill type, its utility is not universal, in fact quite the contrary. Their application to generators connected to transmission lines in which the resistance is about equal to or greater than the reactance decreases the stability. For this case hand regulation or slow-speed exciters and rheostatic regulators are preferred. In this connection it should be noted that the general stability of a system cannot be increased by speeding up the excitation of synchronous equipment at the end of distribution lines, which usually have high ratio of resistance to reactance as compared with high-voltage transmission lines.

In the event of a disturbance which unbalances the voltages

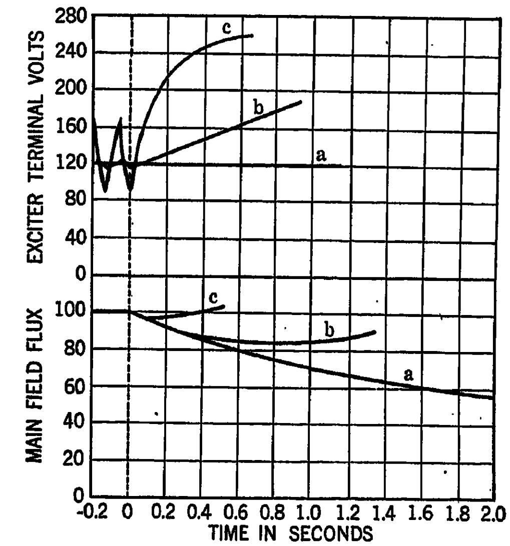

Fig. 2—Effectiveness of High-Speed Exciter in Maintaining Flux in Alternator

Armature current suddenly increased from zero to 100 per cent, zero power factor lagging.

a. Hand regulation
b. Standard exciter with Tirrill regulator
c. High-speed exciter with Tirrill regulator

such as a line-to-ground fault, it is of course necessary that the regulator contacts close and remain closed. This may not occur if the regulator is connected in the usual manner. Rather than decreasing the voltage of the phase to which the regulator is connected analysis has shown that the disturbance might increase the voltage. Proper action can be insured by connecting the regulator through a network which passes only the positive-sequence voltage.

High-speed exciters increase the duty on circuit breakers, but this is probably not an insurmountable difficulty.

R. C. Bergvall: Mr. Hanker and Mr. Fortescue have pointed out that ordinary switching operations are not the limiting conditions which have to be met in considering stability. The limiting condition is the ability of the system to remain in synchronism during short circuits and during the switching operations following the abnormal conditions set up by the short circuits. Experience has shown that line-to-ground short circuits constitute about 90 per cent of the system disturbances and particular attention must, therefore, be paid to maintaining stability under these conditions. With two systems tied together by two parallel transmission lines, it is practically impossible to maintain synchronism if a three-phase short circuit occurs near the generating station or the substation, because the voltage on the tie line is reduced to zero. Various methods have been considered in an effort to increase the possibility of maintaining synchronism, such as rapid relay operation or making the transformer a unit with the line as Mr. Thomas proposed at the 1924 Midwinter Convention, thereby interposing the transformer reactance between the bus and the short circuits. However, in most cases the necessity for flexibility in switching of the high-tension lines makes it impossible to lay out the system in this manner.

The engineers of the Westinghouse Company have been actively investigating the effect of line-to-ground short circuits during the past year. The importance of making such investigations can best be seen by considering a line-to-ground short circuit having 5000 amperes of ground current. This corresponds to a loss of 25,000 kw. per ohm of ground resistance, which is an appreciable kilowatt load to throw on a system already carrying a heavy load.

The magnitude of the ground resistance is an indeterminate factor. A bushing circuit on a transformer would have practically zero ground resistance while a tower located on rocky soil would have considerable ground resistance. The worst condition would be some value of ground resistance between the zero ground resistance and the extremely high ground resistance, provided it was desired to maintain stability under all line-to-ground short circuit conditions.

The problem of determining stability in the case of line-to-ground short circuits is complicated by the presence of unbalanced currents and voltages and by the opening of circuit breakers before the steady-state condition has been reached. When the circuit breakers open the entire load is immediately transferred to the other transmission line and pull-out is likely to result because of the sudden change in load at the same time that the system conditions have been disturbed by the short circuit.

The calculation of single-phase short-circuit currents by the commonly used methods on an extensive transmission network is difficult because the currents and voltages are unsymmetrical and each phase is inductively coupled in the transmission lines, transformers and rotating machines. Furthermore, all rotating machines, provide a distinct phase-balancing action which tends to restore symmetry in voltage and current. A solution of a problem of this type is to be published by R. D. Evans in a future issue of the *Electric World*. Essentially it is an application of the method developed by C. L. Fortescue for the general solution of unbalanced polyphase circuits. Briefly, the voltages and currents of the three-phase grounded-neutral circuit are resolved into the positive-sequence, negative-sequence, and zero-sequence components, which do not react upon each other and may be considered independently. With normal balanced loads only positive-sequence voltages and currents are present, but in the case of a short circuit to ground all three sequence components are involved.

The method employed in investigating the possibility of pull-out occurring during line-to-ground short circuits consists of substituting equivalent impedances in the circuit to represent the zero-sequence and negative-sequence components, thereby leaving only the positive-sequence components which may be handled by the usual methods.

S. B. Griscom: As already pointed out in the discussions certain disturbances on transmission systems, notably the single-phase, line-to-ground short circuit with the subsequent line switching may produce large oscillations in the phase position of the generators about the angle corresponding to their mean output. The system must be designed so as to withstand disturbances which are of common occurrence. This means that the maximum operating load must be considerably less than the power limit of the line. On the other hand, economic considerations demand the transmission of the maximum power possible per dollar of transmission investment.

Two general courses of action are available to increase the economy of transmission. The theoretical power limit of the line may be increased by proper design of the line, including the associated apparatus, or the effect of disturbances can be reduced, enabling a smaller factor of safety to be chosen.

The group of papers presented in February 1924, and the discussions on them, considered in a general way the use of synchronous condensers located at points along the line for the purpose of increasing the amount of power that could be transmitted over the circuits. This scheme was first proposed by F. G. Baum, in a paper before the A. I. E. E., in 1921.

We have since made an extended study of this system which has shown its utility. For transmitting a given amount of power over a line, a certain amount of reactive power must be supplied to it depending on the voltage conditions. The usual method is to supply this at the two extremities of the line; by the generators at one end, and by synchronous condensers at the other.

On long lines it is necessary to sectionalize at one or more points, so that in event of trouble, it will not be necessary to cut out too large a proportion of line. These sectionalizing points are ideal locations for the installation of synchronous condensers, since switch structures and attendants are already there.

By installing condensers at these points, the maximum operating load may be increased, and the voltage regulation at intermediate points greatly improved. This is especially desirable for future interconnections or loadings at intermediate points.

The theoretical limit of a long line may be made to approach the limit of the longest section between points where synchronous machinery is installed, depending upon how well the machines can maintain the line voltage. By the use of machines designed with this object in view, and by using a high-speed exciting system in conjunction with them as mentioned in one of the discussions the regulation can be made very good.

Our studies have shown that it is economically possible to increase the permissible load on a 250-mi., 220-kv. line about 25 per cent by means of suitable installation of synchronous condensers at intermediate points.

The other general method of increasing the carrying capacity of transmission circuits is to lessen the effect of short circuits in causing pull-outs between supply and receiver ends. One method which shows considerable promise is to use an auxiliary control on the governing mechanism, as already mentioned. Another method under consideration is to use circuit breakers on the main transmission circuits, which would operate at speeds considerably higher than those in use at the present time. The utility of this scheme is readily apparent when we consider that if the breaker could be opened at the instant of short circuit, the condition would be in effect only that of line switching, which is much less severe.

Up to the present time, no data is available as to the maximum speed that can be attained by circuit breakers in interrupting large currents at 220 kv. In order to get an idea of what can be gained by using different speeds of circuit breakers, some calculations were made on stability during single-phase-to-ground short circuits, when the faulty section of line was cut out

at different time intervals from the instant the short circuit occurred. The results of these calculations are presented in the form of curves, showing the variation of angular position of the generator rotors with time, for a typical transmission system.

By referring to the accompanying curves, it will be noted that if the circuit breaker opens at the instant of short circuit, there is very little relative movement in phase position of the rotors of the generators with reference to the load. If the short circuit is permitted to hang on for 0.2 seconds, a somewhat greater swing takes place. For 0.4 seconds, the swing is of such a large magnitude that on the second half cycle of mechanical oscillation the systems pull apart as indicated by the fact that the angle continues to increase with time. The same is true with any time of breaker opening up to 1.0 second. From 1.0 to 1.6 seconds stability can be maintained. From these curves, it is evident that if the period of oscillation is of the order of one second, the stability of the system can be greatly improved by the use of sectionalizing cricuit breakers which open the circuit within 0.2 seconds after a short circuit occurs.

If the natural period is greater, a correspondingly higher maximum time is permissible. These curves show clearly the element of chance, due to erratic relay or breaker operation, and explain why a short circuit may cause pull-out on one occasion and not on another when conditions are apparently identical.

Aside from the question of lessening oscillation of the generators and other synchronous machines, the use of high-speed circuit breakers would be of material assistance in minimizing voltage decrement due to demagnetization. On this account, their rupturing capacity must be increased, although the use of a special excitation system might independently impose this requirement.

It may be somewhat premature to mention the use of high-speed circuit breakers of this type, when none have thus far been developed, but the principle purpose of this discussion is to point out possible methods for improving stability.

V. Bush and R. D. Booth: A number of the discussions treat of improvements of transmission system and correlated apparatus and need no further comment in connection with a paper devoted to methods of analysis.

Prof. Karapetoff's discussion is an admirable presentation of the fundamentals upon which the methods of the paper are based, and undoubtedly adds completeness and clarity to the entire subject. It might, however, be in order to point out that the differential equations used by Prof. Karapetoff are linear and also that the coefficient N,—the rate of increase in power transmitted per degree change of the angle between the receiver and generator voltages—is constant. The methods presented in the paper permit analysis of those problems in which the equations are non-linear, and the coefficients are not constant.

Mr. Baum's discussion of the progress of the art of transmission and of operation of systems involving long transmission lines is of general interest. We presume that Mr. Baum refers to steady-state rather than transient conditions when he says that practically infinite bus conditions at the sending generators can be obtained by blocking the governors thereof.

Mr. Wagner's discussion of the possible benefits of high-speed exciter systems and Mr. Griscom's studies of the advantages of high-speed circuit breakers are of great importance to the industry. We presume that Mr. Griscom's curves of desirable operating times apply only to a particular system and for particular values of arc resistance. Also we presume that Mr. Wagner's discussion of the limitations of high-speed exciters is based upon specific data regarding arc resistances and operating times of breakers and governors.

Testing High-Tension Impregnated Paper-Insulated, Lead-Covered Cable

BY EVERETT S. LEE*
Associate, A. I. E. E.

Synopsis.—The increase in voltage rating of cables has necessitated that the tests to assure satisfactory cable be more adequate than as standardized at present. This has resulted in an intensive study of the tests previously standardized, development of new tests, and the design and manufacture of suitable testing equipment to meet the new testing requirements.

Measurements are made upon cables to determine the following properties of the insulation:

Insulation Resistance
Dielectric Strength
Dielectric Power Loss and Power Factor
Capacitance
Ability to Withstand Bending

Insulation Resistance: This measurement is being made in the same way on cables of all voltage rating. The results of the test on high-tension cables are of doubtful value as a criterion of the suitability of cable for use. Continued study of this measurement should be made.

Dielectric Strength: Suitable testing equipment for satisfying the requirements of the increased voltages in dielectric strength tests has been made available. This includes sine-wave generators, adequate testing transformers, appropriate cable testing terminals.

Data is given from which conclusions are drawn as to the magnitude and duration of test voltages. The adequacy of these values will become known through experience. The need for field testing is shown.

Dielectric Power Loss and Power Factor: The tendency is to extend the measurement of dielectric power factor to include each reel length to be shipped. The Schering Bridge for making such measurements is described. The need for standardizing the testing procedure for power-factor measurements is shown.

Testing Installed Cable: The study of so-called "current-time curves" for rating installed cable should be continued. Preliminary measurements made at high frequencies as a means of rating installed cable did not show the results to be immediately usable.

Testing With Direct Current: Data is given to show the d-c.- to a-c.-ratio of breakdown voltage of some samples of 12 kv.-3-conductor cable. Tests indicate that the d-c.-to a-c.-ratio will depend upon many conditions such as nature and structure of the material, thickness of the material, temperature of the material, shape and size of electrodes, and rate of application of the applied potential.

THE report of the Transmission and Distribution Committee of the A. I. E. E. for 1923-1924 contains the following significant statement:[1]

"The most important development during the past year has been the evidence that the cable specifications of the N. E. L. A. and the present Standards of the A. I. E. E. do not insure satisfactory cable for the higher operating voltages.

"This subject is now receiving attention from the manufacturers as well as the users of high voltage cable and as a result of these studies, it is hoped that it will be possible:

First, to make the necessary changes in manufacturing processes and materials so as to secure a satisfactory cable for operation at the higher voltages, and

Second, to devise a method of testing high voltage cable which will determine its operating characteristics in advance of its installation."

The present paper discusses some phases of the second of these two objectives, not that such a method for which engineers are eagerly searching has been finally devised, but because a discussion of the conditions under which the present tests are applied may be helpful in so modifying them that they may be made more adequate.

The tests at present standardized for determining the suitability of cable for use as regards the insulation are as follows:

I. A. I. E. E. Standards 1922.
- A. Tests to be made on each length to be shipped.
  1. High-voltage test
  2. Measurement of insulation resistance
  3. Measurement of capacitance
- B. Test to be made on samples (10 ft. of lead)
  1. Measurement of ultimate dielectric strength

II. N. E. L. A. Specifications for Impregnated Paper-Insulated, Lead-Covered Underground Cable, 1922.
- A. Tests to be made on each length to be shipped
  1. High-voltage test
  2. Measurement of insulation resistance
- B. Test to be made on one reel length per 15,000 ft. of cable
  1. Measurement of dielectric power loss and power factor at about 85 deg. cent
- C. Test to be made after installation when cable is installed by the manufacturer
  1. High-voltage test
- D. Tests to be made on samples
  1. Measurement of dielectric strength
  2. Bending test
     - a. Wrinkling of lead; dielectric strength; visual examination
     - b. Deformation
  3. Measurement of dielectric power loss and power factor.

*General Engineering Laboratory, General Electric Co., Schenectady, N. Y.

1. For references see Bibliography.

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 9-12, 1925.

The electrical characteristics represented in the above tests include all that are now known. The problem is to apply them so that unsatisfactory cable may be separated from satisfactory cable without harming the latter. The following discussion on this subject will, in the main, refer only to high-tension cables with paper insulation treated with mineral compound for circuits rated above 12 kv. The results of tests included in this discussion were obtained from commercial cable manufactured prior to Jan. 1, 1924, except as may otherwise be noted.

Insulation Resistance

Insulation resistance is measured after the high-voltage test on the entire length to be shipped, measuring the leakage current after a one-minute electrification with a continuous e. m. f. of from 100 to 500 volts, the conductor being maintained negative to the sheath.[2] From the results so obtained, a "Megohms Constant" is calculated so that cables of different dimensions may be directly compared. The increase in voltage rating of cables has brought about no real change in method of making the insulation resistance measurement nor have new difficulties therein been encountered. Humidity may still be a disturbing factor by increasing the leakage, though a recent suggestion of surrounding the insulation testing set and operator with a sheath wire, heated by circulating current to keep the testing set dry, has proven entirely effective in eliminating the leakage without causing discomfort through overheating of the test booth.

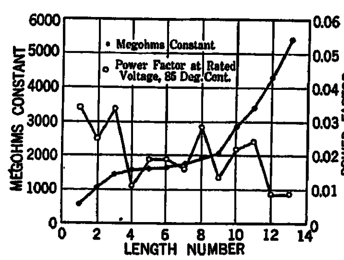

Fig. 1—Megohms Constant and Power Factor of Reel Lengths of 3-Conductor 33-kv. Treated Paper-Insulated Cable

Although measurements of insulation resistance have been made on cables for years and are still being made, the results as determined by the standardized procedure are of doubtful value as being indicative of the suitability or unsuitability of cable for use. It was recently noted that a nail hole through the lead to the paper of a 3-conductor 22-kv. cable caused no noticeable change in the megohms constant derived from measurements made daily after a period of two weeks, the reel being immersed continuously in water. Enlarging the nail hole to the size of a quarter and continuing the measurements daily for two months with the reel immersed has not materially changed the megohms constant from its original value of 3000 before the nail hole was made.

Although not sensitive to such conditions, results are obtained showing sensitiveness to other factors which are not easily determinable. Fig. 1 shows the values of megohms constant obtained from the measurement of 13-reel lengths of three-conductor 33-kv. cable, manufactured to the same specifications during a period covering three months. The ratio of the highest reading to the lowest is in the order of 5 to 1. Values of power factor for each length at 85 deg. cent. at rated voltage, are also plotted and show all lengths of the cable to be of low power factor. The ratio of the highest to the lowest power factor value is 3 to 1. Fig. 2 shows similar values for 18 reel lengths of three conductor 12-kv. cable, showing characteristics similar to those of the 33-kv. cable, Fig. 1. The relation between power factor and insulation resistance is noted to be generally inverse, though not consistently so. These results indicate a relatively wide range of insulation resistance for cable, all of which is apparently satisfactory.

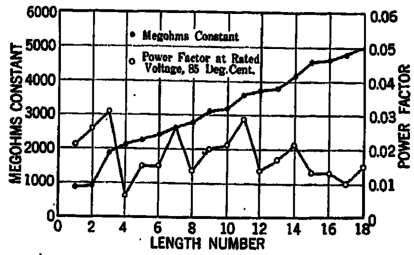

Fig. 2—Megohms Constant and Power Factor of Reel Lengths of 3-Conductor 12-kv. Treated Paper-Insulated Cable

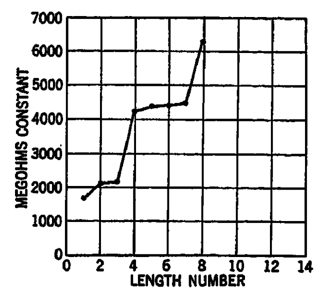

Fig. 3—Megohms Constant of Reel Lengths of 3-Conductor 22-kv. Treated Paper Insulated Cable, Treated in Same Tank at Same Time

Fig. 3 shows the megohms constant obtained from measurement of eight lengths of three conductor 22-kv. cable made from the same kind of paper, treated with the same compound in the same tank at the same time. The ratio of the highest value to the lowest is 4 to 1, yet there has never been any evidence that any one length was more satisfactory cable than another. In general, the ratio under these conditions averages more nearly 2.5 to 1. For the same kind of cable treated in different tanks, however, ratios of 5 to 1 and even 10 to 1 are not uncommon.

It appears, therefore, that insulation resistance measurements are being made on cables of the higher voltage rating just as they have been made for many

years on cables of lower voltage rating. The measurement, though comparatively simple, is of little real value as a means of distinguishing between good and poor cable. Measurements made at higher direct voltages may prove to be more useful but such have yet to be more thoroughly investigated.

Dielectric Strength

The criterion of a satisfactory cable is that it shall successfully operate at its rated voltage in the system to which it is connected and for which it is designed. This requires that every point along the entire length of the cable must be dielectrically strong and continue to be so. The only means now available for determining initially the suitability of a cable as regards dielectric strength is to determine the ultimate dielectric strength of samples of the cable by breaking them down under electrical tension, and then applying a lower electrical tension for a given time to similarly made cables in lengths intended for use, the value and time of application of the test voltage being chosen so as to separate such cable as is dielectrically weak from that which is dielectrically strong without harming the latter. The final criterion for the effectiveness of this test is experience.

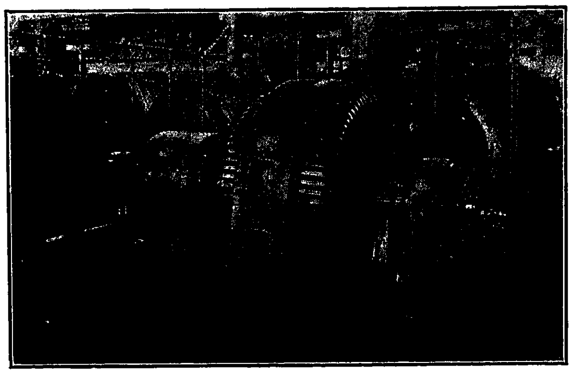

Fig. 4—Sine-Wave Synchronous Motor-Generator Set

Generator rated three-phase, six-pole, 400 kv-a. 12 rev. per min., 900 volts

Motor rated, three-phase, four-pole, 100 h. p., 1200 rev. per min., 550 volts

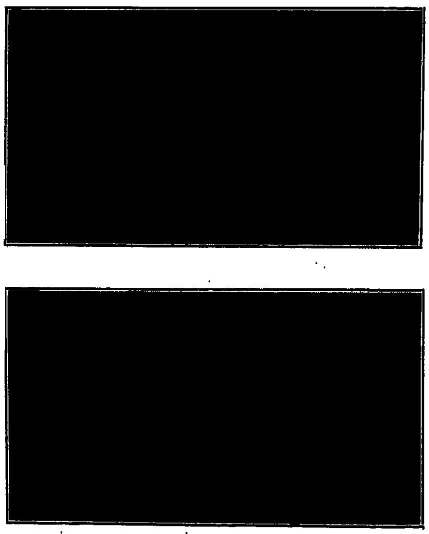

Fig. 5—Wave Shapes of Sine-Wave Generator, Rated Three-Phase, 400 Kv-a., 1200 Rev. Per Min., 900 Volts

Upper curve, no-load voltage wave

Lower Curve, voltage wave, Load of 1242 ft., three-conductor, 33-kv. cable at 85-kv.

The increase in voltage rating of cables has introduced difficulties into the testing procedure of dielectric strength tests, but these are being overcome. At the present time the best samples of single-conductor cable for 66-kv. three-phase circuits have a breakdown voltage on short-time test of from 300 kv. to 350 kv., while the best samples of three conductor cable for 33-kv. three-phase circuits have a breakdown voltage on short-time test of 200 kv. High-voltage tests in the factory on long lengths of the former cable are conducted at from 100 kv. to 150 kv.; on the latter cable at from 82.5 kv. to 95 kv., the time duration being from 5 min. to 15 min., depending upon conditions. Such values as these require testing equipment of high voltage and high kv-a. rating which must conform to standardized requirements, such that the voltage wave shall "approximate as closely as possible a sine wave." In this phase of the work substantial progress has been made.

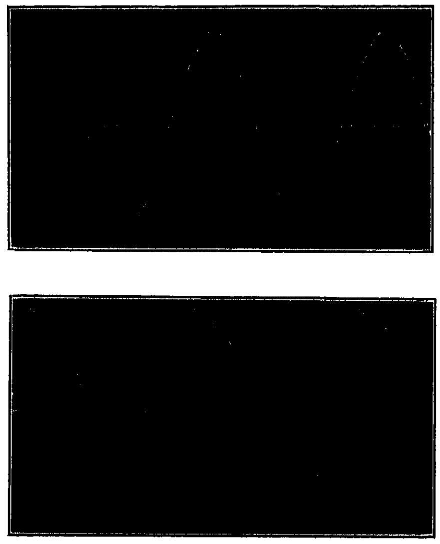

Fig. 6—Wave Shapes of Generator, Rated Three-Phase, 75 Kv-a., 500 Rev. per Min., 550 Volts, in Use for Testing Cable 15 Years Ago

Upper Curve, no-load voltage wave

Lower Curve, voltage wave, load of 702 ft., three-conductor, 12 kv. Cable at 40 kv.

Fig. 4 shows a motor-generator set rated 400 kv-a. at 1200 rev. per min. and 900 volts, of which the no-load voltage wave, and the voltage wave when connected through transformers to 1242 feet (three reel lengths) of 3-conductor 33-kv. cable at 85 kv., are shown in Fig. 5. The characteristics of these waves are:

Load	Deviation Factor	Form Factor
No load	1.2%	1.11_5
Cable load of 1242 ft. of 3-cond. 33-kv. cable at 85 kv	1.0%	1.11_4

Fig. 6 shows wave shapes as obtained from a generator which has been in use for cable testing, for 15 years, rated 75 kv-a. at 500 rev. per min. and 550 volts, of which the characteristics are:

Load	Deviation Factor	Form Factor
No load..............	2.8%	1.11_7
Cable load of 702 ft. of 3-cond. 12-kv. cable at 40 kv.......	30.9%	1.10_8

These comparative values indicate the substantial progress which has been made in the generator design. The excellent characteristics of the waves shown in Fig. 5 for the modern generator are all the more remarkable when it is considered that they are for a load with leading current and of extremely low power factor.

The wave shapes of the modern generators are well within the required limits for testing with sine wave shape and for measuring voltage with a voltmeter following any of the standardized methods, such as through an auxiliary ratio transformer or by means of a voltmeter coil placed in the testing transformer. Ratio transformers being necessarily quite large for use at the high voltages now required, the voltmeter coil placed in the testing transformer becomes a most useful means for making the voltage measurement. A paper on testing transformers has been recently presented to the Institute,[3] in which paper also is included a discussion of voltage measurement together with apparatus available for such measurement.

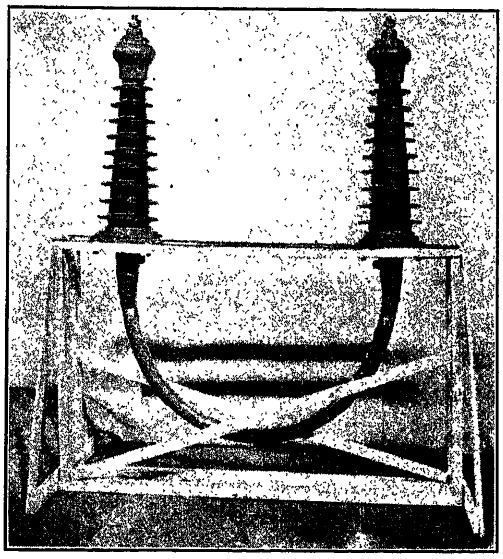

Fig. 7—Two Oil-Filled Cable Terminals, Assembled at the Ends of a Sample of Cable for a 66-Kv. Three-Phase Circuit, for Ultimate Dielectric Strength Test up to 240 Kv.

Probably the greatest single difficulty confronting the cable tester when making dielectric strength tests is that of applying the voltage to the cable, it being necessary to so prepare the cable ends that they will withstand the high voltage without breakdown or flashover, and so that the break will occur under the lead and not in the end-bell. For tests on reel lengths in the factory where the voltages applied for three minutes are not above 100 kv. between conductors for three-conductor cable or between conductor and sheath for single-conductor cable, the problem is not so difficult, there being several designs of end-bells in use. The usual method is to apply an inverted paper cone to the cable end, which is then filled with petrolatum hot enough to pour. Pressed paper or fibre tubes are frequently placed over the separate conductors of three-conductor cable.

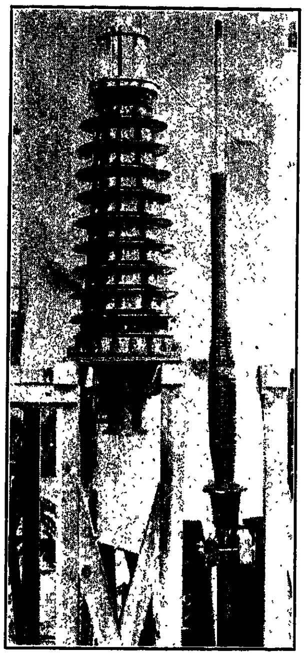

Fig. 8

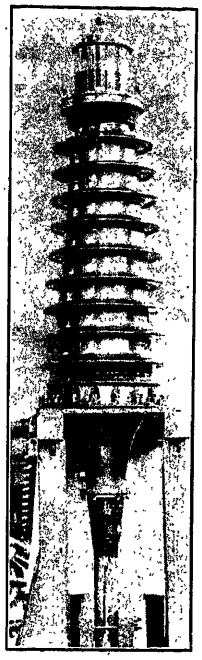

Fig. 9

Fig. 8—Oil-Filled Cable Terminal, Ready for Assembly to a Sample of Single-Conductor Cable for a 66-Kv. Three-Phase Circuit, for Ultimate Dielectric Strength Test up to 350 Kv.

Fig. 9—Oil-Filled Cable Terminal Assembled to a Sample of Single-Conductor Cable for a 66-Kv. Three-Phase Circuit for Ultimate Dielectric Strength Test up to 350 Kv.

For single-conductor cable where the test voltage is above 100 kv., a most satisfactory means of applying the electrical tension has been found to be through the application of a terminal made of a porcelain oil-filled bushing of standard design provided with suitable fittings for proper application to the cable. Fig. 7 shows two such terminals attached to a sample of single-conductor cable with 30/32 in. treated paper for a 66 kv. three-phase circuit. Terminals such as these have been regularly used in testing reel lengths of single-conductor cable in the factory where the test voltage has been 150 kv. for both five-min. and for 15-min.

application; also for ultimate dielectric strength tests up to 240 kv. which is the dry flashover voltage of this terminal. Figs. 8 and 9 show a larger terminal ready for assembling to the cable end, and as assembled to the cable end, the former showing how the cable end is prepared before the terminal is applied. This is done by removing a suitable length of the lead and then building up over the factory insulation with black varnished cloth, covering a portion of this with copper wire or flattened string solder to carry the ground potential of the sheath up over the reinforced insulation a suitable distance to properly distribute the stress.

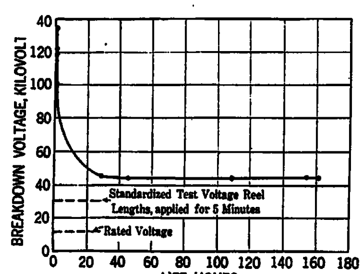

FIG. 10—BREAKDOWN VOLTAGE-TIME CURVES AT 25 DEG. CENT. FOR SINGLE-CONDUCTOR CABLE SAMPLES WITH 9/32 IN. TREATED PAPER INSULATION

A terminal such as shown in Figs. 8 and 9 has a dry flashover voltage of 350 kv. and if the cable remains sound, it is absolutely satisfactory for use in testing cable samples up to a breakdown voltage of that value. Flashover of the terminal may result at a lower value from disturbances which may occur in the cable, in which event a larger terminal may be used.

A terminal such as shown in Fig. 7 weighs 155 lbs. with fittings, and for a factory test on a reel length at 150 kv., where it is not necessary to build up the cable ends with varnished cloth, it requires the time of two men for two hours to apply the terminals and remove them. A terminal such as shown in Fig. 9 weighs 375 lbs. with fittings, and for an ultimate dielectric strength test where the cable ends must be built up with varnished cloth, it takes two men a day to apply the terminals and remove them. The use of such terminals has made possible satisfactory tests of dielectric strength without the difficulties usually attendant the use of built-up end-bells, and represents a most gratifying advance in the art. Suitable terminals are available for the entire range of voltages required in making dielectric strength tests on single-conductor cable.

No satisfactory built-up end-bell has yet been devised for testing 3-conductor cable samples for ultimate dielectric strength where the breakdown voltage is in the order of 200 kv. An average gradient of approximately 250 volts per mil seems to be about the maximum voltage where a built-up end-bell following the usual designs can be used in ultimate dielectric strength test of 3-conductor cable with satisfaction. Above this value, breakdown usually results in a crotch failure between conductors in the end-bell. Out of 12 samples recently tested where the probable failure would be in the order of 200 kv., every sample failed at substantially lower voltage in the crotch in the end-bell, which failures were preceded by excessive leakage over the conductor insulation. Efforts to prevent crotch failures have been made in practise by the use of different filling compounds, such as petrolatum, linseed oil, and transil oil, but as yet without success. The use of long treated paper tubes over the separate conductors has not bettered the results measurably.

Theoretical considerations and calculations indicate that the excessive leakage stress can be kept below safe values only by so designing the external surface of the end-bell that it follows essentially the curve of the conductors as they diverge. This is not simple to do in a built-up end-bell. From a review of all of the factors, it is felt that the best plan is to use a three-conductor oil-filled cable terminal following the practise above suggested for testing single-conductor cable. The early use of such when results will be available for report is contemplated.

Even with proper equipment available for conducting dielectric strength tests, the problem of determining a satisfactory suitability test still remains. The long established test voltage for cables of two and a half times normal rated voltage applied for five minutes[4] has apparently not been satisfactory for the high-tension cables. Such a test, of course, only establishes the condition at the time this is illustrated by the

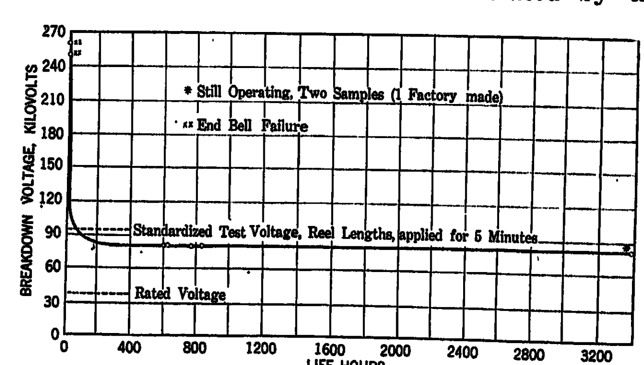

FIG. 11—BREAKDOWN VOLTAGE-TIME CURVE AT 50 DEG. CENT. FOR SINGLE-CONDUCTOR EXPERIMENTAL CABLE SAMPLES WITH 30/32 IN. TREATED PAPER INSULATION

results shown in Fig. 10. Ten samples of 2/0 A. w. g. single-conductor cable insulated with 9/32 in. treated paper insulation were tested, five for ultimate dielectric strength (short-time step-up test) and five for endurance dielectric strength at 44 kv. at 25 deg. cent. The curve connecting the resulting points takes the characteristic form of that for fibrous materials. The normal rating of the cable and standardized test voltage on long lengths of such cable are indicated. The life of the cable at 44 kv. is many hours, and at rated voltage in operation, it is several years; the initial test, however, covers only the first few minutes. Similar results are shown in Fig. 11 for single-conductor

experimental cable with 30/32 in. treated paper insulation, and Figs. 12 and 13 for three-conductor cable for 33 kv. circuit. These results show also the longer life of cables on endurance run at 50 deg. cent. as compared with life at 25 deg. cent. which results are consistently

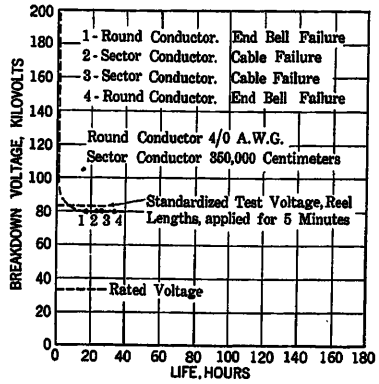

FIG. 12—BREAKDOWN VOLTAGE-TIME CURVE AT 25 DEG. CENT. FOR THREE-CONDUCTOR CABLE SAMPLES WITH 19/64 IN. TREATED PAPER INSULATION ON EACH CONDUCTOR AND 7/64 IN. OVERALL BELT

noted on treated paper cable with different treating compounds and different kinds of paper. The better performance of round conductor as compared with sector conductor with the same insulation thickness is also shown.

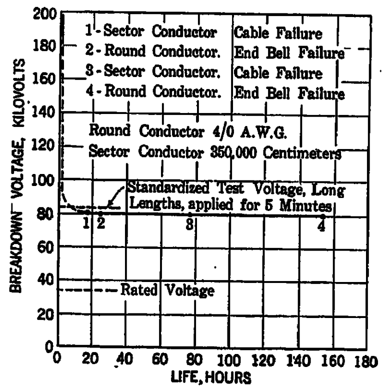

FIG. 13—BREAKDOWN VOLTAGE-TIME CURVE AT 50 DEG. CENT. FOR THREE-CONDUCTOR CABLE SAMPLES WITH 19/64 IN. TREATED PAPER INSULATION ON EACH CONDUCTOR AND 7/64 IN. OVERALL BELT

The two factors involved in the high-voltage suitability test are magnitude of test voltage and duration of application of same. It would be most impracticable to apply the test voltage on all lengths for the time durations shown in Figs. 10 to 13. Fifteen minutes has been suggested rather than the present value of five minutes. The evidence available does not indicate that such an increase would be of any real value. A long time test on a sample length from each lot of cable would, however, be of considerable value. Increasing the magnitude of the test voltage would appear to have merit. The value would have to be finally determined by experience, though an immediate increase in the order of 50 per cent. over present standardized practise for single-conductor cable, and about 20 per cent increase for three-conductor cable does not seem excessive, the lower value for the three-conductor cable being justified because of the inherent differences due to construction.

In this connection there arises again the question of the mechanism of breakdown. If the total number of cables and cable samples examined after breakdown

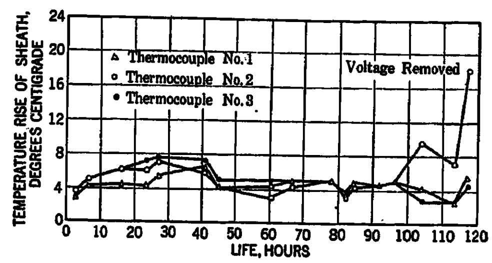

FIG. 14—TEMPERATURE RISE OF SHEATH, SINGLE-CONDUCTOR CABLE SAMPLE WITH 9/32-IN. TREATED PAPER INSULATION, 44 KV. APPLIED

on dielectric strength test to determine the reason for such, was known, the number would be appalling, yet the answer is still wanting. An examination of many cable samples examined after breakdown allows of a classification of such into two general classes; (1) those where the puncture is radial and clean, and (2) those where the puncture is accompanied by deterioration irregularly throughout the matail.

In the latter case many so called "partial failures"

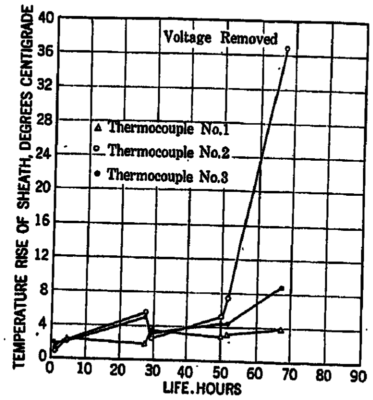

FIG. 15—TEMPERATURE RISE OF SHEATH, SINGLE-CONDUCTOR CABLE SAMPLE WITH 9/32-IN. TREATED PAPER INSULATION, 44 KV. APPLIED

or failures through only a portion of the layers of the insulation are frequently found. Invariably in single-conductor cable these extend out from the conductor part way to the sheath, while in three-conductor cable the failure seems to form in the center of the insulation between conductors and extends towards the conductors.

Efforts to determine the "germ" of a breakdown have been made by subjecting samples of single-conductor cable insulated with treated paper of 9/32 in. thickness to a voltage of 44 kv., exploring the sheath for hot spots

and removing the voltage when a hot spot is found before breakdown occurs. Figs. 14 and 15 show the temperature rise on the sheath of two such samples. When examined, the sample of Fig. 14 showed failure to have started under the hot spot. The first five layers of tape from the lead sheath in were normal. A black spot, which developed as other layers of tape were removed, was found on the sixth tape. Toward the center many small burned spots appeared and a few so-called "tree designs" were found. The sample of Fig. 15 also showed failure to have started under the hot spot. The first twenty layers of tape from the lead sheath in were normal. Extensive tree designs appeared in three regions around the hot spot, together with a dark spot on the twenty-first tape. The designs in the center region continued in for 12 layers and then disappeared. The designs in the other two regions

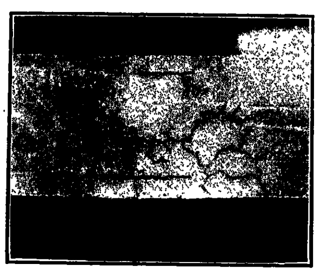

Fig. 16—Design Appearing on the Surface of the Tapes of Treated Paper-Insulated Cable Resulting from the Application of Electrical Tension

joined together 24 layers in and then faded into a burn through the remaining nine layers, the dark spot noted above continuing through to the burn. The nine inner layers had been creased and torn, and the burn extended down through the tears, but no burn was noted in the layer next to the conductor.

The tree designs noted are as shown in Fig. 16, and are as recently reported before this Institute[5] and by others[6]. These designs were traced on the surface of the tapes, the pattern coinciding for adjacent tapes but differing on both sides of the same tape. The design could be scraped off with a knife; it did not appear to follow the fibres. Such designs have been noted previously in laminated treated-paper tubes subjected to high electrical stress, their presence being found in definite fissures between the laminations.

The appearance of many more tree designs in the sample of Fig. 15, which judging by the temperature rise and the radial burned spot had approached nearer to breakdown indicate, possibly, the formation of the tree designs after the beginning of the tendency to radial breakdown. The samples represented by Figs. 14 and 15 were not tightly wrapped, there thus being less lateral dielectric strength. Similar tests, with tightly wrapped paper, have not shown tree-designs though partial radial failures were present. From the shape of the designs and the length of time required for complete failure under these conditions, it would appear that these are formed either locally in a small air space as a result of electrical discharge caused by overstress, or more extensively throughout the laminations because of low lateral dielectric strength. Their presence recalls the need for consideration of both radial and lateral dielectric strength in laminated structures. It is felt that a continued study of these phenomena is merited.

From the results shown in Figs. 10 to 15, it is seen that the initial high-voltage test is quite unable to detect faults which may later come into existence from conditions, some of which become known but many of which remain unknown. This points to the need of testing during operation. The phenomena here shown are, of course, at higher values of electrical stress than under rated conditions, yet these apply, in so far as unexplained failures occur at the rated electrical stress and the time factor is present. In this very connection there has just come to the writer's attention[7] a case in practise where a 17-kv. cable joint was poorly made, the evidence showing that an air space of 3/8 in. was left therein, which was not detected during the high-voltage test at 48 kv. The joint failed later, during operation, from lightning.

Dielectric Power Loss and Power Factor

The measurement of dielectric power loss and power factor of cables for service has in the past been mainly confined to measurements on short samples at voltages up to rated and temperatures up to 100 deg. cent. and on sample reel lengths at rated voltage and temperature of 85 deg. cent[8]. The tendency is to extend these measurements to include each reel length to be shipped, measuring the power factor thereof at room temperature at voltages varying from approximately 1/2 rated to 2 1/2 times rated. The change in power factor between these voltage limits is noted, the theory being that there should be no change in power factor if the insulation is homogenous, the measurement being made outside of the breakdown voltage range.

Such a measurement requires considerable change in application of the methods previously employed for measuring dielectric power loss and power factor. The means employed and the calculations involved must be simple enough for manipulation by the factory testing personnel under factory working conditions. The

range required for cables in use at present is approximately as follows:

Power factor, from 0.002 up, particularly in the range 0.002 to 0.04.
Voltage, 5 kv. to 100 kv.
Current, up to 1 ampere, current leading.
Accuracy, power factor to within 0.002.
Frequency, 25 to 60 cycles.

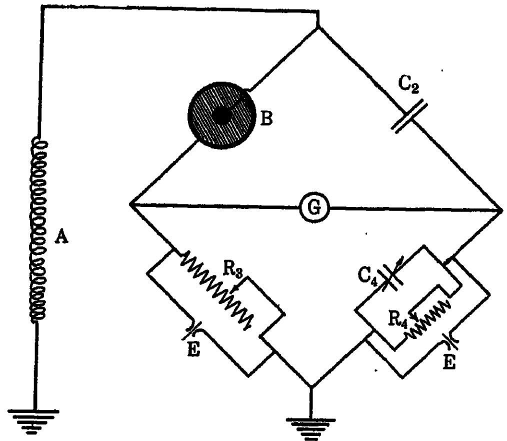

FIG. 17—DIAGRAM OF CONNECTIONS OF SCHERING BRIDGE.

A—Transformer
B—Cable
C_2 Air Condenser
R_3 Non-Reactive Variable Resistor
R_4 Non-Reactive Variable Resistor
C_4 Variable Air Condenser
G—Galvanometer Detector
E—Safety Gaps

Several methods are applicable to this measurement no one of which is entirely free from objections. One method which gives promise is that of the Schering Bridge, which has been described in various issues of the technical press[9]. The diagram of the connections is shown in Fig. 17. A description of the equipment used in such a set-up, which is proving to be satisfactory, is as follows:

The standard air condenser C_2 is a 3-plate condenser following a design previously described.[10] All of the plates are mounted on a common base and are fixed to give a capacitance of 4×10^{-10} farads. The overall dimensions are 10.5 ft. long, 4 ft. wide, and 7.5 ft. high. The non-reactive resistor R_3 is of high-resistance low-temperature coefficient alloy, wound in two sections connected for minimum reactance. The rated current is 1 ampere, and taps are provided to give approximate resistances of 5, 10, 20, 40 and 60 ohms.

The detector G is unique in that a permanent magnet galvanometer recently developed for detecting alternating currents of low value is used. This is shown in Fig. 18. An ordinary three-stage audio-frequency amplifier is used with the galvanometer, thus giving the desired sensitivity. The galvanometer moving system, entirely immersed in oil, is free from the effects of external vibration so that the required sensitivity is obtained without need for elaborate means of protecting against the effect of external vibration.

The non-reactive variable resistor R_4 is of standard design with a maximum resistance of 11,110 ohms. The variable condenser C_4 is of standard design parts, having a maximum capacitance of 0.16×10^{-6} farads.

The safety gaps consist of two contacts separated by two cigarette papers, which form of gap has in the past proven effective. Any discharge through the cable or the condenser goes to ground through the break produced in the paper. The standard air condenser in the above set-up has been short-circuited during operation at 50 kv. with no effect on the apparatus or the operator. The entire measuring apparatus, with the exception of the air condenser and detector, is mounted in a glass-covered case with manipulating handles for safety to the operator, extending through.

The operation of the bridge for a given reading is quite simple. The bridge is balanced by varying R_4 and C_4 until a balance is obtained as noted by the detector. R_3 remains constant for a given range of readings, and the power factor is calculated from the equation,

$$\text{Power factor} = 2\,\pi\, f\, C_4\, R_4$$

where F is the frequency

C_4 is the capacitance in farads of the variable condenser C_4

R_4 is the resistance in ohms of the variable resistor R_4.

If it is desired to obtain the dielectric power loss, the equation is,

$$\text{Watts} = 2\,\pi\, f\,\frac{R_4}{R_3}\,C_2\,E^2\,(\text{power factor})$$

where, in addition to the factors defined above, R_3 is the resistance in ohms of the resistor R_3, C_2 is the capacitance of the standard air condenser C_2, and E is the applied voltage in volts.

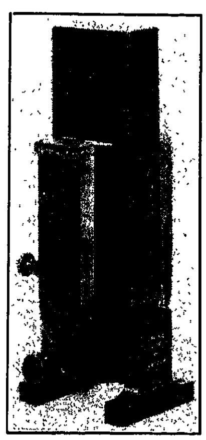

FIG. 18—PERMANENT MAGNET TYPE OF GALVANOMETER FOR DETECTING ALTERNATING CURRENTS OF LOW VALUE

All methods for making such measurements as the above usually appear well on paper but in operation, factors may be introduced which considerably affect results. The results obtained with the Schering Bridge were, therefore, compared with results obtained on the same cable, by the compensated dynamometer wattmeter method,[10] using two instruments, one of low current rating for determining the necessary compensation with the standard air condenser, the other of higher

current rating required when making the measurement on the cable. From results thus obtained, it was found that large errors might be introduced into the bridge reading because of capacitance to ground of the leads from the low voltage side of the standard air condenser and the cable. When effect of this error was reduced to a minimum, results such as shown in Fig. 19 were obtained. These show agreement to within power factor 0.002.

The use of indicating wattmeters alone for such measurements as those described above is highly

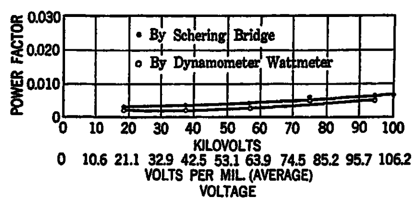

FIG. 19—VARIATION OF POWER FACTOR WITH VOLTAGE AT 25 DEG. CENT. OF A 130-FT. LENGTH OF SINGLE-CONDUCTOR CABLE WITH 30/32-IN. TREATED PAPER INSULATION FOR A 66-KV. THREE-PHASE CIRCUIT

desirable. The very unique application of a water column of varying temperature to change the resistance of a circuit without changing its reactance, recently described before the Institute[11], has great possibilities. An outfit set up with the "tank," of the wattmeter replaced by a long hose, shielded as suggested by Professor Ryan, to allow of continuous measurement has given promise of perhaps immediate application in measuring small amounts of power.

The method of applying the voltage during power-factor measurements on reel lengths of three-conductor cable, is important. A choice exists between the use of three-phase supply and single-phase supply. The former allows the test to be made under operating conditions and only one connection need be made during the test, although the measuring instrument will have to be shifted from phase to phase if only one instrument is used. The use of a dynamometer with a standard air condenser is possible, although shielding the high-voltage windings in the transformer appears to be necessary. The current element of the dynamometer must during measurement be connected between the transformer winding and the grounded neutral. Error due to leakage to ground may thus be introduced since the circuit must be changed from that during compensation with the air condenser.

The use of single-phase supply allows the use of both bridge methods and dynamometer methods. Connections to the cable may be made in several ways, of which representative connections are shown in Fig. 20. Connection A gives a measurement of belt insulation and conductor insulation next to the belt insulation. Connection B gives a measurement of conductor insulation between one conductor and the other two conductors. Two such measurements with two different conductors "high" should suffice. Connection C gives the measurement of conductor insulation between one conductor and the other two conductors and of the conductor and belt insulation between that conductor and the sheath.

Connections A and B are symmetrical as regards calculating the average voltage gradient of the insulation wall under test. In connection C the average gradient over the conductor insulation and adjacent belt insulation will differ from that over the conductor insulation between conductors if the thicknesses of conductor insulation and belt insulation are different. Because of the possible differing stress in the belt insulation and conductor insulation, connection C is not satisfactory for high values of average gradient. Measurements using connection A and connection B with each conductor "high" in succession, certainly explore the cable completely and are, therefore, advisable. Successive measurement with two conductors high in connection B may suffice, as such would include all of the conductor insulation between conductors. Experience thus far indicates that where cable is poor, it is poor symmetrically, so that all of the power-factor-voltage curves show large change. A single measurement may, therefore, prove sufficient.

The objections to the single-phase measurement are that several connections are required during test; and that the rotating field present with 3-phase supply is not present with the single-phase source.

The equivalent value of 3-phase watts and power factor may be calculated from single-phase measure-

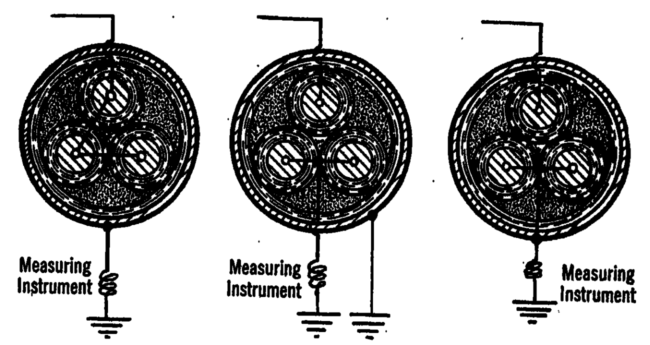

FIG. 20—CONNECTIONS OF SINGLE-PHASE SOURCE TO THREE-CONDUCTOR CABLE FOR POWER FACTOR AND DIELECTRIC POWER LOSS MEASUREMENTS

ments made successively with connections B and A, as follows:

Let W_B = watts measured, connection B, at voltage E

W_A = watts measured, connection A, at voltage $\frac{E}{\sqrt{3}}$

Then, total three-phase watts $= 1.5\ W_B + W_A$.

The three-phase power factor may be taken as the average of the power factor obtained with connection B at

voltage E, and the power factor obtained with connection A at voltage $E/\sqrt{3}$.

The above relations have been proved to check the dielectric power loss and power factor obtained with three-phase supply up to rated cable voltage. For values of voltage above rated, the results appear to be consistent, but check measurements will have to be made before they can be assumed to be reliable with certainty.

For purposes of applying the power-factor-voltage

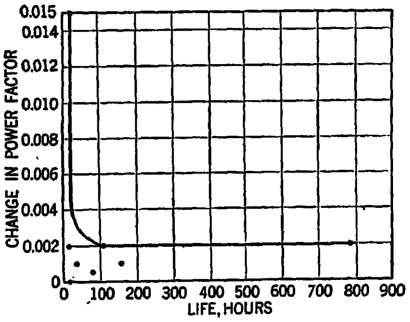

FIG. 21—RELATION BETWEEN LIFE OF SAMPLES OF TREATED PAPER CABLE WITH 9/32-IN. INSULATION, OPERATED AT 44-KV. AT 25 DEG. CENT., AND CHANGE IN INITIAL POWER FACTOR WITH VOLTAGE FROM 27 VOLTS PER MIL. (AVERAGE) TO EIGHTY-SEVEN VOLTS PER MIL. (AVERAGE) AT 25 DEG. CENT.

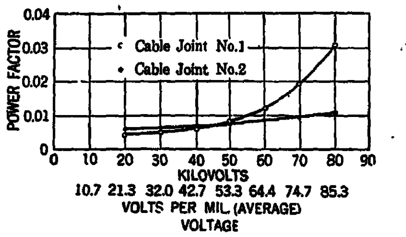

FIG. 22—POWER FACTOR-VOLTAGE RELATION AT 25 DEG. CENT. OF TWO JOINTS OF SINGLE CONDUCTOR CABLE WITH 30/32 IN. TREATED PAPER INSULATION

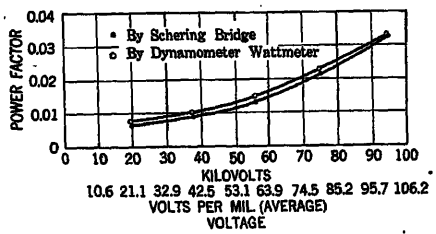

FIG. 23—POWER FACTOR-VOLTAGE RELATION AT 25 DEG. CENT. OF A 100-FT. LENGTH OF SINGLE-CONDUCTOR CABLE WITH 30/32 IN. TREATED PAPER INSULATION SHOWN BY DIELECTRIC STRENGTH TEST TO BE POOR CABLE AND UNSUITED FOR USE

test, it is, therefore, suggested that connections B and A be standardized, and that separate curves be obtained therewith, these to be on the same basis of average volts per mil.

The application of voltages during the power-factor measurement comparable in value to those of the high-voltage test will necessitate the use of larger end-bells. This will prevent the effective application of the usual guard circuits; also a relatively large dielectric power loss may be located in the larger end-bell. Some measurements which have been made in this regard indicate that as long as there is no visible leakage, the difference in result obtained with or without guard rings is negligible. When corona and current streamers are visible, differences of 50 per cent have been obtained. The unsheathed portion of the cable must, therefore, be of sufficient length to prevent this source of error.

The effectiveness of the power-factor-voltage test to separate poor cable from good will have to be determined largely from experience. Fig. 21 shows the relation between life and change in initial power factor for several short samples of cable with 9/32-in. treated-

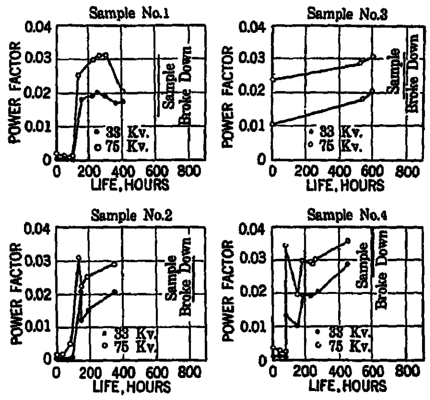

FIG. 24—CHANGE IN POWER FACTOR DURING LIFE OF SINGLE-CONDUCTOR EXPERIMENTAL CABLE SAMPLES WITH 30/32 IN. TREATED PAPER INSULATION OPERATING AT 80-KV. AT 50 DEG. CENT.—MEASUREMENTS OF POWER FACTOR MADE AT 33-KV. AND 75 KV.

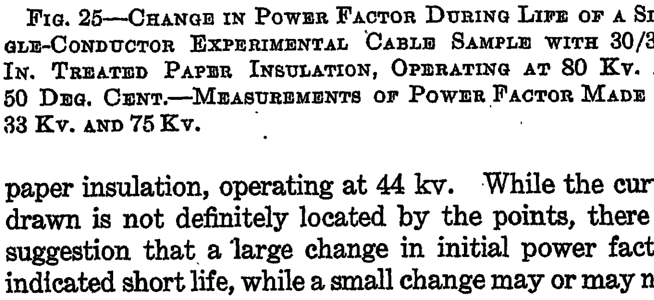

FIG. 25—CHANGE IN POWER FACTOR DURING LIFE OF A SINGLE-CONDUCTOR EXPERIMENTAL CABLE SAMPLE WITH 30/32-IN. TREATED PAPER INSULATION, OPERATING AT 80 KV. AT 50 DEG. CENT.—MEASUREMENTS OF POWER FACTOR MADE AT 33 KV. AND 75 KV.

paper insulation, operating at 44 kv. While the curve drawn is not definitely located by the points, there is suggestion that a large change in initial power factor indicated short life, while a small change may or may not indicate long life.

Fig. 22 shows the power-factor-voltage relation for two cable joints of single-conductor cable with 30/32 in. paper. Cable joint No. 1 was hand-made and lasted two min. at 175 kv.; cable joint No. 2 was machine-

made and lasted 36 hours at 225 kv. Fig. 23 shows the power-factor-voltage relation for a length of cable with 30/32 in. paper shown by dielectric strength test to be poor cable.

A 200-ft. length of cable* similar to that for which the power-factor-voltage curve is shown in Fig. 19, was connected from one line, to neutral of a three-phase 110-kv., 60-cycle commercial circuit, at a voltage from conductor to sheath of 63.5 kv. It operated continuously at no-load for 10 days when failure occurred at a point 30 feet from one end. Examination revealed absolutely no discernible reason for the failure, the cable appearing to be perfect throughout. The defective end was cut from the length, voltage again applied, and same has been running continuously for 90 days. (January 1, 1925.)

It has been noted that the power factor of a cable changes during its life. Fig. 24 shows the results of measurements of power factor made at different times during the life of four samples of single-conductor experimental cable with 30/32 in. treated-paper insulation, when operating at 80 kv. (85 volts per mil, average) at 50 deg. cent. In sample No. 3 the paper was treated with a petrolatum-rosin mixture, while the others were treated with straight petrolatum.

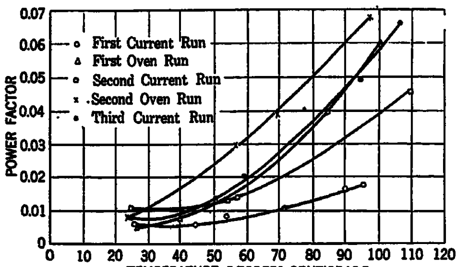

FIG. 26—POWER-FACTOR-TEMPERATURE CURVES OF SINGLE-CONDUCTOR CABLE WITH 30/32-IN. TREATED PAPER INSULATION, THE CABLE BEING HEATED BY OVEN AND CIRCULATING CURRENT

Fig. 25 shows results on a sample which has operated for over 3500 hours at 80 kv. at 50 deg. cent. In this connection it is interesting to note that a measurement of power factor made at a life of 250 hours gave a value of 0.17 at 75 kv. and 0.14 at 33 kv. No error could be found in the measurement at the time, nor have subsequent tests on other cables shown such large change as this. These values have, therefore, been omitted from the curve which has been made dotted in this region. The comparatively large change in power factor of the sample in Fig. 25 is interesting in the light of the long life of the sample.

Such results, showing change in power factor with life, are not new as they have been noted on tests with different papers under electrical tension. Similar results have also been noted in the case of armature coils as well as having been reported to this Institute[12].

Apparently the change in power factor within the limits shown has little effect upon the dielectric strength of the cable. It is evident, however, that continued electrical tension affected the cable.

When making measurements of either dielectric power loss or power factor at temperatures above room temperature, it is quite necessary that the cable or cable sample be heated uniformly throughout. If this is not done results such as shown in Fig. 26 will be obtained where the power factor of a sample of single-conductor cable with 30/32-in. treated-paper insulation was measured in order

1st, by circulating current through the conductor and measuring conductor temperature, using this value as the temperature.
2nd, by placing the sample in an oven for four hours and measuring both sheath and conductor temperature, which check.
3rd, by repeating the 1st run.
4th, by repeating the 2nd run.
5th, by repeating the 1st run.

The results show that not only is the power factor higher when the temperature throughout the cable is uniform, but they also show increasing values with continued heating. This suggests that temperature measurements on cables intended for use should not be carried to values above the operating values.

TESTING INSTALLED CABLE

The evidence available on the endurance of cable indicates the need of continued testing after the initial tests and installation of the cable. A good example of results obtained by methods departing from those standardized for testing cables has been reported to the Institute[13] by Messrs. Phelps and Tanzer in connection with tests conducted to rate cables after installation. The application of the method of rating by so-called "current-time" curves to low-loss paper-insulated cables has been carried on to a limited extent, with results which, although usually negative, still are of such a nature that the method is not considered to be absolutely inapplicable. This study should be vigorously continued.

Opportunity has been given to test single-conductor cable with 30/32 in. treated paper insulation, known to be poor cable, up to direct voltages of 450 kv. applied for 15 minutes, without evidence of impending failure as shown by current-time curves taken periodically during the test.

Suggestion has been made that high frequency might be utilized for making capacitance or power-factor measurements on installed cable, the bridge and generator equipment required being of such a nature as to make it quite easily portable. Table I shows results of capacitance and power-factor measurements made at 100 kilocycles on short samples of single-conductor cable with 9/32 in. treated paper insulation before and after endurance life run at 44 kv. The length of life does not seem to be predicted by the value of the initial power factor.

*Manufactured after Jan. 1, 1924.

TABLE I

Sample	Endurance Test at 44 Kv.		Power Factor at 100 Kilocycles	
	Temperature Deg. Cent.	Life Hours	Before Test	After Test
1	25	77	0.0105	0.0103
2	25	86	0.0103	
3	25	89	0.0106	0.0102
4	85	139	0.0114	
5	85	139	0.0106	
6	85	1055	0.0105	0.0143*
6	85	1055	0.0105	0.0093
7	85	1535	0.0116	0.0102

*Measurement made with failure in sample.
Measurements on other samples made "After Test" were made after cutting out the failure.

Values of power factor taken after test with the failure removed show practically no change from initial values.

Several measurements of power factor made at 1000 cycles on cable samples with 30/32 in. treated-paper insulation gave results from which no concord could be noted as regards life. The low voltage, about 25 volts, at which these measurements are made is probably a factor. It is interesting to note, however, that measurements made at 100 kilocycles on cable samples of different kinds of papers showed power factors differing by 50 per cent, though for samples of any given kind of paper, the variations were of the order as shown in Table I. The method appears, therefore, to be of value in detecting different materials, but does not seem to be sensitive to deterioration in a portion of a given material.

Testing with Direct Current

Experimental work is being continued in the application of direct current to the testing of cables in order

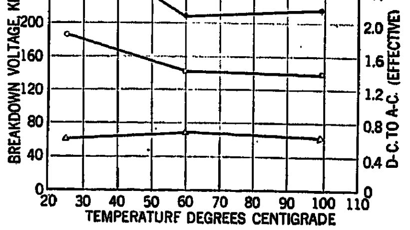

Fig. 27—Relation Between D-C. and A-C. (Effective) Breakdown Voltage Above Ground at Different Temperatures of Three-Conductor 500,000-cm. Sector Cable. with Treated Paper Insulation 9/64 In. on Each Conductor. 1/16-In. Overall Belt

that its apparent advantages may be utilized in this field. The large number of d-c. cable-testing sets now in use by the operating companies should allow of accumulation of a considerable amount of data showing the desirability of their use in the field.

Fig. 27 shows results of tests made on samples of three-conductor 500,000 cm. sector cable with treated-paper insulation 9/64 in. on each conductor, 1/16-in. overall*. The a-c.-breakdown tests were made by starting at 40 kv. applied and held for five min. and then raising five kilovolt each 15 seconds until breakdown. The d-c.-breakdown tests were made by starting at 100 kv. held for five min. and raising five kilovolt each 15 sec. until breakdown. Three tests were made on each section of the cable by applying the test voltage to one conductor with the other two and the lead sheath grounded. In this way each conductor was tested separately from copper to sheath.

These results show a ratio of d-c.- to a-c.- effective breakdown value somewhat higher than previously assigned from the results available at the time, but the evidence is accummulating that the ratio will increase as the thickness of the material increases. Recent tests on varnished cloth in sheet form up to a thickness of 10 sheets or 120 mils substantiate this conclusion.

Continued experimental work and study of the problem indicates that although for any given breakdown voltage with alternating current there is a corresponding breakdown voltage with direct current, each of these values depend upon several factors such as the nature and structure of the material, thickness of the material, temperature of the material, shape and size of electrodes, and rate of application of the applied potential. Such a condition obviously prevents standardization of a general value for the d-c.- to a-c.- breakdown-voltage ratio, but rather requires that each individual case be considered separately. This confirms what has been pointed out previously.[14]

Conclusions

1. Values of insulation resistance as heretofore obtained are of doubtful worth as a means for distintinguishing between satisfactory and unsatisfactory cable.

2. The test for dielectric strength is the most important and the best now available as a suitability test. The difficulties in testing due to the increasing voltage rating of cables are being overcome. Indications are that the present standardized values of test voltage should be increased. Increasing the time of application a few minutes is of doubtful value; a long-time on a sample length has merit. Short-time ultimate dielectric-strength tests should be made on samples taken from reel lengths. The bending tests, as at present, should be continued. Recognition should be given to the fact that many things may happen to the cable after the high-voltage test which this test cannot detect. Hence the advisability of periodic testing at voltages which will not injure sound cable and which will only affect cables where the deterioration has been abnormal.

3. Measurements of dielectric-power loss and power factor are of value, and should be continued. The evidence indicates that good cable will show low dielectric-power loss and power factor, and that the change in

*These samples were supplied by the Commonwealth Edison Co.

power factor of good cable with varying voltage at room temperature will be small. The power-factor voltage test may not always be infallible, however. There is need for standardizing the power-factor voltage test, as regards the nature of the source, the method of connecting same to the cable, the temperature of the cable, and the reporting of the results.

4. Development work towards new methods for testing and rating installed cable during life have not produced new tests which are suitable for superseding those already in use.

5. The increasing use on the part of the operating companies of d-c.-cable-testing sets, together with the experimental work being carried on, should allow of a determination of the most suitable application of direct-current to cable testing that its apparent advantages may be fully utilized.

In closing, the author wishes to acknowledge his indebtedness to others in the General Electric Company who have allowed him to use results of their work in this paper.

Discussion

D. W. Roper: The paper by Mr. Lee (the best discussion of the subject of testing high-voltage cable that has ever been presented to the Institute) contains a great amount of interesting information all drawn from the experience of one cable manufacturer. Some of the conclusions which he draws are, therefore, rather limited in their application as they refer solely to the particular type of insulation with which he is familiar. As will appear later in this discussion, there is a wide variation in the characteristics or properties of the insulation made by the different manufacturers. For the purpose of broadening our view and thus improving our perspective, and not for the purpose of making any invidious comparisons between the products of the several manufacturers, I am going to quote some of the results that we have obtained in testing the product of a number of cable manufacturers, in the hope that I may be able to show how some of the conclusions given by Mr. Lee should be modified.

On page 114, Mr. Lee cites the case of the failure of an experimental length of cable connected to a 110-kv. three-phase overhead line, and states that the examination revealed absolutely no discernible cause for the failure.

About one-third of our failures in service result in a similar manner.

In another paragraph on the same page, the author states that the study of the current-time curves obtained with insulation-resistance measurements should be vigorously continued. On this point I thoroughly agree with him and offer him our continued assistance and bespeak for him the cooperation of other operating engineers who are in a position to assist. The development of additional methods of testing cable should result in the

discovery of causes of failure for which no explanation can now be given.

In Fig. 1 of the paper is given some data regarding the variation in insulation resistance of fourteen reels of cable, the maximum range being of the order of 10 to 1. A study of our records shows that in three shipments of similar cable ranging from thirty to sixty lengths, the maximum range in insulation resistance was 1.6 to 1 as compared with Mr. Lee's figure of 10 to 1 for fourteen reels. The author thinks that such measurements are of little value as a means of distinguishing between good and poor cable. In view of the data regarding other makes of cable which have been quoted, it appears that the results given by the author indicate that in his factory they have not secured control of all of the factors which affect the quality of their insulation. It also appears that studies made for the purpose of eliminating the present variations in insulation resistance will result in methods that will bring about an improvement in the product, and that there is an even greater chance of such a result than that the studies of current-time curves of insulation resistance will result in the discovery of improved methods of testing.

No methods of testing high-voltage cable will be satisfactory until it is possible to detect and reject at the factory all cable which contains the germ of a failure which will occur shortly after the cable is placed in service, such as the example cited by the author. This requirement, while it may appear somewhat idealistic, becomes more important as the operating voltage of the cable is increased. On a 12-kv. line we may be able to carry a maximum load of 8000 kv-a.; on a 33-kv. line, this figure will be about 15,000 or 20,000 kv-a.; on a 66-kv. single-conductor line, the load may be 40,000 or 50,000 kv-a.; and on a 110,000-kv. single-conductor line, the maximum load may be 70,000 kv-a. These figures, which are illustrative, and not intended to be strictly accurate, show that the importance of continuous service inceases rapidly with the operating voltage.

The record of a number of recent installations of high-voltage cable made in this country and abroad, as shown in Fig. 1 herewith indicates the general trend of thickness of insulation as related to the operating voltage. This record indicates that the operating voltage is increasing at a faster rate than the thickness of insulation. This means that as the operating voltage increases the dielectric stresses increase, and if the cable is to be as successful in operation as cable of the lower voltages, there must be a continuous improvement in the quality with the increase in the operating voltage. It is, therefore, quite necessary, as stated by the author at the beginning of his paper, that improvements in cable manufacture should be paralleled by improved methods or additional methods of testing, so that we may be able to distinguish good cable from cable that will prove unsatisfactory in service.

The rainbow that the engineers of some manufacturers, as well as engineers of operating companies, including the speaker, have been chasing for a number of years is the search for some single test that will discriminate between good and poor cable. But impregnated-paper insulation is such a complex structure and as made at different factories has such wide variations in its several properties, that the discovery of any single test that will prove adequate seems to be just as hopeless as the discovery of perpetual motion. Impregnated-paper insulation has a number of different qualities, as set forth by the author, such as insulation resistance, dielectric strength, dielectric loss, etc., and these qualities are so interrelated that it is difficult, or perhaps impossible, to improve the insulation in one particular, without having some effect on the other qualities, and these several qualities individually have very different values in determining whether the cable will prove successful in service.

In Fig. 2 herewith are shown the maximum and minimum dielectric strength values obtained in accordance with A. I. E. E. Standards on short lengths of cable for all of the sizes purchased by the company with which the speaker is connected, during the last two years. All of these cables have met the requirements of the N. E. L. A. Specifications and the A. I. E. E. Standards. It will be noted that the range in dielectric strength varies from 5 to 1 for low voltage cables to about 1.5 to 1 for 20-kv. single-conductor cable, and 2.4 to 1 for 33-kv. cable. It appears fairly evident from these data that the several cable manufacturers place very different weights on the importance of dielectric strength.

In Fig. 3 are shown a number of curves showing the variation of dielectric loss with temperature which are typical of the product of practically all the leading cable manufacturers in the world, each one of whom thinks that in this particular feature his cable is entirely satisfactory. With such wide variation in the forms of the curves and in the values of the losses at the maximum operating temperatures, it does not appear that all of them can be right.

Fig. 4 shows in a similar manner typical ionization curves; that is, the variation of power factor with voltage. One manufacturer contends that there should be no variation in the power factor between 50 per cent and 150 per cent of normal voltage, while another manufacturer contends with equal force that a

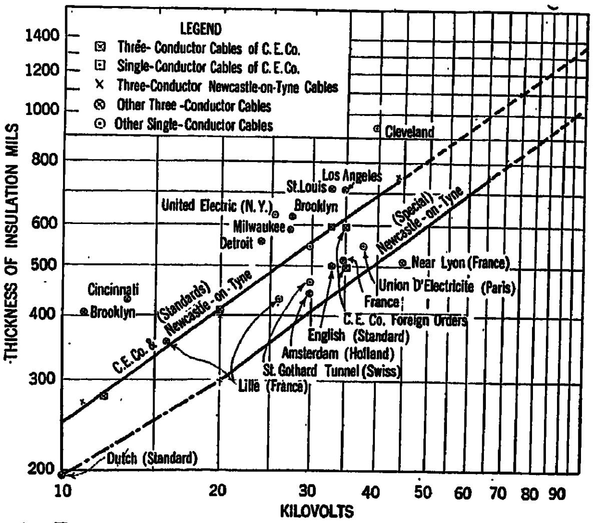

FIG. 1—RELATION BETWEEN THICKNESS OF INSULATION AND OPERATING VOLTAGE

variation of 2 per cent over about the same range of voltage is permissible. No one manufacturer makes cable which is the best in all of those qualities described by the author which collectively indicate its excellence, and, in the face of such conflicting statements presented by the various cable manufacturers that are equally skillful and reputable, what is the purchaser to do?

During recent years, improvements in cable manufacture have been so rapid that it is not possible for an operating company to buy cable of several different combinations of the qualities illustrated, and then wait for five or ten years to determine from operating experience which of the several varieties is the best before purchasing any more cable. Commercial developments and increases in load compel the operating companies to buy cable every year, and even if they should wait for five or ten years before buying more cable, they would then be told by the manufacturers that such cable was no longer made, due to their improvements in manufacture and cable of a different combination of qualities would be offered.

Table I shows the writer's suggestion for a solution of this problem. In it are listed all of the test requirements given by the author. There are also given in the third column under the heading *Weight for Best Performance* the writer's judgment as to the relative weight which should be assigned to each of those qualities or properties. As set forth in the table, all of these

cables comply with the N. E. L. A. Specifications and the A. I. E. E. Standards, but it will be noted that they pass the specifications with widely different margins in the various particulars. The cable which gives the best results in the ionization test is not the best in dielectric loss nor dielectric strength. As these

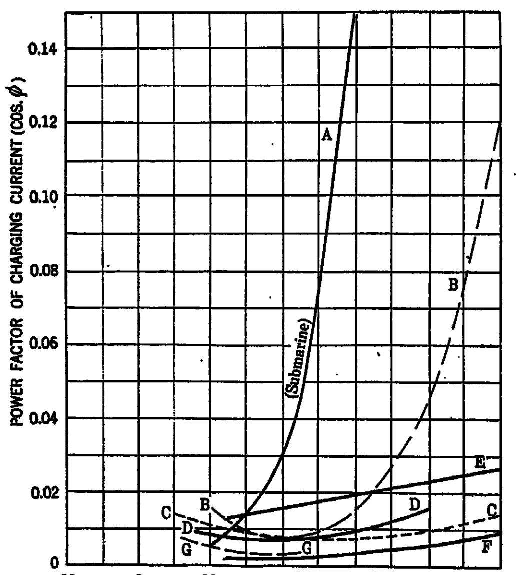

FIG. 3—VARIATION OF POWER FACTOR WITH TEMPERATURE FOR HIGH VOLTAGE CABLES

Curves *B*, *C* and *D* are guarantees. Curves *A*, *E*, *F* and *G* are of test results. All curves are for 60 cycles except *A* and *C*, which are for 50 cycles.

figures in the column called *Weight for Best Performance* are the personal opinions of the writer, it is entirely possible that they are all wrong or that a different method of calculating the relative performance of the several manufacturers from the test records should be used. A number of similar tables have been calculated, using radically different figures in the column of *Weights for Best Performance.* These calculations show that changing the figures in this column to any other figures which appear to be within reason makes but slight changes in the relative order of the manufacturers.

Such calculations indicate that the general method is correct; but some adjustment of the details may be necessary to secure greater accuracy. It is not pretended that the figures at the foot of the table correctly represent the relative merit of the cables on a percentage basis, but it appears that the table does determine, with reasonable accuracy, their relative order of merit.

It should be possible by a study of the test records and the operating records to determine with a fair degree of approximation the proper figures to be used for the weights for best performance, and after this has been done, the rating of the cables consists mainly of simple arithmetical calculations from the test records. After such a tentative assignment of weights has been agreed upon by the manufacturers and the operating companies,

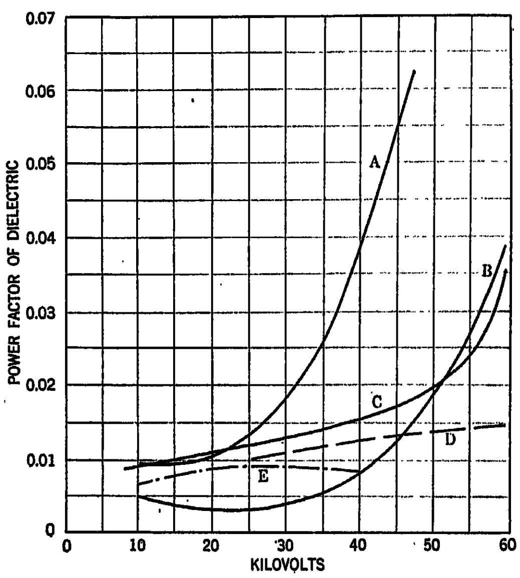

FIG. 4—IONIZATION TESTS ON THREE CONDUCTOR HIGH-TENSION CABLES

All 33-kv. cables except *D*, a 10-kv. cable

then the manufacturers have a definite statement of the desired combinations of qualities to guide them in the improvement of their product.

The operating companies, on their part, should carefully analyze all of their cable failures, with the assistance of the manufacturers, and agree upon the particular quality or property of the cable whose deficiency was responsible for each failure, and from the mass of operating records of this kind which are available for study, modify not only the weights for best performance from time to time in accordance with operating experience, but also the minimum requirements of the specifications.

There is no country in the world in which the engineers of the manufacturing companies and those of the operating companies are so well organized as they are in America, through their technical associations, like the A. I. E. E., and the commercial associations like the N. E. L. A. and the A. E. I. C. to bring about such cooperation in a proper way. If this cooperation can be secured, there appears to be no good reason why the American cable manufacturers in a few years should not be leading the world in the manufacture of high voltage cable, instead of occupying their present subordinate position.

W. F. Davidson: Mr. Lee has presented a very helpful sum-

mary of the present status of testing high-tension paper-insulated cables so far as concerns tests to be made in advance of installation, but I feel that it is unfortunate that he does not have more information to present in regard to tests intended to determine the fitness of the cable to meet the requirements of continuous operation.

The tendency to use higher test voltages and slightly longer times of application in tests on reel lengths and samples seems to be a step in the right direction, for it will tend to eliminate weak spots and it is always the weak spots that cause trouble. But there are many things which we cannot learn from short-time tests, or even from tests of several hours duration. Several operating companies using cables at the higher operating voltages have lately found signs of a slow but very noticeable deterioration. In many cases this has been accompanied by the formation of a substance variously known as "*X*", "wax," or "cheese." Efforts to produce this substance in the laboratory have generally been unsuccessful except where the time of test has been prolonged to many hours; short-time tests yield no results. This experience would seem to indicate the desirability of making tests on samples of cable using a voltage only slightly—say, 50 per cent—in excess of the rated voltage and then making a thorough examination, including chemical tests, after two hundred or three hundred hours. There is another point, which may be touched on later, and that is the need for more elaborate tests to detect the presence of injurious impurities.

The data presented to show the significance of insulation-resistance values are certainly almost enough to lead one to discard them entirely from cable specifications. However, they seem to have a value which Mr. Lee has overlooked. The user of cable is vitally interested in securing cable of uniform quality—999 ft. of superlatively good cable cannot keep a line going if 1 ft. is defective,—and it is my feeling that uniform cable will show reasonably uniform insulation resistance. When one stops to consider the very complex nature of cable insulation, it is not surprising that no simple relation has been found between insulation resistance and other characteristics of the insulation. But this does not, to my mind, afford a valid reason for rejecting them. As an example of that point in mind and illustrating what is commercially possible, I have plotted the insulation-resistance readings (see Fig. 5) on successive reel lengths of cable brought up for test in two factories. In one case the ratio of maximum to minimum values is about 1.32, while in the other case it reaches 15.6. These cables have not been in operation long enough to permit a statement to be made as to their operating performance, but it is interesting to note that the first lot of cable gave distinctly superior results on all of the other tests. As I see it, this means that the factory processes in the first case were more carefully controlled than in the second case.

Several curves are presented with the paper to show the relation between the test voltage and the time required to secure failure, but I feel that in their present form they are somewhat misleading. Take Fig. 10 as an example: We find that nearly instantaneous breakdown was secured with five variations of test voltage between 132 kv. and 100 kv. and we also note that 44 kv. produced failures in times varying from 30 hours to 160 hours. A curve has been drawn to pass through all of the points with remarkable precision. One might be led from this curve to assume that the cable would operate indefinitely at 43 kv. The experimental data seem rather too few for determining a curve and one would wish that figures were available to show the life of the cable at, say, 30 kv.

Partial failures, such as are described, have long been known to those who have studied cable insulation and we find frequent reference to them in the technical literature. I think it is going a little too far to suggest that these failures generally occur near the center of the insulation. Undoubtedly they do occur, as Mr. Lee observes, at points where the insulation is unusually weak or where the stresses are high but this point may be quite as well near the conductor as at the center of the insulation. In a number of samples taken from cable of ten different makes, burns have been observed rather more frequently at the point of high stress—that is, at the surface of the conductor. For the obvious reason that the conductor is itself practically an equi-potential surface the tree designs are not found near the surface of the conductors but other forms of partial failure are very common.

Reference is made to the direct-current or kenotron testing method outlined by Messrs. Phelps and Tanzer in a paper pre-

Date: February 5, 1925.

sented before this Institute. Where attempts have been made to apply this method to low-loss cables it has been the common experience that it was difficult to get satisfactory results. Some experience along this line with the Brooklyn Edison Company seems to indicate that the difficulties are very largely the result of the rapid decay of the charging current. Whereas the old cables tested in Philadelphia showed that from two to three minutes is required for the current to reach a fairly steady value,

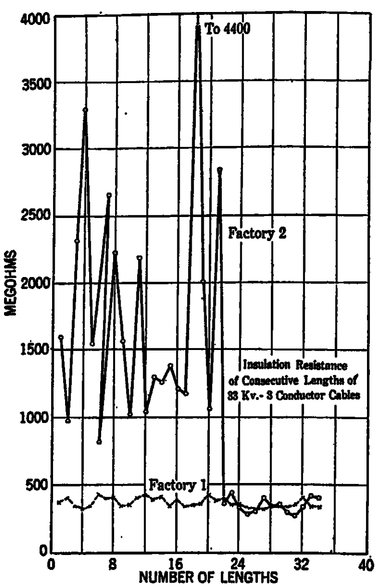

FIG. 5—INSULATION RESISTANCE OF CONSECUTIVE LENGTHS OF 33-KV., THREE-CONDUCTOR CABLES

low-loss cables show steady current values after about ten seconds. This makes it impossible to rely upon readings taken visually but special high-speed curve-drawing instruments have been used with very satisfactory results.

The illustrations shown here indicate the type of results which can be secured, although it must be admitted that the case chosen is somewhat extreme. Fig. 6 herewith shows a reproduction of the graphic millimeter record with the voltmeter record transferred to it as a solid line. It will be noted that *A* and *B* conductors behaved as good conductors should behave, while *C* conductor showed excessive leakage. Just previous to the test, this feeder had been tested at the normal value of 135,000 volts, direct-current conductor-to-conductor for five minutes and 95,000 volts, conductor-to-sheath for five minutes but, as indicated, even this high voltage had failed to remove all of the faults. Conductor *A* and *B* were grounded, and *C* conductor was raised to 98,000 volts and after five minutes failure occurred in a defective joint. When this had been removed the feeder was tested at 135,000 volts and 95,000 volts as before. Then the tests shown in Fig. 7 were obtained. A few such cases as this seem to be ample justification for the use of this method. They also point to the moral that high voltages alone do not give sufficient assurance that a piece of cable on a complete feeder can operate at the rated voltage.

In passing it may be worth while mentioning that the kenotron test method offers real advantages in the nature of sizes of testing equipment and ease of testing. A test set designed for 200,000 volts from conductor to conductor with a 250-milliampere output has been built and mounted on a 6-ton motor trailer. It would be quite impossible to move about a-c. testing equipment capable of handling the same feeders. Moreover, experience in Brooklyn with comparatively high d-c. test voltages has failed to bring forth any evidence indicating damage to the cables as a result of repeated direct-current tests.

J. B. Whitehead: There is general agreement nowadays that insulation resistance based upon the one-minute observation is of questionable value. The reason is that insulation resistance has little bearing upon the loss and upon the performance of a cable, unless the resistance happens to be extremely low. In the latter case, however, one of the puncture tests would be certain to pick it up. The loss due to insulation resistance is a negligible part of the total loss of a normal cable, being of the order of 1 per cent or 2 per cent. The one-minute test is an indication of the dielectric absorption or residual charge of the cable. Taken at one minute this particular quantity has no special interest. If the rate of absorption could be measured for a small fraction of a second we should have important information. The loss in a dielectric is almost entirely due to absorption. It would be very important if we could know the type of variation of the absorption during time intervals corresponding to fractions of the complete period of the alternating voltage. The laws of absorption are not sufficiently definite to enable us to deduce these values from the one minute test.

Will Mr. Lee please tell us whether the curves between the power factor and insulation resistance give the order in which the observations were taken? The curve for insulation resistance ascends continuously and if the points were taken in order it should be easy to trace the causes of the changes appearing. If these one-minute observations give the absorption it is easy to suggest two possible reasons for the differences shown. Absorption is most sensitive to the presence of moisture and also to temperature changes. A further factor often leading to erratic one-minute readings is the influence of the preceding state of the material. Small traces of residual charge will often cause wide variations in the one-minute reading.

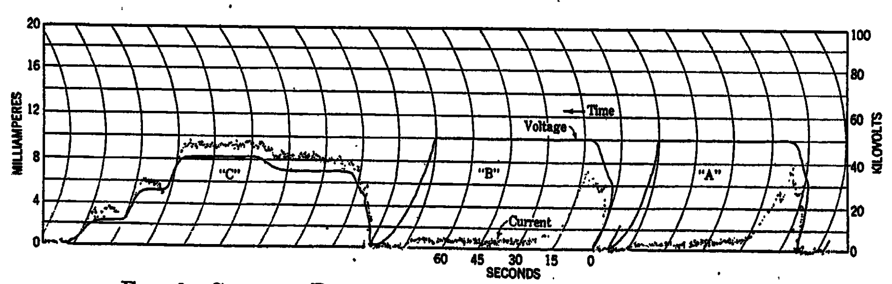

FIG. 6—GRAPHIC RECORD OF KENOTRON ON CABLE SHOWING ONE LEAKY CONDUCTOR

Breakdown of cable insulation may be divided broadly into two types; direct puncture, and slow heating. The latter may begin as due to normal absorption loss, but ultimately it is a heating due to the passing of current. It seems to me that in the case of cables breakdown must fall into the second class. Cable insulation has pronounced absorptive qualities and this accounts for practically all of the initial losses. It is of immediate importance therefore, in determining a proper test for picking out as defective cable, to consider the test from the standpoint of its influence upon the internal losses. Thus, I believe that the high-

voltage puncture test should not stretch beyond a comparatively short interval of time, as its chief function should be the picking out of flagrant imperfections. If a high puncture voltage is applied during a considerable length of time, an abnormal duty is imposed upon the insulation from the standpoint of heating, and increasing absorption due to temperature. The losses vary as the square of the voltage, and as even a higher power of the temperature. Two and one-half times normal voltage causes an *initial* rate of increase of loss of over six times normal. It seems to me, therefore, that the suggestion of the author to increase both the value and duration of the voltage test is open to serious question because of the extreme abnormal duty which may be imposed on the insulation.

I agree with the author that not too much importance is to be attached to the power-factor test. The power factor involves not only the loss but also the capacity of the cable. Both these quantities are variable and you may have a cable that is open to suspicion from the standpoint of loss, but which may not be defective as based upon the power-factor test. Naturally if the power factor is abnormally low it is a good indication of trouble.

I offer the suggestion therefore that the best method for testing cables as they come through the factory is the measurement of the loss, and to as high a degree as possible, the distribution of the loss along the length of the cable. I am quite conscious of the difficulties of such a plan but I believe that everyone will agree that cables ultimately fail due to increasing local losses. Fortunately however the rate of increase of these local losses is initially not very rapid. A measurement of the total loss on a length of cable may completely screen the presence of a dan-

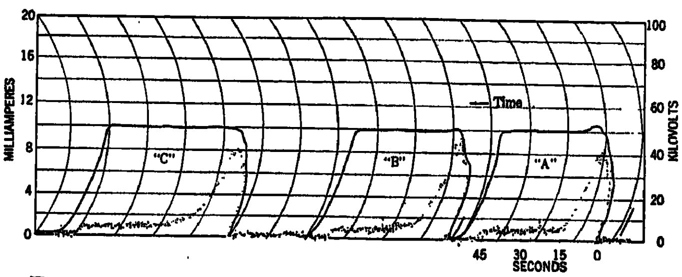

FIG. 7—RECORD OF KENOTRON TEST ON GOOD CABLE

gerous local loss. The ideal test therefore would include not only the total loss test but a measurement of the time rate of change of temperature at intervals over the entire reel length.

R. W. Atkinson: I shall limit my remarks to the method of measuring dielectric loss by the a-c. bridge. My earliest work in cable engineering was in measuring dielectric losses by a bridge method. I have retained an enthusiastic interest in that general type of measurement of dielectric loss because of the very great advantages it has over many other methods.

The bridge Mr. Lee has described undoubtedly accomplishes in a very satisfactory manner the measurements for which he has used it. We have been using a bridge method that has a greater range of adaptability than Mr. Lee has apparently expected from his method, and I think it may be of interest to give a very brief description of that method and a rough comparison of the differences between the two. This may be done briefly, because our method has recently been published in the February issue of the *Electric Journal* (1925, p. 58).

I shall describe our bridge in terms of Mr. Lee's Fig. 17. The left-hand side of Mr. Lee's bridge is shown as a condenser, the cable, in series with a resistance R_3. The right-hand side of the bridge is the condenser C_2, and a resistance R_4 shunted by a variable condenser. In our bridge, the variable condenser C_4 is absent, and we have a variable resistance in series with C_2. This of course is the Wien bridge which has been used by many and which was described in a Bureau of Standards bulletin about 20 years ago.

In order to make it available for high voltage, we have made one important change. Fig. 17 shows the cable and the high-voltage condenser connected together and the junction point connected to the source of high voltage. In our bridge we have opened this junction; the high voltage is connected to the cable, and a low voltage is connected to the right-hand side of the bridge. This requires an additional low-voltage transformer on this side, and necessitates a compensation, the value of which is determined by means of a standard or zero-loss condenser which is connected across the high-tension side of the line at all times that the cable sample is connected thereto, and which is connected in the bridge circuit in place of the unknown condenser by means fo a voltage-switching connection.

The general method of operating the bridge is to compensate by a special compensating circuit so that the loss is read correctly on the zero-loss condenser, the low-voltage switching connection is made, and the condenser or cable is then measured.

With the Wien bridge, the same voltage is connected to both halves of the bridge. If it is desired to use this method at high voltages, a great many difficulties are introduced because of the fact that the resistance in series with the condenser, C_2, is at high voltage. By opening the bridge and having high voltage on the cable only, these difficulties are avoided. With the Schering bridge described by Mr. Lee, some of these difficulties are avoided by eliminating the variable resistance at high voltage and using a variable condenser at low voltage as shown in Fig. 17.

I notice that Mr. Lee uses as much as 10,000 ohms in R_4. With the detecting circuit that we have, we are able to measure extremely small samples with a maximum resistance of 1000 ohms in the corresponding arm. If there is any capacity, as there usually is, between the right-hand corner of the bridge and ground, there will be an error in power factor, unless it is corrected, of exactly the same sort in either bridge, and of the same sort as the adjustment in power factor that is purposely made by Mr. Lee's condenser C_4. With 1000 ohms, which is the maximum resistance we use, that error is only 1/10 as much as it would be with 10,000 ohms. We have found it convenient and satisfactory to compensate for this error where it is desired to make accurate measurements. In general, the accuracy possible is to about 0.01 per cent in power factor. We often do not try to go this far, but it is quite possible even to exceed that degree of accuracy.

Another advantage of our arrangement over any other form of bridge that I have seen described is that it is suitable for the measurement of three-phase losses. The primary of one of our transformers is reversed in direction, and the bridge then becomes available in exactly the same way that a dynamometer-wattmeter is used in connection with the three-phase measurement of power factor of cables.

In conclusion, I would like to add that our resistances are independently variable, so that power-factor balance may be made without reference to the capacity balance which makes for a very wide range of adaptability of this method of measurement.

W. A. Del Mar: There are listed in Mr. Lee's paper five classes of tests, all of which are intended to indicate whether cable will be reliable in operation. These tests are all more or less accepted and standardized, in spite of the fact that no one can prove a very definite connection between most of them and the subsequent reliability of the cable.

Thus the insulation resistance test is known to be meaningless. The author has shown how an immense variation in the value of the insulation resistance occurs even in cable impregnated at the same time and in the same tank.

The factors which affect the insulation resistance of the cable are the resistivity of the oil, the resistivity of the paper, and the relative amounts of oil and paper.

Take the matter of the oil alone: The oil which is furnished

to the cable manufacturers is a very small matter to the oil refiners. To them lubricating oils, etc., are the principal things. They do not, as a general thing, pay very much attention to the very exacting requirements of the cable manufacturers. The result is that in purchasing oil with a specified minimum resistivity, the variation in resistivity is likely to be very great, sometimes of the order of 100 to 1. There is a similar situation with regard to the paper, but it is not such a big factor as the oil. Of course, the ratio of oil to paper also depends somewhat upon the tightness of the paper and the perfection of impregnation.

Hence, there is really no reason why one should get a uniform resistivity, and I rather suspect that it never is obtained except at very low values. You will have noted, in Mr. Davidson's curves, that the manufacturer who showed a uniform resistivity had a uniformly low one, whereas the one who had variable resistivity was generally high, and at one time it came down to, but not below, the other. I should rather suspect that, in the case of the manufacturer who had the low resistivity, there was either some unknown leak in the testing circuit or improperly dried or over-oxidized oil which rendered all the values constant.

With regard to the dielectric-strength test, there is considerable misunderstanding about that, as is to be seen from the arguments about the direct-voltage proof test. Experiments have been made which show that cable tested with direct voltage has a tendency to break down at about 2.4 times the voltage that causes it to fail with alternating voltage. From this fact it is commonly deduced that proof tests with direct voltage should be 2.4 times the proof tests with alternating voltage. I do not think that this is a logical deduction because we are not interested so much in the conditions at breakdown, as we are in applying a test which will not initiate injury, and we are yet lacking in information as to the relative voltages, direct and alternating, which initiate deterioration.

The dielectric-loss test has been shown to be useful in distinguishing between two classes of cable, namely, those in which accumulative heating occurs at low temperature and at high temperature; it has, however, been rather generally assumed that because a cable with 5 per cent power factor is better than one with 20 per cent, therefore a cable with one per cent power factor is better than one with 5 per cent.

I do not think that we have been justified in being so enthusiastic about very low power factors. There are experimental reasons, substantiated to a certain extent, by practical experience which indicate that very low power factors may be dangerous because of the inability of the cables to absorb transients. When a transient gets loose on a line, if there is no place for it to be absorbed, it is likely to cause damage. This effect is of little importance at 13,000 volts, but becomes of increasing importance as greater voltages are used.

Some definite information on this was published by G. W. Partridge in the *Electrical Review*, 1924, vol. 94, page 992. Some of the old Ferranti cables were on the same system as some modern cables. The old cables having high dielectric losses, especially in the joints had quite an advantage over the low-loss cables in the small number of pressure rises which occurred, especially at times of light load.

The capacitance test is in the same class as the megohm test; it does not mean anything in relation to the value of the cable. It is one of the survivals from the old days of telegraph-cable engineering.

The last of the five tests listed is the bending test, which seems to me a way of passing the sins of the cable installer and designer onto the cable manufacturer. The bending test seems to be in the nature of a confession on the part of the operating companies. It has stood and still stands in the way of progress in high-voltage cable design.

What do we need to assure the permanent success of a cable? We need five things:

First, ability to carry the normal voltage.

Second, ability to carry or dissipate probable transient voltages.

Third, chemical stability.

Fourth, high temperature of accumulative heating.

Five, adequate but not excessive flexibility.

The first and fourth problems have been fairly well solved—ability to carry the normal voltage and the making of the temperature of accumulative heating high—but the other three have not been fully solved. American cable manufacturers ought to be given an opportunity to concentrate upon solving those problems instead of on trying to get uniformity in megohms, certain values of capacity, flexibility and other things which do not mean anything at all.

E. W. Davis: There can be no doubt that the standard acceptance tests as applied to low-tension paper cables are not a safe basis for determining the quality and performance of paper cable for the higher working voltages. For low-tension cables, the mechanical and physical tests of the insulating materials are often of equal if not greater importance than the electrical tests. But as we pass from low-voltage to high-voltage cables, and especially as we approach the high operating voltages of 33,000 and 66,000 volts, the results of electrical tests assume tremendous importance. By a relatively short-time test, we must be able to determine the suitability of a paper cable for long-time operation. At the present time, we have much to find out about the electrical properties of a finished cable and the relation of these properties to the electrical properties of the various materials that go into the construction of the cable.

It has often been found that paper and impregnating compounds which show the best results for mechanical and physical properties have the lowest values for electrical properties.

While the insulation resistance of a cable as it is measured at the present time may be of doubtful value, yet the fault may not be in the method of measurement, but rather one of interpretation. We have not as yet been successful in establishing any relation between d-c. resistivity and power factor. On the other hand, when we have had paper cables that showed insulation resistance values below normal, we have invariably found the cause either in materials used or processes through which the cable was put during manufacture.

Long-time high-voltage tests are undoubtedly a necessary part of acceptance tests of to-day, to determine the suitability of a cable for high-voltage operation. On the other hand, the length of time and the proper magnitude of the voltage are unknown quantities.

Standarization of testing apparatus, especially apparatus for making dielectric-loss and power-factor measurements, is a matter that should receive attention. All the present methods give fairly satisfactory and consistant results at the higher temperatures, but results at low temperature (20 deg. cent. and 40 deg. cent.) vary considerably with the kind of apparatus used to make the tests. The Schering bridge offers, perhaps, a satisfactory solution for this problem.

The question of high-voltage d-c. testing is still open to discussion. As in high-voltage a-c. testing, the question of the proper magnitude of the voltage is of vital importance. The speaker has in mind a cable system that apparently withstood an a-c. test of 30,000 volts but failed when retested on 25,000 volts d-c. No satisfactory explanation for this phenomena has been offered.

C. L. Dawes: Mr. Lee in connection with the description of the Schering bridge mentions a three-stage audio-frequency amplifier which increases the sensitivity of the detector to the necessary value. At Harvard University, in connection with research being conducted under the N. E. L. A. Paper Cable Research Committee, we have developed an amplifier almost identical in design to the one used by Mr. Lee. In view of several recent queries concerning the design and use of such amplifiers,

Mr. Lee suggested that a description of such an amplifier might be of interest to the Institute at this time.

In some of our measurements we use a high-voltage bridge, two of whose arms have impedances of several megohms. For a detector we use a vibration galvanometer also of the iron-vane type, but unlike the one described by Mr. Lee, it has electromagnets and also it must be critically tuned. In order to function properly in our bridge the detector must have not only high power sensitivity but must also have a very high input impedance because of the high impedance of the bridge arms with which it is associated. We were unable to make the galvanometer itself fulfill these functions even when all the design factors were carried to the limit. Since the input impedance of a thermionic tube is very high, the use of such tubes in the detector circuit immediately suggested itself. Accordingly, a tube amplifier was designed and constructed, the details being worked out by Mr. G. H. Browning, a Research Fellow in Electrical Engineering.

At first, the amplifier consisted of seven stages but later as the galvanometer was improved the number was reduced to three. A diagram of the amplifier is shown in Fig. 8.

Owing to the low frequencies with which we work, it was found desirable to use resistance coupling between stages, rather than than transformer coupling. Special 102-D tubes were used for the two stages, since this type of tube has an amplification factor of 30 or 40, whereas the usual amplifier tube has an amplification factor of only 7 or 8.

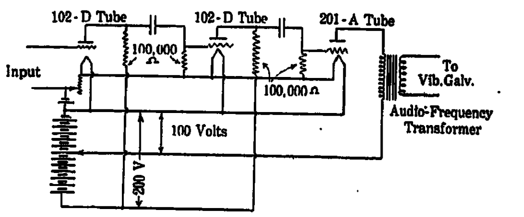

FIG. 8—AMPLIFIER FOR USE WITH GALVANOMETER

In the last stage a 201-A or similar tube is used because its plate-circuit resistance is substantially equal to the highest transformer input impedance which it was practicable to construct. This transformer between the last tube and the galvanometer is necessary in order to reduce the transition loss between the tube and the galvanometer, the galvanometer impedance being only of the order of 1500 ohms at 60 cycles.

This amplifier theoretically gives an amplification of 3000, and rough tests have shown it actually to be approximately 1000. Although at first sight this amplifier appears simple, it was necessary to overcome many difficulties before it became practicable. Considerable experimenting was necessary to determine the proper relation between grid condenser and the resistance of the grid leak. The amplifier is very sensitive to magnetic and electrostatic fields and hence must be carefully shielded from both. The shielding must be sufficient distance from the tubes to prevent capacitive feed back. The input lead and the galvanometer lead must be twisted and surrounded by grounded sheaths, and yet the capacitance between these two sets of leads must be very low or feed back will result. With a high-impedance bridge, such as we use, it is absolutely necessary to bring the two input leads to ground potential, as otherwise capacitance e. m. fs. between these leads permit stray currents to flow in the bridge, resulting in a false balance.

C. F. Hanson: At the bottom of page 112 in Mr. Lee's paper he makes the statement that three-phase power factor may be taken as the average of the power factor obtained with connection B at voltage E, and the power factor obtained with connection A at voltage $E/\sqrt{3}$. I wish to say that my experience confirms that statement.

At the bottom of page 113, Mr. Lee suggests that connections A and B in Fig. 20 be standardized. These connections require single-phase testing and consequently four different connections on the cable are necessary to obtain the power factor in various parts of the insulation. To make these four different connections consumes a considerable amount of time. I should prefer three-phase testing because only one connection has to be made. The transfer of the measuring instruments from one phase to another can be done with properly designed air switches at ground potential. The time saved and the convenience gained is desired from a production point of view.

If the ground on the sheath, connection B, Fig. 20, is removed and the sheath, instead, is connected to the middle point of the high-tension winding of the testing transformer, the current flowing in the wire connected to the lone conductor of the cable will be fairly accurately the three-phase charging current of the cable at voltage E. The three-phase dielectric power loss may accordingly be obtained with only one single-phase reading. Obviously, the lead sheath of the cable needs to be insulated from ground in order that the measuring instruments may be at ground potential.

James A. Duncan: I was very glad to note the remark made this morning by a cable manufacturer's representative to the effect that the manufacturers are now keeping an eye open to the possibility of impurities entering the cable in the oil used. I have in my hand a sample of paper given me as a fair representative piece of what had been put into a number of reels of cable made by a certain manufacturer for the Brooklyn Edison Company. This piece of paper has a resistance of less than an ohm and an average dielectric constant of infinity and a power factor which I have not measured, but which is probably somewhat excessive for so-called "insulation."

In this connection it seems well to consider some of the impurities which certainly exist in cable insulation and some of the reactions which are known to take place with such materials.

Ozone, for instance, causes a number of reactions to take place in hydrocarbon oil. Messrs. E. W. Blair, T. S. Wheeler, and W. Ledburry report in the September 1924 *Journal* of the Society of Chemical Industry an experiment in which ozone was bubbled through boiling normal saturated hexane. The formation of formaldehyde and acetaldehyde in relatively large quantities and of small amounts of water, carbon monoxide and carbon dioxide were definitely shown to result. Probably all the acids up to the hexoic and the hexyl hexoate ester are also formed.

It has long been known that certain metals catalyze the sludging process of mineral oils. Dr. Hans Staeger in the *Schweitz Elektrotechnischer Verein Bulletin* for March 1924 discusses the present state of our knowledge on this subject, including the very valuable part which his own experiments have contributed. He finds the presence of copper, brass, nickel, iron, zinc, tin, aluminum, lead, constantan and rheotan accelerate the acidulation of, and consequent sludge formation in, the oil. The magnitude of the effect varies, of course, with the metal and the time.

Four hundred per cent more sludge was formed in 1000 hours in a sample of oil in contact with copper than in a similar pure sample. The sludges usually consist of both soluble and insoluble (in oil) parts, and each of these parts may consist of both neutral and acid constituents. The oils oxidize the metals and in the case of copper, brass, zinc and lead actually partially dissolve them. Copper, zinc and lead have been detected in the sludges formed in the presence of these metals. The insoluble sludge with lead contained 20 per cent of the metal.

Both aluminum and iron have been detected in samples of the so-called "cheese" or wax formation found in three different cables. These impurities are easily traceable to the paper used in cable manufacture. The aluminum presumably goes into the paper in the form of alum, which is used as a size. I have detected it in five samples of paper, but failed to detect it in fibre just before it enters the last beating process in the paper manufacture.

The form or amount of aluminum in the "cheese" has not yet been determined. Samples of cable paper from every cable-paper mill and from every cable factory in the country have failed to produce so much as a square millimeter in which the presence of iron cannot be detected. The chemical test for iron is extremely sensitive and it is very possible that one might detect chemically iron occurring in such small quantities as to be of no importance.

To avoid making this mistake, I have also applied a physical test by means of a magnet.

It is astounding to me that the cable manufacturers are using "insulating" paper which contains pieces of iron of sufficiently large dimensions to be picked up with a magnet. I have several pieces of paper with such spots of iron in them that it is possible to ring a door bell in a battery circuit including two flat electrodes "insulated" from one another by the paper.

Aside from the conductivity of the iron, it is extremely objectionable for another reason. One could hardly imagine a better situation for the production of ionization than a region bespeckled with rough bits of metallic iron, unless it were bits of copper.

Suppose we think of a cable as consisting of a very large number of small unit lengths and think of each of these units as consisting of a condenser and a resistance in parallel. These units will then all be connected in parallel. If we admit that, for reasons outlined above or otherwise, one of these units may be very different from the average of the rest. Suppose, for example, its conductivity is very high and its capacity either high or low. It then becomes immediately obvious why one would not expect the average resistance and the average capacity, dielectric constant, or any quantity depending upon the capacity to bear any single relation to each other, for the reason that when in parallel capacities add arithmetically, while resistances add reciprocally. One very low resistance may be the predominant factor in a parallel connection, while a low capacity would offset the average for the set very slightly.

For example, in a cable supposedly divided into a thousand equal units, if one unit were altered so as to have one-thousandth the resistance and one-thousandth the capacity of its normal amount, the average capacity would be altered 0.1 per cent, while the average resistance as determined by measuring the whole cable would change approximately 50 per cent.

It seems to me, therefore, that the resistance ought to be one of our best tests because it can not be uniformly high unless every individual element of the cable is at least fairly high. In testing a length of cable in the ground power-factor measurements might not distinguish between a uniformly poor cable and one merely containing bad spots, while a kenetron test, for instance, will burn through the weakest element of a spotty cable.

Herman Halperin: Near the beginning of the paper it is stated that "the best samples of three-conductor cable for 33 kv. have a breakdown voltage on short-time tests of 200 kv." Three different makes of this kind of cable purchased by the Commonwealth Edison Company have had breakdown voltages of over 200 kv., and on one make the maximum voltage was 315 kv. In the latter case the average breakdown on about five random samples was almost 300 kv. between conductors. These data are quite different from the figure given by Mr. Lee.

The average gradient obtained in these samples was over 400 volts per mil on one sample and over 600 volts per mil on the other sample, which values are about double the value of 250 volts per mil given by Mr. Lee as being about the best obtainable.

The cable insulation is a very important part in potheads and even though we have trouble with failures in the crotch on samples, it appears to me that the voltages obtained by breakdowns in the potheads are an indication of the quality of the cable. For instance, in tests on seven makes of three-conductor, 33-kv. cable in Chicago and at the factories, we have found that old deteriorated 33-kv. cable might fail in the crotch at 125 kv., while better or new cables of the same make would fail at about 180 kv. Then the new samples of the three makes of 33-kv. cable previously mentioned withstood tests of over 200 or 300 kv., after which they had failures in the potheads.

The suggested increase of 20 per cent for full-reel high-voltage tests on three-conductor cables at the factory, seems to be insufficient. We have tested about twenty lengths of various makes of 200-ft. section of 12-kv. three-conductor cable and found that some cable which had been in service and failed due to defects in the cable, has withstood tests of 46 kv. for one, two, or three hours. These lengths had previously withstood factory tests of 30 kv. for five minutes. Increasing that factory test to 36 kv. would have easily allowed considerable unsatisfactory cable to pass the requirements. An increase of 50 per cent is more reasonable to insure satisfactory cable, but even then some unsatisfactory cable might pass this test. It is for this reason that it is necessary to have the other tests in order that all the tests together will insure cable which will be satisfactory for operation.

For instance, as pointed out in his Figs. 19 and 23, which show the variation of power factor with voltage at room temperature, if the increase in power factor is small the cable is superior to "poor cable" which has the large increase in power factor shown in Fig. 23.

On the twelfth page a large number of factors are enumerated for the d-c. to a-c. ratio, and a conclusion is given that each individual case must be considered separately. This would result in a complicated set of formulas which would probably be impracticable. It appears to me that the ratio could be changed on the basis of some major considerations, such as temperature and thickness of insulation.

Apparently the ratio now being used, that is, 2.4, is conservatively low because Mr. Lee's tests show that the proper ratio is 3.0 for cable with insulation for 12-kv. service, and he states the ratio increased for larger thicknesses.

S. J. Rosch: The author describes for the object of his paper "an attempt to devise a method of testing high-voltage cable, which will determine its operating characteristics in advance of its installation."

In looking through this paper, I find a series of statements of present practise accompanied by a series of statements showing the results of certain tests made by the company with which the author is associated. I fail however to see any real constructive criticism as to what values should be used as criteria for the determination of the suitability of cable before it leaves the factory. I am not wholly in sympathy with the author's conclusions and the discussion I shall present, is an attempt to clarify some of the points which in my opinion the author's paper has failed to do.

Of all the mysteries presented to the electrical engineer for solution, the most baffling in my estimation has been the impregnated paper cable. It seems to me that the greatest cause for this mystery has been provided by the cable purchaser. To amplify this statement, let me say that the greatest cause for the lack of a proper understanding of cable phenomena has been the vast multitude of specifications supplied by various purchasers for high tension cable.

Take for example a cable for 13-kv. service. Specifications for this type of cable range from a wall of 9/64 in. on the conductors and 5/64 in. on the belt to 14/64 in. on the conductors and 8/64 in. on the belt. One can readily conceive that of two cables made of the same materials under the same routine, the cable with the heavier wall of insulation will certainly have the greater factor of safety. If, therefore, we start comparing the operating performance of 13-kv. cables of several utilities, we find ourselves comparing cables which should be alike, but which are absolutely foreign to each other.

Until the present time, the purchaser has been specifying every criterion for the determination of cable quality, but apparently

the best of these specifications have been unable to pick out defective material. I believe it would be well to pause for a moment to see if we can trace some of the underlying causes for this fact. The testing of a cable generally consists of two phases, namely,

(a) Tests made on the full cable length.

(b) Tests made on a sample of this cable.

Right here in my opinion is the crux of the situation for there has been entirely too much testing of the samples, and not enough of the cables. Look through your N. E. L. A. reports or the proceedings of the A. I. E. E. and you will find that although cables intended for 33-kv. service have failed after only three months of service, nevertheless samples which were supposed to be representative of these cables, could not be broken down at 230,000 volts. Furthermore cables whose samples did not break down at these high values, are operating without any difficulty whatsoever. What inferences can we draw from the above? The ones that I would draw are as follows:

1. That the dielectric strength of a sample is not to be taken as indicative of the dielectric strength of the cable.

2. That there may exist a compound which has high initial values, but which deteriorates rapidly under actual service conditions.

3. That there may exist a compound which has moderate initial value, but which remains practically constant for a period of years.

If what I say be true, the solution must be obvious. The standards by which a cable is measured must be revised. In revising these standards, we must bear in mind that it is the cable and not the sample which is to be placed underground. We must therefore begin studying the cable more closely and look to the sample to give us only such additional information as cannot be revealed by the cable. I shall now take up the various tests in their order.

Full-Reel High-Voltage Test

Until such time as the thicknesses of insulation for various working voltages are standardized, I believe that the following test values should be used.

For cables up to 15 kv. the test voltage should be either 100 volts per mil or two and a half times the rated voltage, the larger of the two values being the one to be used for the test voltage. The voltage should be applied for five minutes. For cables rated at 16 kv. to 25 kv., the test voltage should be either 125 volts per mil or two and a half times the rated voltage, the larger of the two values being the one to be used. The voltage should be applied for five minutes. For cables rated at 26 kv. and over, the test voltage should be computed on the same basis as that prescribed for the 16- to 25-kv. class except that the period of application be fifteen minutes instead of five.

On cables rated above 15 kv. one reel out of every ten should receive an additional test of twice the working voltage applied for one hour. I consider all of the above tests as the best yet advocated for the determination of high-quality long-endurance cable. The values advanced are not high enough to overstress the insulation, and yet provide a very considerable factor of assurance that the cable will stand up under the rated service conditions. The last test, namely, the one applied for one hour to one out of every ten reels, is one of the most important in that it gives a fair idea of the endurance ability of the cable in general. Choosing one reel out of every ten, is almost the same as giving each reel an endurance test, since the reel selected, will practically represent the condition of each particular batch of cable as it is manufactured.

Insulation Resistance

The subject of insulation resistance has always been more or less of a joke in the paper-insulated cable industry. Every attempt at some form of standardized specification has recognized this fact in one way or another. In the Report of the Underground Systems Committee of the N. E. L. A. of 1922, embodying specifications for Impregnated Paper-Insulated Cable, under section 8, the first paragraph reads as follows, "The insulation resistance in a quantity having little significance except as a guide to the uniformity of the product; that is to say, a cable of high insulation resistance may be no better than one of comparatively low insulation resistance. Any important variation revealed by test should be investigated with a view to ascertaining whether the particular length has undesirable characteristics."

On page 105 in Mr. Lee's paper appears the following statement "Although measurements of insulation resistance have been made on cables for years, and are still being made, the results as determined by the standardized procedure are of doubtful value as being indicative of the suitability or unsuitability of cable for use." Mr. Lee further points out that in one case on thirteen lengths of 33-kv. cable manufactured during a three-months' period, the ratio of insulation resistance between the highest and lowest cable was as five to one. He goes one step further by saying that in another case, on eight reels of 22-kv. cable made from the same paper, treated in the same compound, in the same tank at the same time, the ratio of insulation resistance between the highest and lowest cables was as four to one, and yet there had never been any evidence to prove that one reel of cable was any better than the other. It is practically impossible in the light of our present knowledge to attempt to explain the cause for the variation in the last mentioned case because apparently the conditions were identical throughout.

In spite of all of the foregoing, inspectors have rejected cables for a lesser variation in insulation resistance, simply because the cable manufacturer has been unable to expound some theory that would plausibly explain away these variations. On page 306 of the *Electrical World* issue of February 7th, 1925, under an article entitled "Progress in High-Voltage Cable Manufacture," various causes are cited that led one large cable purchaser to reject cables in 1924 and among these is listed insulation resistance. I am citing this case to show that although insulation resistance has not been considered of importance in determining high-quality cable, nevertheless, purchasers have used the results of this test to reject cables.

If insulation resistance as now measured is meaningless, is there some method for making this test that will prove of greater value? I believe there is.

Fig. 9 shown here represents the present method of making insulation-resistance measurements, namely, taking each conductor against the other two and the sheath which in turn is connected to earth. The faultiness of this method lies in the fact that we do not get the resistance of the various leakage paths separately, but collectively.

Fig. 10d shows conductor No. 1 against No. 2, No. 3 and sheath and ground as in the ordinary method. Fig. 10e shows conductor No. 2 against No. 3 using both poles of the source of d-c. potential and giving an absolute resistance of the field between conductors. Fig. 10f shows conductor No. 3 against the sheath and ground which enables us to explore the field between one conductor and the sheath. Fig. 10g shows conductors 1, 2 and 3 against the sheath which in turn enables us to explore the entire belt insulation.

This method uses only one additional test per reel of cable. It is not new, having been used as far back as 1910 to the speaker's recollection, but it certainly tends to reveal considerably more concerning the leakage paths in a cable than the one shown in Fig. 9 which is in general use at the present time. Furthermore, tests *d, e, f* and *g* have a further value in that they

should bear a definite relationship to one another. For example, if the value of insulation resistance obtained on

d.................. = 100 per cent
Test *e* should be approximately = 160 per cent
Test *f* " " " = 125 per cent
Test *g* " " " = 70 per cent

With the different types of compounds in vogue today, where the compound used might be a mixture of some solid substance combined with a very fluid oil, the relationship between these tests might vary, but the same rate of variation should exist for that particular manufacturer's cables. There is one other point I would like to advance, that in the case where the insulation resistance appears to be low, the best way to determine whether it really is low, is to submit it to a three-minute electrification test. It is obvious that a conductor having a weak spot in its

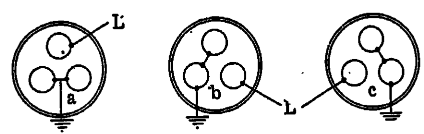

FIG. 9—PRESENT METHOD OF MEASURING INSULATION RESISTANCE

insulation cannot have the same rate of electrification for three minutes as a good conductor.

POWER FACTOR, DIELECTRIC LOSS AND IONIZATION

One of the largest cable purchasers in this country recently reviewed the results of tests made during 1924 on a very large order of 13-kv. cable. This order was divided among six different cable manufacturers, the entire order having been inspected by what is undoubtedly the best testing organization in the country. This purchaser attempted to rate the six cable manufacturers according to the tests obtained, with the following results:

The manufacturer who had the greatest number of wrinkles in his insulation, the greatest number of creases in his paper, in short the poorest mechanical conditions in his cable, this same manufacturer who had the poorest impregnated cable, the lowest dielectric breakdown on a hot sample, the lowest dielectric breakdown on a cold sample after bending, this same manufacturer nevertheless, had the best ionization characteristics, namely, the smallest variation in power factor between stresses of 20 and 100 volts per mil, and also had the very lowest dielectric loss of all the cables manufactured for this purchaser.

Let me bring up one more point. The company with which the speaker is associated, in 1900 manufactured and installed the first 25,000-volt cable ever made in this country. Tests made recently on samples of this cable, showed that it had power factor of about 30 to 40 per cent at 100 deg. cent., that it would fail miserably on the bending test at − 10 deg. cent., and nevertheless this cable is operating to this very day with a smaller number of proportionate failures than any cable of similar design manufactured within the past ten years. One must necessarily ask the question as to how important are ionization, dielectric loss and power factor in the pre-determination of the suitability of a particular cable for a certain definite service.

In Fig. 24 of Mr. Lee's paper, sample No. 3 which had the highest initial power factor of all four samples nevertheless stood up after 600 hours under the particular life test with a much smaller variation in power factor than the three others which had the lower initial values. All of the above in my estimation points clearly to the fact that power factor, dielectric loss and ionization have very little effect on the dielectric strength of a cable. In other words, a high power factor may or may not be accompanied by a high dielectric strength or vice versa. It seems to me that in the past, we have been a bit too rash in condemning certain types of cables, and overrating others on the basis of test performance on dielectric loss, power factor and ionization. In the paragraph immediately above Fig. 24 Mr. Lee states "The Effectiveness of the power factor-voltage test to separate poor cable from good will have to be determined largely from experience." I am in absolute sympathy with Mr. Lee on that score and believe that although these measurements should not be discouraged, they should not be wholly used as a means for picking good cables from bad.

There is no question that of two cables, the one having the lower dielectric loss, will have the higher current-carrying capacity. Let us confine ourselves therefore, to a reasonable value of power factors say a maximum of 5 per cent at 80 deg. cent. and 10 per cent at 100 deg. cent. and not attempt to try to make cables as perfect condensers. I can see no valid objection to any series of tests, but I do object to setting up these tests as a criterion, when their value as such has not been substantiated to the satisfaction of all concerned.

SAMPLES

A 10-ft. sample cut from the end of a reel of cable can be used to reveal the following:

(a) It may show that the cable which it represents can stand a bending test, but it cannot reveal whether or not a 10-ft. sample cut from the other end of the cable, will be as good as the first in meeting the bending test.

(b) It may show that the cable which it represents has a high dielectric breakdown strength at 85 deg. cent. but there is nothing to indicate that a 10-ft. sample cut from the middle of the cable would yield as high a value. Tests made by the speaker on a number of samples cut from cables of different makes, have shown considerable variation in dielectric strength although the particular samples were taken adjacent to each other.

(c) A 10-ft. sample can however be made to show the physical make-up of the cable, the method of application of the insulation, the tensile strength of the insulation after drying and impregnation as compared to average values obtained on the new treated paper. In this way the inspector can tell whether the extremely high insulation resistance or low power factor obtained on a certain cable has been obtained at the expense of over-drying the paper insulation or whether it is inherent in the materials of which the cable has been manufactured.

I would therefore recommend, in the absence of any better suggestions, that these physical and electrical tests on samples

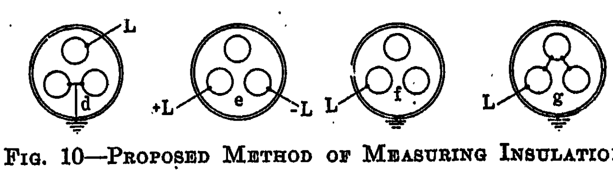

FIG. 10—PROPOSED METHOD OF MEASURING INSULATION RESISTANCE

be continued, always bearing in mind however, what the results obtained actually mean, and how far they can be applied in fixing cable quality.

RATIO OF D-C. TO A-C. IN D-C. HIGH-VOLTAGE TESTING OF CABLES

The subject of d-c. high-voltage testing has assured some importance of late and has also brought out some adverse criticism due to the arbitrary way in which a ratio of 2.4 has been fixed. We know that when testing a cable with alternating current the insulation is subjected to the maximum value of the voltage wave, we should therefore conclude that it would be able to stand an equivalent d-c. value which should be equal to 1.41 times the maximum a-c. value. Instead of this however,

we find that an arbitrary value of 2.4 times the root-mean-square a-c. voltage has been taken, which gives a value of 1.7 times the maximum a-c. value, or an increase of over 21 per cent over the theoretical d-c. value to be used. With all due respect to the splendid work done by investigators both here and abroad, we are nevertheless confronted with the fact that the true ratio does depend upon the nature and structure of the material, upon the thickness of the insulation, upon the temperature of the material, the size and shape of the conductors and the rate of application of the applied potential. In other words of two similarly designed cables, one may be impregnated with a compound where the ratio of d-c. to a-c. may be more than 2.4 but the other may be less than that value, nevertheless both cables will have equal life when passing the a-c. installed voltage. In fairness to all concerned until more knowledge has been obtained on the results of this form of testing, I would suggest that each manufacturer be permitted to specify the ratio of d-c. to a-c. with which he would allow his cables to be tested. I am a firm believer in d-c. high-voltage testing of cables and expect to see the day when this form of testing will supersede all others now in use on both the factory and installation tests of cables.

Proof Testing After Installation

I am a firm believer in proof testing of cables and would recommend that twice a year, cables be tested at one and a half times the rated voltage for fifteen minutes. This would not overstress the cable insulation, and yet would be sufficient to give assurance that the cable was going to operate satisfactorily. Above all, I would earnestly recommend that the utility engineers inform the cable manufacturer of the results obtained on his cable during service, so that he can link up the experience gained in the factory with that obtained under actual operating conditions.

I. M. Stein: I was very much interested in the new galvanometer mentioned in this paper, and am sorry Mr. Lee didn't say more about it. Very often in a-c. measurements, progress is retarded by lack of a suitable detector. When we have a new one, it may open up paths for further progress. I hope, therefore, Mr. Lee can tell us more about his new detector.

I had the pleasure of reading Mr. Atkinson's paper on Bridge Measurements of Dielectric Losses, which appeared in the February issue of the *Electric Journal.* The detector used by Mr. Atkinson is somewhat different from Mr. Lee's and doesn't require any amplification. I am wondering if Mr. Lee can tell us the advantage of his detector over the one used by Mr. Atkinson, which I believe is an iron-core dynamometer.

Bridge methods are known to have the advantage that the detector does not have to be calibrated, as in a bridge the detector is used as a null instrument. However, there are null methods which are not bridge methods, and one which is particularly suitable for measuring the power factor of cables is shown herewith in Fig. 11.

In the method shown an uncalibrated dynamometer serves as a null detector. This does not mean that there is no current flowing through one of the dynamometer coils, but rather that whatever current is flowing through one coil is in quadrature with that in the other.

The operation consists merely of rotating the inductometer until the dynamometer indicates zero; then the power factor is read directly from the scale of the inductometer, which may have a range of 0 to 5 per cent power factor.

A direct-reading power-factor scale is obtained by compensating (with a condenser and shunting resistance) for the residual inductance of the inductometer, the inductance of the potential coil and the phase angle of the potential transformer. The phase angle of the potential transformer may vary somewhat with the applied voltage, and one terminal of the compensating condenser is made adjustable to take care of this phase-angle change. The adjustable terminal of the condenser is coupled with a voltage scale, and by setting the index of this scale to the working voltage, the change in phase angle of the potential transformer is compensated automatically.

It is usual to make tests at a low voltage and at five times this voltage. A range-changing switch may be provided, which operates on both the series coil and the potential coil in such a way as to give the same sensitivity at low voltage and five times low voltage, still retaining the direct-reading power-factor scale.

Unlike Mr. Atkinson's bridge arrangement, this equipment is intended for one use only; namely, for measuring the power factor on full-reel lengths of cable. Because of the simplicity of the arrangement, together with the direct-reading power-factor scale, only a few seconds are required to make each measurement.

H. W. Eales: It is probably fair to say that the need of users still exceeds the capability of the makers taken in numbers. The data developed in the paper applies mainly to short lengths of land cables of moderate voltages, with maximum of 33-kv.

Departure from these values brings the user into untried fields. Testing equipment has been designed for short lengths and moderate voltages, the number of makers equipped to test cables of very high voltage and long lengths being very few. Those who use 66-kv. to 132-kv. cable have very little experience of others to go by.

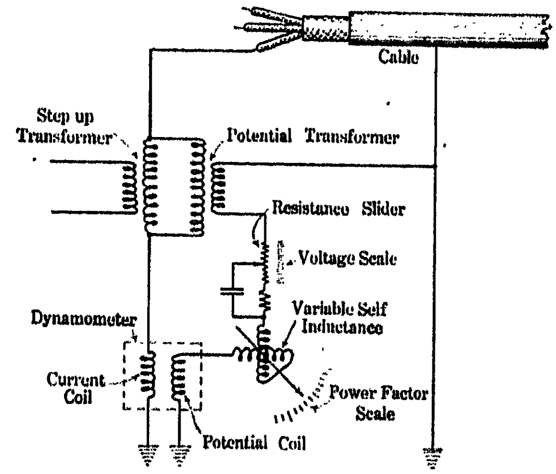

Fig. 11—Method of Measuring Power Factor of Cable

Fortunately, progress is made by trial. Unusual interest is therefore attached to the 66-kv. and 132-kv. installations at Cleveland and Schenectady respectively, and to the announced purchase of 35-kv. 350,000-cir. mil three-conductor sector submarine cables which are to be installed in the Mississippi River at St. Louis, each of which will be made up in half-mile lengths without splice, or twice the length heretofore attempted for this class of cable.

R. W. Wieseman: When alternating current is used for testing, the wave shape of the applied voltage must remain the same throughout the test if consistent and dependable results are to be obtained. The sine wave is universally recognized as the standard wave form of voltage.

In cable testing it is extremely important that the generator should have a sine wave of voltage at all conditions of load. The generator voltage wave must therefore be free from all harmonics, especially tooth ripples. Otherwise the condenser capacity of the cable will greatly amplify the harmonics and the current wave will be saw-tooth instead of smooth, also additional dielectric losses will occur in the cable insulation. Furthermore, the generator must be stable throughout a wide voltage range when delivering large leading-zero-power-factor currents.

The testing generator shown by Fig. 4 of the paper was de-

signed especially for cable testing. The excellent voltage-wave characteristics shown by Fig. 5, and by the table at the bottom of page 106, were obtained by a suitable choice of armature winding pitch and distribution. This type of generator can be short-circuited either three-phase or single-phase and the full normal-load current wave at zero voltage has a maximum deviation factor of only 1.5 per cent. A generator which has these characteristics is ideal for testing purposes.

P. W. Sothman: "Too many of our high-tension cables are coming up to specification but not up to expectation." In other words we test the proposed cable and find everything o. k. We put it into service and too large a percentage fails under operation, which shows that there is something wrong.

Quite often the consulting engineer is called into conference too late, *i. e.*, after trouble occurred which in many instances could have been avoided.

The characteristics which we know and have observed in overhead high-tension transmission lines are familiar to us. In underground cables the phenomena are often 10 to 20 times more severe in destructive effect than in overhead systems, due to the characteristics of a cable. The result of our work on overhead lines has been the design of surge-preventing or surge-reducing apparatus. In the underground systems nothing or very little has been done to make the over-potentials, surges, etc., harmless or to prevent them.

There is much room for closer cooperation between the cable manufacturer and the utility company. Each one should place the observed facts open to constructive criticism and discussion.

We learned from one discussor that the oil companies do not pay any too great attention to the quality of the raw materials delivered. The same is true of the paper manufacturers, which simply means that the cable manufacturers must treat the materials individually and cannot adopt a standard method. The treatment should be continued until tests prove the material has been made satisfactory.

The company which installs the cable also should do its part. I have seen cable pulled into duct in such a manner that the force applied was greater than the elastic limit of the cable. I even know of cases where new cables were pulled in two. Furthermore, the tools used in the laying of cables are often obsolete and not suitable. For instance, the pulleys through which the cables move often have flat grooves instead of grooves to fit the contours of the cable. The bearings in the guide pulleys are often common holes, whereas roller bearings would reduce the friction greatly and should be used. See Fig. 12. The consequence of such flat grooves is that the cable is damaged and will not perform properly.

Personally, I do not approve of our cable specifications in respect to dictating the minimum insulating thickness, as this does not spur the cable manufacturers to use the very best insulating material. My suggestion would be to say, "The insulation or distance between conductors should not be more than so many thousandths of an inch."

G. E. Luke (by letter): It is noted that the insulation resistance of the cable is measured after a one-minute application of the d-c. voltage. It is well known that such a reading is not the true ohmic resistance, since the transient current measured at this time interval may be several times greater than the final steady value due to the absorption effect. Hence, in a general way, this current will be a function of the power factor as shown in Figs. 1 and 2. It is suggested that this apparent resistance be measured at the end of a five or ten minute period since such a value would be very near to the true resistance; also a reading should be taken 10 to 30 seconds after voltage application. The ratio of the short-time reading to the long-time reading would be approximately the ratio of the absorption current to the true conduction current and would be an indication of the condition of the cable. (See paper by Phelps and Tanzer, A. I. E. E., 1923, p. 54.)

In the conclusions (1) the author says "Values of insulation resistance as heretofore obtained are of doubtful worth as a means for distinguishing between satisfactory and unsatisfactory cable." It is agreed that such measurements will not classify average-grade and high-grade cable but should in some cases be able to distinguish between defective cables and passable cable. Thus in electric machines insulation resistance is taken before the high-voltage test in order to determine if the insulation is in condition to withstand the test. In such cases a very low resistance might indicate absorbed moisture or defective insulation.

In reading the data given in Figs. 10 to 13 on breakdown voltage-time curves at various temperatures, nothing could be found as to whether the temperature specified applied to the conductor, sheath or ambient air. For example, in Fig. 10 the temperature given was 25 deg. A voltage application of several times normal value will result in an elevation of the insulation temperature, hence it would be interesting to know the maximum insulation temperature for each test. This raises the question—Was the insulation breakdown due to high temperatures, chemical action, or to a dielectric puncture at normal temperatures? Of course, combined effects may be present; however, it is suspected that the thermal action dominates.

It is suggested that the longer life of the cable on endurance run at 50 deg. cent. compared to 25 deg. cent. may be due to the lower viscosity of the impregnating compound and hence better distribution. If this is true, then it is an argument for the more fluid compounds.

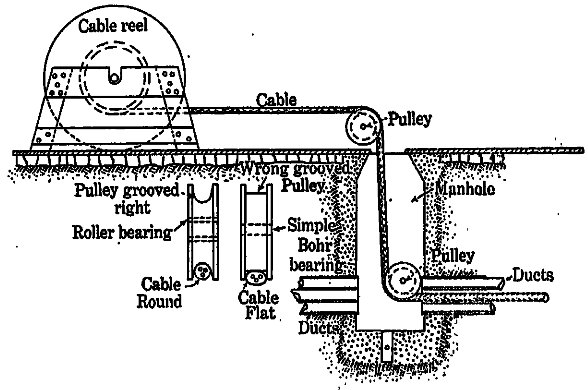

Fig. 12—Use of Pulleys for Pulling Cable

Regarding the nature of the failures as outlined in two classes, (1) those where the puncture is radial and clean, and (2) those where the puncture is accompanied by deterioration, we also experience similar failures in armature coils. Those of the first class are usually due to a sudden application of a high voltage, while those of the second type are due to a long-time application where cumulative chemical and thermal action may dominate. Failures of the first type may be due to voltage impulses of very short duration and may be classed as fundamental dielectric punctures.

The efforts to determine the "germ" of a breakdown by exploring the sheath temperatures were interesting. It would be of value to know the maximum internal insulation temperature corresponding to the sheath temperatures measured. This "hot-spot" correction would be considerably greater were it not for the equilization of the temperatures due to the conduction of heat along the heavy lead sheath.

The tree designs on some of the paper due to corona in the air spaces emphasize the fact that good impregnation is desirable. This raises the question—What per cent of the free space is filled in practise? In other words, what per cent of air space can be expected in such cables

E. S. Lee: It has been a great pleasure to have such excel-

lent data presented to us in the discussion of this paper, particularly since the general conclusions of the paper are substantiated thereby.

Dr. Whitehead asks whether the curves between the power factor and insulation resistance give the order in which the observations were taken. The answer is, no. These data are plotted with the values of insulation resistance in ascending order, the lowest value first. Power factor values are plotted corresponding with the respective values of insulation resistance. This method of plotting (in order of ascending or descending values without regard to time) has considerable merit in cases where a large number of observations of a single quantity are obtained, since a graphic picture of the variation of the observations is clearly presented.

Regarding insulation resistance, I recognize, as all do, that we would like to have every piece of similar cable that comes from the tanks to be of the same insulation resistance, and that we would like to have that value just exactly the right value. At the expense of having it thought that perhaps our processes were not absolutely controlled, I have taken data to show the wide variation that may exist, and data have been presented by others showing this same wide variation in other cables. But what I had hoped to hear in discussion was that where the variation is large the cable will not live, and that where the variation is small the cable will live. There does not seem to be evidence to substantiate such a conclusion, however, which is all that I have tried to say in my paper.

As regards dielectric strength, I think there is nothing else to say. I have merely suggested that present standardized values should be increased. In the absence of a rational basis for establishing values of proof-test voltage, we will have to arrive at such values through conference, and modify them from experience. Referring to Figs. 10 to 13, the temperatures indicated are ambient. Mr. Davidson's suggestion that the data are not extensive enough to justify lines being drawn through the points with precision is quite right. The lines might better have been drawn dotted. The purpose of the curves was to give a picture of the relation of the present standardized test voltages, rated voltages, and breakdown voltages.

Mr. Atkinson's scheme for adapting his bridge for measurement of power factor and dielectric power loss from three-phase supply is quite unique and appears to have great merit. It is quite possible that the Schering bridge may be somewhat similarly modified to allow of such measurement therewith.

Regarding Mr. Stein's question about the dynamometer, it is a remarkably fine instrument. It requires no tuning. We use it down in the factory. It stands on the table, with men working all around it, the crane running about ten or fifteen feet above it, and still it does its job. It is oil-filled. Its sensitivity is about two-fifths, I calculate, of what Mr. Atkinson gives in his paper, which is, I think, about 50 microamperes per millimeter. This would then be about 20 microamperes per millimeter. This is with the amplification, which is 100 or 125. So it isn't quite as sensitive as Mr. Atkinson's, but it does the work.

Mr. L. T. Robinson has often said: "When we used to have only one bridge in the laboratory, we could measure the resistance of anything very accurately and get its value. But when we got two bridges" he said, "we couldn't do quite as good a job in measuring the resistance."

Well, we have had the dynamometer wattmeter method and used it. Mr. Shanklin operated with it and got good results. So when we applied the Shering bridge we said, "Let's see what we shall get" and the paper shows you what we have been able to get under probably the best conditions. I show differences there in power factor of 0.002, that is, 0.2 per cent power factor, and in one case the bridge is high and in the other case the dynamometer is high, which is good. We have had results that vary as much as 0.4 per cent between the two measurements, but nothing more than that. So I feel that we are in very good agreement, and this little galvanometer does it.

As regards testing installed cable, I am gratified to have Mr. Davidson bring data which show that he has arranged that all of the d-c. tests which will be made on his system will be available in graphic form, with the voltage and the current values shown together on one instrument chart. Thus a permanent record of what has occurred will be available for study, which should enable us to learn more of the value of the d-c. test.

As regards the d-c. to a-c. breakdown voltage ratio, I wish again to call attention to the fact that while for any given breakdown voltage with a-c. there is no doubt a corresponding breakdown voltage with d-c., the relation between these two is dependent upon so many variables that each case has to be considered separately. Such a situation, therefore, requires caution in drawing conclusions relative thereto.

One more thing: We obtain the breakdown with d-c. and we obtain it with a-c., and we take the ratio. What we want, however, is a suitability test. That is, we want to put some kind of a test on the cable and not break the cable down. We want the cable to continue to live and be useful, but we want to know whether it is of such value that we ought to continue to let it live and be useful. That is the whole point.

The best we can do, is to obtain a proof-test voltage value from what data we have, and we have the breakdown ratio. If the breakdown ratio for a particular kind of insulation is 2.4 and we say that is the best we have, then we are using the best we have, though that may not be exactly what we want. We have to find out by experience. But if we will recognize how we arrive at the value of d-c. to a-c. ratio, that is, from breakdown values, and that we are applying it to a proof test, then I am sure any differences that may appear on the surface will easily be straightened out, and everybody will be in absolute agreement.

As to Mr. Roper's tabulation, such an idea has merit and it seems that if we can continue to cooperate in obtaining what is considered by all to be a fair rating of the various items presented in that tabulation, it will be a step in the right direction. I want to note in this connection, however, that we are rating a good many properties that are not directly measurable. That is, we look at a thing, and we feel of it, or something of that kind, and then give it a rating. We would like, however, to be able to measure it in some way or another, which is what we must strive to do, as has been brought out by several discussors.

In a lighter vein, if Mr. Duncan's remarks are recalled, it might be thought perhaps that the title of this paper should have been "Testing High Tension Iron-Impregnated-Paper-Insulated Lead-Covered Cable." But with all due respect to the paper samples that he may have, and with all due respect to what has been said about the variations in oil, I want to say that the folks who supply the compound and the folks who supply the paper are interested in supplying the cable manufacturers with material that is as uniform as possible. And, in turn, the cable manufacturers are taking those materials, with what variations may exist therein, and are putting them through the necessary processes to produce long lengths of uniform insulation. A satisfactory means of determining the uniformity along a 500-ft. length of cable is not available however, since all the test methods now used (which do not destroy the cable) give a summation of the whole. One of the greatest needs of the art is a test method for determining the uniformity of insulation without harming it. Such is a subject for both industrial and collegiate research which ought to be actively pursued.

Predicting Central Station Demand and Output

BY FARLEY C. RALSTON[1]

Member, A. I. E. E.

Synopsis.—For relatively long-term predictions of central station demand and output, of the order of one year or more, the use of constant (or approximately constant) yearly percentages of growth is common and well understood. This method is frequently applied by straight, or nearly straight, line projection of the plot of past data on semi-logarithmic paper.

When the term of the prediction is less than one year, or when detailed estimates are required throughout any year, this method fails on account of the seasonal variations.

In this paper is investigated the nature of the seasonal variations in the daily load curve of the company with which the author is connected, as they affect the output and the peak demand.

The variation of the kilowatt-hour output is first analyzed: and it is found that, in a year fairly free from abnormal business conditions, a plot of the "normal midweek day" outputs on semi-logarithmic paper can well be rationalized to a curve whose components are an inclined straight line and a single-frequency sine curve.

This curve is represented analytically by the following equation:

$$y = J\, e^{kr}\, [\,1 + L \cos (0.986\, r - M\,)^{\circ}\,]$$

In this equation, e is the base of the natural system of logarithms: r, the number of days (positive or negative as the case may be) counted from a given zero date: and J, k, L and M are parameters to be determined for each curve.

Factors are included for determining the output on holidays, Sundays, Mondays and Saturdays, as compared with adjacent "normal" midweek days."

For short-term peak demand predictions, the method employed is to separate into three components that portion of the daily load curve beginning at 2.30 P. M. and ending one and one-half hours after sunset.

These three components are a constant "base load," an "afternoon block" and an "evening block."

In the formula;

$$z = A\, F\,(t) + B\, f\,(t) + C$$

expressing this condition, the maximum value of the afternoon block is designated A, the maximum value of the evening block B, and the value of the base load C.

Both F (t) and f (t) are found to be exponentials in the data used and their forms are given with methods of evaluating the parameters.

However, even this stage having been reached, the formula is still in awkward shape for obtaining, analytically, the solution most often desired,—namely, the value of the peak demand and the time at which it will occur.

A graphical construction is, therefore, developed which solves simultaneously for these two quantities. This solution is equally valid if the form of F (t) and that of f (t) are defined only graphically, it is not necessary that their analytical expression should be known, nor even that they should be analytical in character.

* * * * *

For a variety of reasons, predicting future conditions is frequently necessary in most commercial enterprises. As regards the peak demand and output of central station companies, the forecasts required fall into two distinct classes.

Long Term Predictions

The first class extends usually from one year or thereabouts to a number of years in the future, admitting of latitude in the estimation of values increasing with the length of view.

The methods of making forecasts of this class are quite simple and well understood, and will not be discussed here in detail.

It should be stated that the material of this paper is almost entirely taken from the records of the company with which the author has been connected for some time; but such data from other companies as has been available support the view that the theory developed is of very general application.

In the case of the company mentioned, and in most others, it is found that, taken over a number of years, the growth of the yearly kilowatt-hour output and the maximum yearly peak approximates very closely to a constant yearly percentage increase. For this type of load growth, plotting on semi-logarithmic paper is particularly suitable, since the plot then approximates to a straight line.

To estimate the growth for any period in the future, it is merely necessary to project this straight line as far as is required, allowing for such modifying conditions as may be anticipated. Fig. 1 shows the result of such a plot for the company mentioned above.

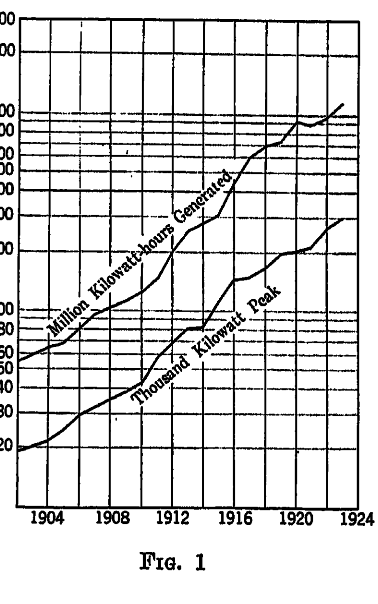

Fig. 1

If the growth does not approximate to a constant yearly percentage increase, it is only slightly more difficult to project the actual growth-curve, whatever its shape, into the future for the required period, allowing as before, for modifying conditions.

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 9-12, 1926.

SHORT TERM PREDICTIONS—GENERAL

The second class includes predictions of relatively short extension into the future, from one year or thereabouts down to a few hours. In this class of predictions, of course, considerably greater accuracy is desired.

To companies working under an operating budget system, it is important to predict the monthly outputs for each month of the budget year, in order that suitable allocation can be made among the individual stations and proper allowance made for fuel cost, etc. The prediction of daily peak demand for several months ahead is of value in arranging construction and major maintenance schedules. It is useful to a load dispatcher to know, on any given day, (in the middle of the afternoon, for instance) what peak demand he must expect that day, particularly so, if the day is unusually dark and stormy, making probable a high peak and preventing the direct use of the days immediately preceding as a guide.

In the following analysis the term "normal midweek day" will be used extensively. Tuesdays, Wednesdays, Thursdays and Fridays will be designated "normal

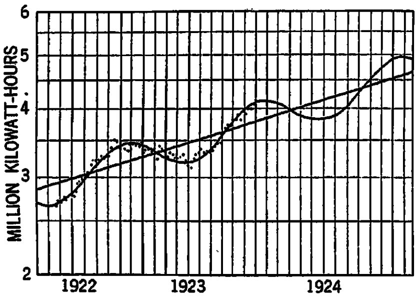

FIG. 2

midweek days;" omitting, however, any of these which happens to be a half holiday, a full holiday or the day after a full holiday. For instance, in the week containing Thanksgiving Day, there are only two "normal midweek days," Tuesday and Wednesday.

SHORT TERM PREDICTIONS—KILOWATT-HOUR OUTPUT

Probably everyone who has investigated the variation of central station output throughout the year has observed the periodic nature of this variation. On more or less rational grounds, based on the practically single-frequency harmonic variation of the principal cause of the output variation (the variation of the hours of daylight), the presence of a single-frequency harmonic component in the output variation would be suspected. But as output data are usually available by calendar months, the regular character of the periodicity is not apparent. Two factors account for this; first, the varying number of days per month, and second, the varying number (both among different months of the same year and among corresponding months of different years) of normal midweek days, Mondays, Saturdays, Sundays and holidays per month.

In eliminating the effect of these factors, the value of using only the normal midweek day outputs or, better still, the average of these for each week, is shown by Fig. 2. The points plotted on this chart indicate the average normal midweek day output for each week of 1923 and of the latter part of 1922. Semi-logarithmic paper has been used for this plot because it is natural to expect the growth during short periods of time to partake of the same exponential character as that over longer periods.

It is comparatively easy to insert by inspection an inclined base line having superimposed on it a sine curve which approximates the plotted points quite closely.

In inserting this base-line, it should be noted that its height and inclination are determined by the requirements that its alternate intersections with the group of plotted points must be exactly one year apart; also that the upper and lower lobes of the curve must be of equal heights. It is to give an additional point of intersection that the extension into the preceding year is made.

The form of the equation expressing this curve analytically is

$$y = J\,e^{kr}\,[\,1 + L\cos\,(0.986\,r - M\,)°\,] \qquad (1)$$

in which e is the base of the natural system of logarithms;

r, the number of days (positive or negative as the case may be) counted from a given zero date; and

J, k, L and M—parameters to be determined for each curve.

The coefficient 0.986 is the ratio of 360 (the number of degrees in a circumference) to 365.25 (the average number of days in a calendar year).

In the equation (1), the term $J\,e^{kr}$ represents the base line. When $r = 0$

$$J\,e^{kr} = J$$

In Fig. 2, if January 1, 1923, is taken as the zero date, J is equal to 3,190,000,—the ordinate of the base line at that date.

The value of k is given by the slope of the base line. For instance, on January 1, 1923, ($r_0 = 0$) $J\,e^{kr} =$ 3,190,000; on January 1, 1924, ($r_1 = 365$) $J\,e^{kr} =$ 3,800,000.

$$\frac{J\,e^{kr_1}}{J\,e^{kr_0}} = \frac{e^{365k}}{e^0} = e^{365k}$$

$$\frac{3{,}800{,}000}{3{,}190{,}000} = 1.192 = e^{0.176}$$

$$e^{365k} = e^{0.176}$$

$$k = \frac{0.176}{365} = .000482$$

M is equal to the number of days from the zero date to the spring intersection of the complete curve with the base line, less one fourth of 365.25; or to the number of days from the zero date to the fall intersection of the complete curve with the base line, less three-fourths of

365.25. In Fig. 2, M has been found to have the value 2.

Let r_2 be the value of r which makes the expression $(0.986\, r - M)$ equal to zero; and let y_2 be the corresponding value of y. Then

$$L = \frac{y_2}{J\, e^{k r_2}} - 1$$

In Fig. 2, $r_2 = 2.025$, and the date is January 3, 1923. On that date, $y = 3{,}460{,}000$ and $J\, e^{kr} = 3{,}193{,}000$; therefore,

$$L = \frac{3{,}460{,}000}{3{,}193{,}000} - 1 = 0.0836$$

The complete equation representing the curve of Fig. 2 is then

$$y = 3{,}190{,}000\, e^{0.000482r}\, [1 + 0.0836 \cos (0.986\, r - 2)°]$$

It would, of course, be possible to locate this curve and deduce the values of the parameters by strictly analytical methods, using least squares, etc.; but the labor of doing this would not be justified by the accuracy and consistency of the data.

If no change is expected in the rate of growth, the base-line and sine-curve are projected into the ensuing year with the slope unchanged. If, however, it is expected that other influences, not predictable from past performance, will affect the rate of growth, either upward or downward, the inclination of the base-line and consequently of the sine curve, must be modified accordingly. In either event, the ordinate of the projected curve at any point gives the value of the kilowatt hour output for an average normal midweek day at the date corresponding to the abscissa.

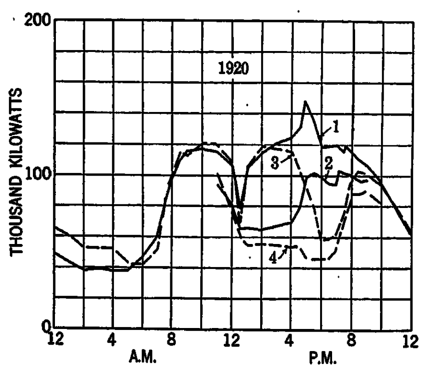

Fig. 3—Curve 1—Monday, Nov. 29
2—Saturday, Nov. 27
3—Thursday, May 27
4—Saturday, May 22

To derive the monthly outputs from the values for normal midweek day output throughout the year, it is necessary to determine the number of normal midweek days' output to which each week's output is equivalent. It has been found in the experience of the company mentioned above that the following relations hold quite closely among the days of any week:

Average of normal midweek days	1.00
Monday or day after full holiday	0 96
Saturday or half holiday	0.86
Sunday or full holiday	0.57

By combining these multipliers correctly for each week or fraction in a month, the total monthly output may be estimated.

The method here outlined may not give greatly superior results to purely empirical estimating by one thoroughly familiar with the characteristics of load variation for a number of years; but it is much more desirable in that it affords a logical analytical basis for estimating instead of placing dependence entirely upon a "trained guess."

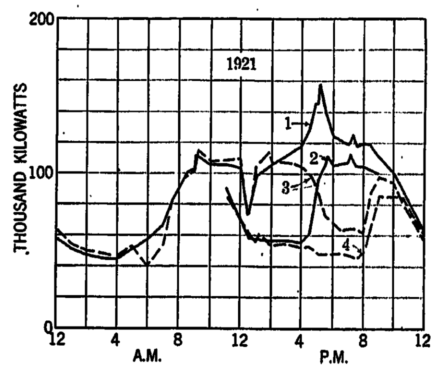

Fig. 4—Curve 1—Tuesday, Dec. 6

Short Term Predictions—Peak Demand

The following analysis of daily load curves is valid only for systems whose seasonal load variation is unrestrained. For instance, it does not apply to the 25-cycle load of the company mentioned earlier, because the demand in this system is restricted by contract limitations; all demand above a definite value being carried by another system in parallel. It is applicable, however, to the 60-cycle system of this company and the accompanying illustrations are taken from load curves of this system.

The analysis is based on the separation of that portion of any daily load curve starting about 2:30 P. M. and ending about one and one half hours after sunset into three components—a constant "base load," an "afternoon block" and an "evening block." In Fig. 3 are shown typical summer and winter week day load curves for the year 1920, and portions of the load curves for adjacent Saturdays. The portions of the Saturday curves which resemble closely the week-day curves, are omitted for clearness. Figs. 4 and 5 show corresponding sets of curves for the years 1921 and 1922. In the summer curves of all these charts, the outlines of the upper parts of the afternoon and evening blocks are easily distinguishable, since the superposition of the blocks is of negligible effect, except in the lower parts

on week-days. The winter curves present greater difficulties; and it is particularly in reference to these that accurate predictions are usually of value.

Purely empirically, it has been found that the lowest value of an adjacent Saturday afternoon is suitable as a value of the constant base load for week days. Rationally this choice is not without justification, since on Saturday the afternoon block is practically negligible.

Fig. 6 shows typical winter load curves only for the year 1923, a week day and an adjacent Saturday. In this figure the separation of the week-day curves into three components has been made graphically, the base load (which will be designated C) being equal to 96,000 kw.; the maximum value of the afternoon block (which will be designated A) being 76,000 kw. and the maximum value of the evening block (which will be designated B) amounting to 105,000 kw. By inspection it is found that the highest combination of the afternoon and evening blocks which can be made occurs at 5 o'clock, when the afternoon block has the value of

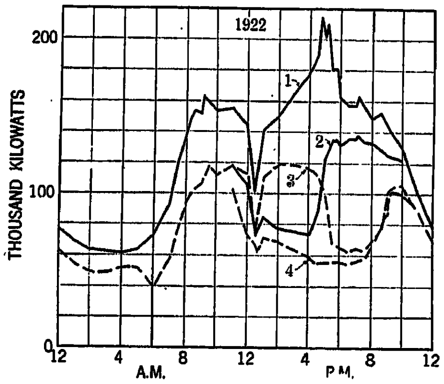

FIG. 5—CURVE 1—THURSDAY, DEC. 14
2—SATURDAY, DEC. 9
3—MONDAY, JUNE 26
4—SATURDAY, JUNE 24

56,000 kw. and the evening block the value 101,000 kw. The resultant of the three components is then 96,000 plus 56,000 plus 101,000 = 253,000 kw. The actual peak of this curve occurred at 4:57 P. M., and amounted to 250,000 kw.

For any given date, the portion of the daily load curve under consideration can be closely represented by an expression of the form

$$z = A\,F\,(t) + B\,f\,(t) + C \qquad (2)$$

in which t = hours P. M.

$F\,(t)$ is a function of t, whose analytical form is as yet undetermined, defining the shape of the afternoon load block; and similarly $f\,(t)$ with respect to the evening block. C = on a Saturday, the minimum kw. demand of the afternoon; on a week day, the minimum kw. demand of the preceding Saturday afternoon.

$$A = (\text{kw. demand at 2:30 P. M.}) - C$$

When the load curve is such that the value of the afternoon block 1.5 hours after sunset is negligible (on Saturdays through the entire year, and on week days from spring to early fall) B = (kw. demand 1.5 hours after sunset) $- C$. But the days, when the presence of an appreciable afternoon block component 1.5 hours after sunset masks the value of B, are just the days for which a knowledge of its value is most desired—namely, late fall and winter week days. For these days B must be determined in another manner, to be described later.

The demand at 2:30 P. M. has been chosen for determining A, because at that time complete recovery from

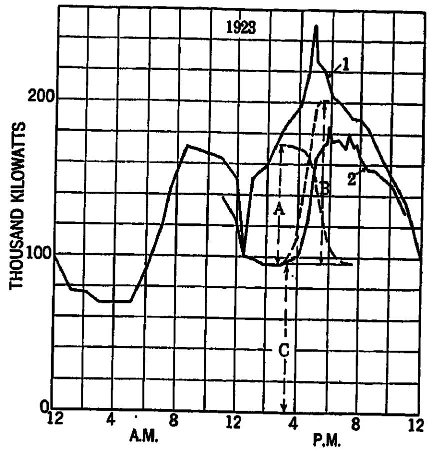

FIG. 6—CURVE 1—THURSDAY, DEC. 20
2—SATURDAY, DEC. 15

the noon dip has been made, and also the value of the evening block is negligible, even at the season of maximum overlap.

The choice of 1.5 hours after sunset as the time for determining the value of B was likewise guided by the fact that at that time the rise of the evening block to its maximum value is complete, and also, even in the

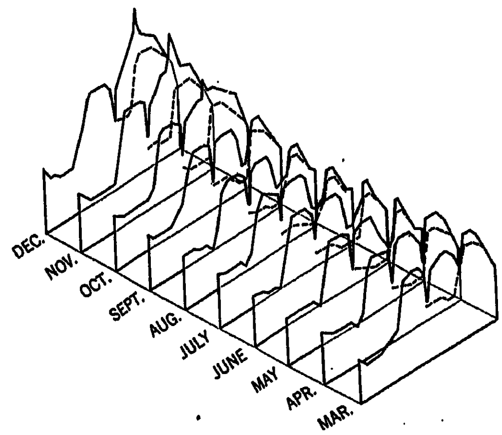

FIG. 7—TYPICAL WEEKDAY LOAD CURVES (SOLID), AND PORTIONS OF SATURDAY LOAD CURVES (DOTTED) FOR EACH MONTH FROM MARCH TO DECEMBER, 1923.

summer, no falling off from this maximum has occurred.

Fig. 7 shows the seasonal variation for the year 1923 in greater detail. It is a diagrammatic form of the Annual Load Relief Map, described in a paper by W. L. Robertson (TRANS. A. I. E. E., Vol. 36, p. 1073); using for the sake of clearness only a single pair of curves per month.

Inspection of Figs. 3, 4, 5, 6 and 7, conveys the impression that both functions, $F(t)$ for the afternoon drop-off and $f(t)$ for the evening pick-up, are exponential in character. This impression is confirmed if for each of these functions superposed curves for a large number of days, taken in various years and at various seasons, are plotted.

It is easy to derive comparable values of these functions, suitable for superposing, from the data available in the daily load curves. Division of the load curve values, $A\,F(t)$ and $B\,f(t)$, by A and B respectively, gives directly the corresponding values of $F(t)$ and $f(t)$, which may then be expressed either as decimals or in percentage for plotting.

It has been found that the composite plot of the afternoon block curves can be well represented by the curve of Fig. 8, for which equation is of the form

$$F(t) = e^{-[a(t-p)]^4}$$

in which p is the zero time at which the decrement commences; and a is the reciprocal of the number of hours from p to the time when the value of $F(t)$ is e^{-1} or 0.368, since when

$$e^{-[a(t-p)]^4} = e^{-1},\ [a(t-p)] = 1 \text{ or } a = \frac{1}{t-p}$$

The insertion of the particular values of p and a taken from Fig. 8 results in the equation

$$F(t) = e^{-[0.429(t-3.15)]^4}$$

It is found that the composite plot of the evening block curves is best fitted, not by a single curve, but by a family of similar curves, forming a band about 20 min. in width. The extreme curves of this band—those for a clear day and for a very dark day—are shown in Fig. 9.

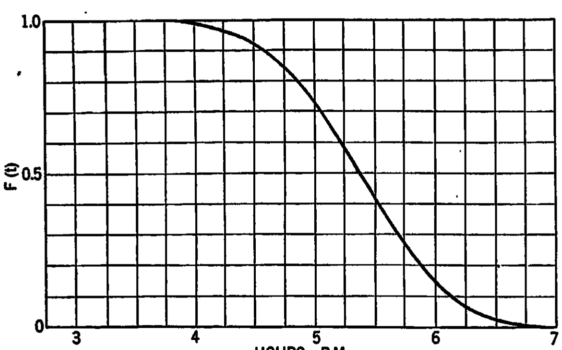

FIG. 8

For any condition of cloudiness between these extremes, a correspondingly intermediate curve would represent the evening block. The form of the equation of these curves is

$$f(t) = e^{-[b(h+q-t)]^2}$$

in which h is the time of sunset, hours P. M.; q is the number of hours from h to the zero time when the maximum value of the evening block has been reached; and b is the reciprocal of the number of hours from the time when the value of $f(t)$ is e^{-1} or 0.368 to the zero time, $h + q$.

The following particular values are met in the curve family of Fig. 9:

b is equal to 1.

q ranges from 1.25 for a clear day to 0.917 for a very dark day.

h varies nearly harmonically through the year, from about 4:20 P. M. in late November and early December to about 7:15 P. M. in late June and early July.

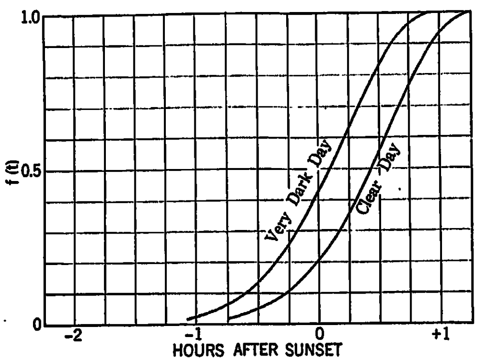

FIG. 9

The method of determining the value of B for weekdays during the period of overlap of the afternoon and evening blocks, rests on a relation observed between the Saturday and week day values of B through the remainder of the year. Reference to Fig. 7 will indicate the existence of a ratio approximately constant between the Saturday and week day values of B for the months March to September inclusive. Table I, giving numerical values of A, B and C taken from the curves of Fig. 7, confirms this indication and shows that the approximate value of the ratio is 0.75.

Assuming the ratio 0.75 to hold also for October, November and December, the week-day values enclosed in parentheses have been derived from the corresponding observed Saturday values; and these derived values have been used successfully in estimating the week-day peak.

TABLE I
VALUES OF A, B AND C IN THOUSAND KILOWATTS FOR THE LOAD CURVES OF FIG. 7

Weekday	Saturday	A Weekday	B Weekday	B Saturday	C Weekday and Saturday
March 5	March 3	75	85	65	70
April 6	April 7	80	85	63	67
May 11	May 12	80	80	60	65
June 13	June 9	85	75	55	65
July 11	July 7	85	65	50	65
Aug. 3	Aug. 4	80	65	50	70
Sept. 25	Sept. 22	85	80	65	75
Oct. 19	Oct. 20	82	(93)	70	80
Nov. 15	Nov. 10	80	(96)	72	85
Dec. 20	Dec. 15	76	(105)	79	96

Since the analytical form of each component of the portion of the daily load curve under consideration has now been determined, with suitable values of the para-

meters for various conditions, it would be possible, when it is desired to find the time and value of the peak for any particular date, to set up the complete equation, inserting for h its proper value taken from a table or curve, and for q a value depending on the state of the weather; to differentiate with respect to t; to equate the derivative to zero; and to substitute the value of t, thus obtained in the original equation. This procedure, however, would be out of the question by reason of its complexity. A graphical method, much simpler but equally accurate, has been developed to overcome this difficulty.

Equation (2) is repeated here in the functional form rather than in the analytical form, since, in the graphical method, it is not necessary that the analytical expression for each of the functions $F(t)$ and $f(t)$ be known, nor even that they should be capable of being expressed analytically.

$$z = A\,F(t) + B\,f(t) + C \tag{2}$$

Differentiating (2) with respect to t.

$$\frac{dz}{dt} = \frac{A\,dF(t)}{dt} + \frac{B\,df(t)}{dt}$$

Equating to zero and dividing by A,

$$\frac{dF(t)}{dt} + \frac{B}{A}\,\frac{df(t)}{dt} = 0$$

$$\frac{dF(t)}{dt} = -\frac{B}{A}\,\frac{df(t)}{dt} \tag{3}$$

Geometrically, the term $\frac{dF(t)}{dt}$ represents the slope of the curve of Fig. 8 at any value of t; while the term $-\frac{df(t)}{dt}$ represents the slope, not of one of the curves of Fig. 9, but of its negative—that is, a curve having ordinates of the same absolute value, but extending downward from the horizontal axis. The term $-\frac{B}{A}\,\frac{df(t)}{dt}$ correspondingly represents the slope of a curve whose ordinates are $-\frac{B}{A}$ times those of one of the curves of Fig. 9; and whose functional form is therefore $-\frac{B}{A}\,f(t)$.

Equation (3) indicates that the geometrical condition for a maximum of z is that the slopes $\frac{dF(t)}{dt}$ and $-\frac{B}{A}\,\frac{df(t)}{dt}$ shall be equal. Fig. 10 shows the graphic method of accomplishing the solution. In this figure, the solid lines indicate lines drawn on a fixed sheet, the solid curve being a repetition of the curve of Fig. 8 and the fine vertical line being drawn at the time of earliest sunset; while the dotted lines indicate lines drawn on a sheet of tracing cloth, celluloid or other non-opaque material, which is adjustable to any desired position on the fixed sheet. The curves on the movable sheet are members of the family represented by $-\frac{B}{A}\,f(t)$, taken for values of $\frac{B}{A}$ ranging, as indicated, from 0.6 to 1.4 at intervals of 0.2. On the sheet the variation in position of the curves, with respect to the time of sunset, due to weather conditions, is taken into account, not, as in Fig. 9, by having a single axis of sunset time and shifting the curves between the extremes shown, but by having a single set of curves and shifting the axis of sunset time correspondingly. In using these sheets, it is, of course, necessary to maintain the horizontal and vertical axes of the movable sheet horizontal and vertical with respect to the fixed sheet.

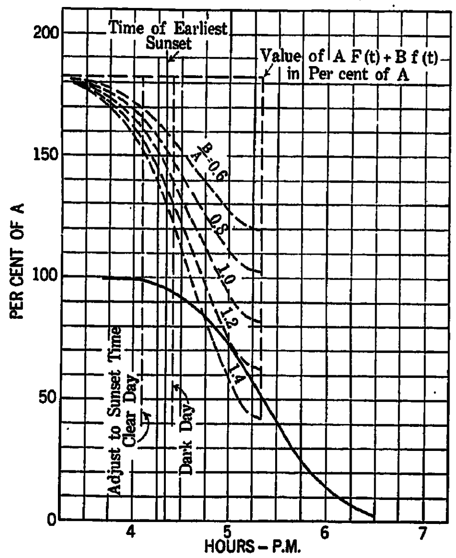

FIG. 10

In order that times on the movable sheet and on the fixed sheet shall correspond, either one of the extreme positions of the sunset axis on the movable sheet or some intermediate position (depending on the state of the weather) must be adjusted to coincide with the time of sunset as read on the scale of the fixed sheet. Then, holding this horizontal setting, the movable sheet must be adjusted vertically until the curve bearing the correct value of $\frac{B}{A}$ is tangent to the curve on the fixed sheet. At the point of tangency the slopes of the two curves are equal, and this satisfies the condition of Equation (3) for a maximum value of z.

Not only does the abscissa of the point of tangency

indicate the time at which the peak occurs; but also the ordinate of the point of tangency gives the value of the afternoon block in per cent of A at that time, and the height from the point of tangency to the horizontal axis of the movable sheet, read on the scale of the fixed sheet, indicates the value of the evening block at the same time, likewise in per cent of A. Therefore, the ordinate of the horizontal axis of the movable sheet, read on the scale of the fixed sheet, gives the value of the sum of the afternoon and evening blocks.

In the particular example shown in Fig. 10, $\frac{B}{A}$ is 1.2 (this would be the case if B were 90,000 and A 75,000 kw., for instance), the day is very dark and sunset occurs at 4:25 P. M. When the movable sheet is adjusted horizontally so that the line for a dark day coincides with the time 4:25 P. M. on the fixed sheet, and vertically so that the curve $\frac{B}{A} = 1.2$ is tangent to the curve on the fixed sheet, the abscissa of the point of tangency gives 5:03 P. M. as the time of the peak, and the ordinate of the horizontal axis of the movable sheet gives the value of $[A\, f\,(t) + B\, f\,(t)]$ as 182.5 per cent of A. The peak value of the load curve is then given by the equation

$$z = C + 1.825\, A$$

The estimation of peak demands by any method based on the values of the actual total peak for corresponding periods of past years is open to several criticisms.

In such a method, no consideration is taken of the possibility that one or more of the previous years may fail to give a reliable indication, on account of the absence of stormy weather at the time of the peak. It is also tacitly assumed that the shape of the load curve remains constant. This assumption is equivalent to the assumption that the three components, A, B and C, distinguished in the present investigation, increase in the same ratio; and this assumption is not justified.

Furthermore, it is difficult not only to make a reliable estimate of the peak at a given date in the future, but also to correlate and check such an estimate, when made, with actual peaks as the given date approaches.

On the other hand, the separation of the components of past peaks allows the growth of each component to be observed individually, regardless of whether or not it has been combined at any particular date with the maximum overlap. It is then relatively simple to project the growth of each component, at its own growth-rate, to the desired date, and to combine the estimated values properly.

The reliability of an estimate of peak prepared in this way results both from the accuracy with which the individual components may be predicted and from the probability of compensating errors in the values of the components.

A great advantage in this method is that, after an estimate has been made, it may readily be checked at any time as the date approaches by noting whether the values of the components taken from current load curves confirm the original estimate or indicate the necessity of a revision.

The Thermal Time Constants
of Dynamo-Electric Machines

BY A. E. KENNELLY*
Fellow, A. I. E. E.

Review of the Subject.—*Considering the thermal behavior of a dynamo-electric machine intended for continuous service, its acceptance tests require, at present, only a limiting temperature elevation under a continuous rated load. For the intelligent operation of a machine after it has been put in service, additional information is desirable concerning its thermal behavior under changes of load. This subsidiary thermal information concerning a machine with a continuous rating may consist of (1) its final temperature rise under some steady load other than its rated load, such as either 75 per cent or 125 per cent of the rated load, and (2) its thermal time constant.*

The thermal time constant of a machine, assumed as conforming strictly to an exponential law of temperature rise above a constant ambient temperature, after being transferred suddenly from one steady load to another, is taken as the time required to attain $1-\epsilon^{-1}$ *or 63.2 per cent of the final temperature change. This may be called the exponential thermal time constant. This is a fundamentally scientific quantity; but is very awkward to remember or to explain to a person not well versed in the mathematical theory of the subject.*

It is recommended in the paper that for all practical engineering work, a new time constant called the binary time constant be used. It would correspond to the "Period," or "Half-value period," already used in the Science of Radio-activity and in measurements of Radio active decay. A binary time constant is that time in which a machine, assumed as conforming to an exponential law of temperature change, after being suddenly transferred from one steady load to another, attains one half of the final temperature change (50 per cent). In two binary time constants, it will then attain ¾ (75 per cent) of the final temperature change, in three of them ⅞ths (87.5) and so on. This is an easy relation to remember and explain. A binary thermal time constant may be taken, for practical purposes, as 70 per cent of the classical exponential time constant. It is more strictly 69.32 per cent.

Although dynamo machines do not rigidly follow an exponential law of temperature change, for reasons discussed, yet for many purposes the deviation therefrom may be ignored. It is recommended that the binary time constant of all such machines may be adopted, where practical, for industrial use.

In rotating machines, there are two thermal time constants, the constant-loss time constant, and the variable-loss time constant. The latter, expressed as a binary constant, is the practical one presenting itself for use.

The binary thermal time constant has also useful applications in correcting the final ambient temperature during a continuous-load test, when the ambient temperature has been observed to change.

It is proposed to discuss the nature, applicability and advantages of the thermal time constants of dynamo machines, from an engineering standpoint. Although, broadly speaking, the subject is not new, it is believed that certain new branches of it are here presented for consideration.

Steady State Thermal Condition

We may assume, to begin with, that a dynamo machine is operated continuously under a steady load, and in a place where the whole environment (air, walls, floor and ceiling) is maintained at a steady ambient temperature T_a deg. cent. In practise, these conditions can only be imperfectly realised, and the temperature of the environment fluctuates with time, besides being subject to some variation in different parts at any one moment. Under the conditions assumed, however, the machine will attain eventually a steady thermal condition. We may assume that, at least as a first approximation, the thermal conductance of the steel stator framework and rotor core are sufficiently great to maintain a virtually uniform temperature in all their parts. The insulated windings, however, when steadily heated by the working currents, may develop very appreciable thermal drops, or differences of temperature, in different parts, owing to the interposition of thermal resistance in the insulating materials. Setting aside these differences for the present, we may assume that the whole machine arrives at a steady maximum temperature T_m deg. cent. or attains a rise of temperature above the environment of

$$\Theta_0 = T_m - T_a \qquad \text{deg. cent.} \qquad (1)$$

The heat dissipated from the machine to the environment, due to the elevation of temperature, escapes by three different ways,—conduction, radiation and convection. The quantitative laws of these three modes of dissipation are very different; but it is generally admitted that, within the range of working temperatures permitted in dynamo machines, the dissipation may be regarded as proportional to the temperature elevation, and also that most of the heat in modern open machines is dissipated by fluid convection; *i. e.*, by circulating air, in the case of generators and motors, and by circulating oil in the case of transformers. Consequently, if p watts are steadily generated in the machine as heat, the thermal dissipation must also amount to p watts, or

$$p = \Theta_0 \, s \qquad \text{watts} \qquad (2)$$

where s is the thermal dissipation coefficient of the machine, in watts per deg. cent. temperature elevation, including all three modes of dissipation. The dissipation coefficient s might be measured in simple cases by measuring the internally wasted power p, and the maximum temperature elevation Θ_0; but for ordinary purposes, s does not require to be known with precision. It is evident that s increases with the size of

*Harvard University and the Massachusetts Institute of Technology, Cambridge, Mass.

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 9-13, 1925.

machine for any given type; because the thermal waste of energy p, at rated load, increases with the size, while Θ_0, the temperature elevation under rated load, remains the same, or nearly the same.

Maximum Temperature Permissible

The modern theory on which the thermal rating of dynamo machinery is based, considers that there is a certain working temperature, above which the insulating material undergoes thermolysis or active deterioration. This is the critical temperature for the type of insulation employed. Below the critical temperature, it is supposed that the working lifetime of the insulation is indefinitely long. The hottest spot on the conductor of the machine is therefore at all times to be kept from exceeding the critical temperature, which, for class A insulating materials of impregnated cellulose, is at present set at 105 deg. cent. The hottest spot in the winding of a machine may not be accessible to temperature measurement, and must ordinarily lie on the inner surface of the insulation, next to the copper conductor. By allowing a conventional drop of temperature of 15 deg. cent. between the hottest internal spot of the insulation and those external parts into or onto which exploring thermometers may be applied, the maximum permissible observable temperature under continuous rated load becomes 90 deg. cent. by thermometer. Field windings may have their average temperatures conveniently measured by resistance, and for such measurements a conventional drop of 10 deg. cent. is taken as developed between the hottest spot and the measured value.

Available Output as Dependent on Temperature Rise

It is generally accepted, as the result of experience, that for practical purposes, the ultimate temperature rise at normal sea-level barometric pressure is independent of the initial and ambient temperature within the usual range. Thus, whether we operate a machine in a cool, outdoor space at 10 deg. cent., or in a warm engine room at 40 deg. cent., the rated output of the machine, steadily maintained, will bring about the same ultimate temperature rise of say 50 deg. cent.; so that the outdoor machine would show 60 deg. cent., and the engine-room machine 90 deg. cent. This independence of the temperature rise greatly simplifies the discussion. On the other hand, the density of the air, as determined by the local reading of the barometer, has a marked influence on the dissipation constant s of rotating machinery; because although the radiation of heat and conduction of heat by solids are independent of the air density, the convection of heat by air circulation is immediately affected. By International Electrotechnical Commission (I. E. C.) agreement, no correction needs to be introduced until the elevation is 1000 meters above sea level; although a graded, rather than a sudden, correction would be logically preferable.

If the loss of energy in a machine were always in direct proportion to the output; *i. e.*, if the efficiency were constant at all loads, the ultimate temperature elevation by (1) might be expected to increase directly with the load. If the rated output ultimately produced 50 deg. cent. rise, half the rated output might be expected to produce 25 deg. cent. In practise, however, the losses increase more rapidly than the output, and different machines differ in this respect. Consequently, the ultimate temperature rise increases faster than the output. If we plot the observed maximum temperature rise against output, we obtain a rising curved line, the precise algebraic expression for which may be complicated. If, however, we confine ourselves to outputs between say 50 per cent above and 50 per cent below the normal rated output, we may expect to find that the ultimate temperature rise Θ_0 is, to a first approximation, a simple power of the output or

$$\Theta_0 = c\,P^n \qquad \text{deg. cent.} \quad (3)$$

where c is a constant, P the watts output (maintained long enough to reach substantially constant maximum rise) and Θ_0 is the rise in deg. cent. corresponding thereto. This means that if the output and temperature rise are plotted on logarithm paper, the graph will be approximately a straight line. This is indicated in Fig. 1, where the abscissas are in percentage of the rated load, and the ordinates indicate the ultimate observed temperature rise. Thus at 100 per cent of rated load, the observed temperature rise is 43 deg. cent. and at 125 per cent of rated load, it is 64 deg. cent. The straight line $A\,O\,C$ may be taken as representing the behavior of temperature rise versus output between 50 per cent and 150 per cent of rated load, for the particular machine considered. Then the exponent n of formula (3) is the ratio of $O\,B$ to $A\,B$ in the figure. This is nearly 1.8 in the case shown, so that over the range of load considered, the temperature rise varies approximately as the 1.8th power of the load. Reciprocally, the output varies as the $1/n$th power of the temperature rise, or in the ratio $A\,B : B\,O$, which is 0.56 in Fig. 1. The output in this case varies as the 0.56th power of the temperature rise.

In order to know, with reasonable precision, how the temperature rise of a machine behaves with respect to sustained outputs, we need either a diagram like Fig. 1, or the value of the *temperature—output exponent n* in (3). This value differs with the size, type and make of machine. It commonly lies between 1.4 and 2.0. Equivalent information would be the temperature rise at say 25 per cent sustained overload.

In order, therefore, that the particular machine of Fig. 1 should not develop a higher observable thermometer temperature than 90 deg. cent., the output should be 108 per cent for an ambient temperature of 40 deg. cent., 120 per cent for an ambient temperature of 30 deg. cent., and 130 per cent for an ambient temperature of 20 deg. cent. Good operating practise might call, however, for some reduction of these loads, as no margin would be allowed on them for accidental variations in

ambient temperature or other irregularities of service.

The present I. E. C. international rating of a machine, with class A insulation, calls for an ultimate temperature elevation of 50 deg. cent. under continuous load, as the test rating. The maker's rating would presumably be slightly less, so as to fall within the test rating. The machine whose thermal behavior is indicated in Fig. 1 would be 7 deg. cent. below the test rating, or its rating could be increased 8 per cent without exceeding the I. E. C. limit.

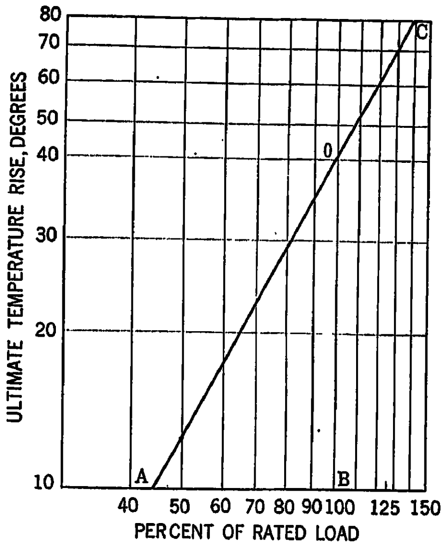

FIG. 1—APPROXIMATE STRAIGHT LINE RELATION BETWEEN ULTIMATE TEMPERATURE RISE AND STEADY LOAD FOR A DYNAMO MACHINE

THE TRANSIENT STATE OF TEMPERATURE ELEVATION

When the output of a machine is changed abruptly from one steady value to another, or when at constant output the ambient temperature changes quickly from one steady value to another, the thermal state of the machine changes slowly from the initial condition to a final condition, corresponding to the impressed change. The transition is a transient phenomenon; although it may require many hours to complete, within the limits of engineering measurements, and theoretically the full transition requires infinite time. From an engineering viewpoint, the temperature change in the machine is a transient. It has long been known[1] that under the assumed limitation of constant losses in the machine during the transition, the transient is a simple exponential transient, like that of the current strength in a simple continuous-current circuit containing both resistance and inductance. It has recently been shown by P. Girault[2] that the temperature transient is still simply exponential when the iron losses are constant, but the copper losses increase according to the resistance temperature coefficient of the windings.

It is proposed to carry this proposition here one stage further, and to show, on the assumption that the iron losses also follow a straight line law of change from the initial to the final temperature, the change in temperature of the machine will remain a simple exponential transient, with a time-constant curve.

Fig. 2 indicates a simple circuit of resistance R, and non-ferric or air-cored inductance $\mathfrak{L}$, carrying a steady initial current of I_1 amperes from a storage battery of negligible resistance, through a recording oscillograph O. A switch, S enables the e. m. f. of the battery E to be suddenly increased from 20 to 50 volts, or suddenly diminished from 50 to 20. A sensitive relay A, automatically inserts a protective resistance r in circuit with the upper part of the battery, when the switch S places that battery on short-circuit.

EXPONENTIAL TIME CONSTANT τ_ϵ

If I_1 be the initial steady current strength (amperes) and I_2 the final steady current, after throwing the switch at time $t = 0$, the transient current i at any intermediate instant, according to well-known principles, is

$$i = I_2 + (I_1 - I_2)\,\epsilon^{-\frac{t}{\tau}} \quad \text{amperes} \quad (4)$$

where ϵ is 2.71828 . . ., the Napierian base and

$$\tau = \mathfrak{L}/R = \tau_\epsilon \quad \text{seconds} \quad (5)$$

a time constant, equal to the inductance in henries divided by the resistance in ohms, which is 0.005 second

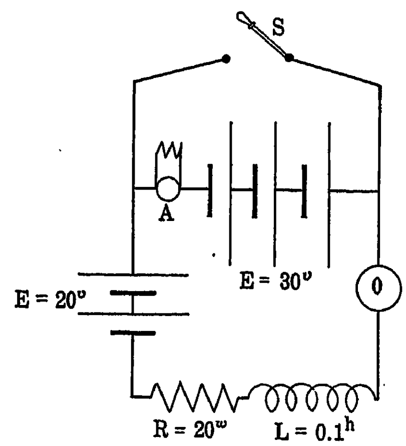

FIG. 2—SIMPLE CONTINUOUS-CURRENT CIRCUIT FOR DISPLAYING A SIMPLE EXPONENTIAL TRANSIENT

in the case of Fig. 2, and which we may call an *exponential time constant*, denoted by the symbol τ_ϵ, to distinguish it from other time constants to be considered later.

Fig. 3 indicates the transient current curve $A\ B\ C$ . . . $N\ O\ P$, on opening switch S, as we might expect to

2. "Sur l'échauffement d'un organe de machine électrique soumis à des pertes dans le fer constantes, et à des pertes par effet Joule," P. Girault, *Rév. Gén de l'Electricité.* 2nd & 9th Dec. 1922, Vol. XII, pp. 873 and 874; also 28th July and 4 Aug. 1923, Vol. XIV, pp. 115 and 147.

find it recorded by the oscillograph O Fig. 2. The current starts at $I_1 = 1.0$ ampere for $t = 0$. After the lapse of τ_ϵ, one exponential time constant, it has reached C, at 1.948 amperes, having risen 0.948 out of the total change

$$\Delta = I_2 - I_1 = 1.5 \quad \text{amperes} \quad (6)$$

that it has to cover. The fraction $0.948/1.5 = 0.6321$, may be called the *attainment*, at the point C considered. The remainder Cc,

$$\delta = I_2 - i = 0.552 \quad \text{amperes} \quad (7)$$

is what is left to be overcome. The fraction

$$\frac{\delta}{\Delta} = \frac{0.552}{1.5} = 0.3679$$

may be called the *deficiency* at this point. At any instant, the sum of the attainment and the deficiency is unity. At C, one exponential time constant from A, the deficiency is always $1/\epsilon$, or 36.79 per cent, and the attainment 63.21 per cent.

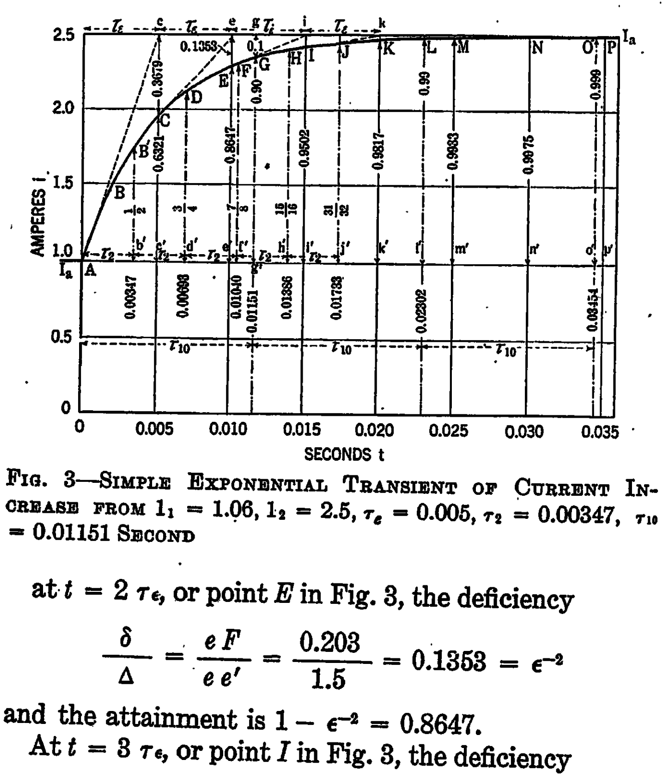

FIG. 3—SIMPLE EXPONENTIAL TRANSIENT OF CURRENT INCREASE FROM $I_1 = 1.06$, $I_2 = 2.5$, $\tau_\epsilon = 0.005$, $\tau_2 = 0.00347$, $\tau_{10} = 0.01151$ SECOND

at $t = 2\,\tau_\epsilon$, or point E in Fig. 3, the deficiency

$$\frac{\delta}{\Delta} = \frac{e\,F}{e\,e'} = \frac{0.203}{1.5} = 0.1353 = \epsilon^{-2}$$

and the attainment is $1 - \epsilon^{-2} = 0.8647$.

At $t = 3\,\tau_\epsilon$, or point I in Fig. 3, the deficiency

$$\frac{\delta}{\Delta} = \frac{i\,I}{i\,i'} = \frac{0.0747}{1.5} = 0.0498 = \epsilon^{-3}$$

and the attainment is $1 - \epsilon^{-3} = 0.9502$. This is probably the simplest statistical relation to express, or to remember, concerning an exponential time constant; *i. e., that in three of them, the deficiency is very nearly 5 per cent.*

It is to be noted that at any point of the curve, such as C, Fig. 3, the tangent $C\,e$ cuts the final current line I_2, at a time distance beyond c, of $c\,e$, equal to the exponential time constant. Consequently, if we know the final steady current I_2, and can trace the curve of the transient at any point with sufficient precision to draw the tangent, we can measure the time constant τ_ϵ graphically, the subtangent on the final line I_2 being constant, and equal to τ_ϵ.

We may rewrite equation (4) in the form

$$i = I_2 + \Delta\,\epsilon^{-\frac{t}{\tau_\epsilon}} \quad \text{amperes} \quad (8)$$

or in the case of Fig. 3

$$i = 2.5 - 1.5\,\epsilon^{-\frac{t}{0.005}} \quad \text{amperes} \quad (9)$$

Because $I_1 - I_2$ is negative, we apply the negative sign to Δ.

The exponential time constant is, from a mathematical standpoint, the fundamental property of the simple exponential transient; but it is awkward to employ practically, or to explain in simple terms. When we say that after the lapse of one exponential time constant the deficiency is 1/2.71828, we do not convey a simple conception, except to a person familiar with the mathematical subject of exponentials.

BINARY TIME CONSTANT τ_2

We may, however, restate (8) as follows

$$i - I_2 = \delta = \Delta\,\epsilon^{-\frac{t}{\tau_\epsilon}} \quad \text{amperes} \quad (10)$$

$$\frac{\delta}{\Delta} = \epsilon^{-\frac{t}{\tau_\epsilon}} = \epsilon^{0.69315 \times \frac{t}{0.69315}} \text{ deficiency ratio} \quad (11)$$

But

$$\epsilon^{0.69315} = 2 \quad (12)$$

so that

$$\frac{\delta}{\Delta} = 2^{-\frac{t}{0.69315\tau_\epsilon}} = 2^{-\frac{t}{\tau_2}} \text{ deficiency ratio} \quad (13)$$

where

$$\tau_2 = 0.69315\,\tau_\epsilon \quad \text{seconds} \quad (14)$$

That is, we may transfer the deficiency from the Napierian base ϵ to base 2, and substitute for the exponential time constant a new time constant τ_2, which is very nearly 70 per cent of τ_ϵ. This new time constant τ_2 may be called, for distinction, the[3] *binary time constant.* The binary time constant would then correspond to what has already been known for some years as the "Period," or "Half-value period," in the science of Radio-activity, and in the measurement[4] of radio-active decay.

In Fig. 3, the time $A\,B' = 0.00347$ second, is shown as equal to the binary time constant τ_2. At the time $t = \tau_2$, the current will have reached B', and the deficiency δ/Δ at this moment is 2^{-1} or ½. The attainment is likewise ½. Again, at $t = 2\,\tau_2 = 0.00693$ second $= d'$, the deficiency is $2^{-2} = ¼$, and the attainment $1 - 2^{-2} = ¾$. Similarly, at $t = 3\,\tau_2 = 0.0104 = f'$, the deficiency is $2^{-3} = ⅛$, and the attainment $1 - 2^{-3} = 7/8$, corresponding to point F. Five binary time constants are marked on Fig. 3, as far as j', where

3. "Time Constants for Engineering Purposes in Simple Exponential Transient Phenomena" by A. E. Kennelly, *Proc. Nat. Acad. Sciences.* Nov. 1924.

4. "Practical Measurements in Radio-Activity." Makower and Geiger, 1912, p. 81.

the deficiency is $2^{-5} = 1/32$, and the attainment 31/32.

The binary time constant τ_2 is just as sound mathematically as the fundamental exponential time constant τ_ϵ, and is always approximately 70 per cent of the latter. The binary time constant has the practical advantage that it is easier to remember and explain. In τ_2, the attainment and the deficiency are both ½, or 50 per cent. In the next τ_2, the attainment is to ½ of what was left over, or to ¾, and so on. This is an easy concept to remember or to explain. It is recommended that, in engineering, exponential time constants be replaced by binary time constants.

Decimal Time-Constant τ_{10}

Although from the practical and descriptive standpoints, the binary time constant τ_2 has marked advantages over the exponential time constant τ_ϵ, neither of these lends itself to ease of computation at indiscriminate values of t. We may however rewrite (11) in the form

$$\frac{\delta}{\Delta} = \epsilon^{2.3026 \times -\frac{t}{2.3026\tau_\epsilon}} \qquad \text{deficiency ratio} \qquad (15)$$

$$= 10^{-\frac{t}{\tau_{10}}} \qquad \text{deficiency ratio} \qquad (16)$$

where

$$\tau_{10} = 2.3026\,\tau_\epsilon \qquad (17)$$

By substituting the *decimal time constant* τ_{10} for the exponential time constant, we obtain in (16) an expression for the deficiency at any assigned value of t, which can be evaluated quickly with the aid of any ordinary table of logarithms.

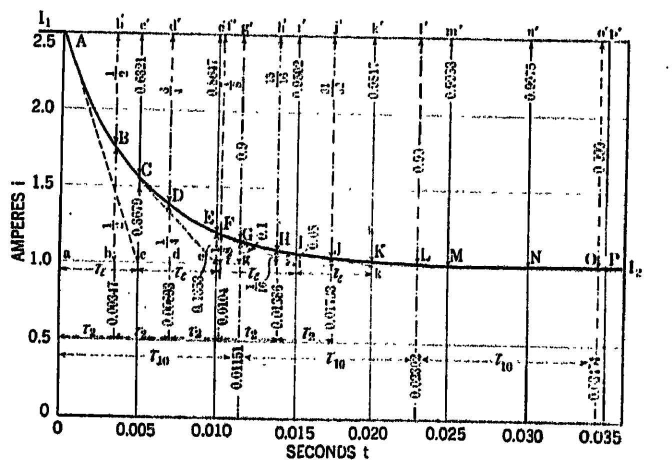

Fig. 4—Simple Exponential Transient of Current Decrease from $I_1 = 2.5$ to $I_2 = 1.0, \tau_\epsilon = 0.005, \tau_2 = 0.00347, \tau_{10} = 0.01151$ Second

In Fig. 3, the point g', where $t = 0.01151$, marks one decimal time constant. At this moment the current is at G, and the deficiency is 10^{-1}, or 0.1. The attainment is $(1 - 10^{-1})$ or 0.9. Again, at $t = 2\,\tau_{10}$, the current has reached L, where the deficiency is 10^{-2} or 0.01, and the attainment is $1 - 10^{-2}$, or 0.99. At $t = 3\,\tau_{10}$, the deficiency, at 0, is 10^{-3} or 0.001. From a practical standpoint, the decimal time constant is too long, since the attainment is then 0.9.

Fig. 4 shows the corresponding transient of decrease, when the switch S of Fig. 2 is closed. The curve in Fig. 4 is the same as in Fig. 3, but inverted. The same formulas apply and

$$i = 1.0 + 1.5\,\epsilon^{-\frac{t}{\tau_\epsilon}} \qquad \text{amperes} \qquad (18)$$

All three time constants τ_ϵ, τ_2 and τ_{10} are indicated in Fig. 4, and their applications are the same as in Fig. 3.

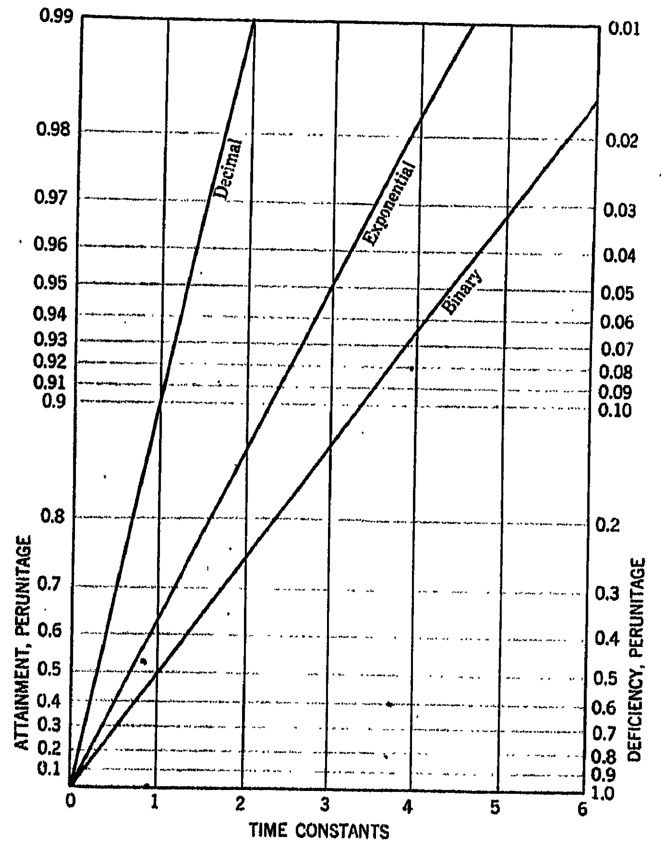

Fig. 5—Rectilinear Attainment-Time Constant Diagram on Inverted Arith-Log Paper, for Decimal, Exponential and Binary Time Constants

Straight-Line Graphs of Deficiency and Attainment on Inverted Arith-Log Paper

Fig. 5 shows that the graphs of attainment and deficiency become straight lines on inverted arith-log paper for all three time constants. Thus at one time constant, the attainment is 0.5 with the binary, 0.632 with the exponential, and 0.9 with the decimal time constant. With the aid of this chart, computations relating to simple exponential transients may be greatly simplified, for most engineering purposes. The temperature rise of any machine, under steady load and steady ambient temperature, will trace out a straight line with time as in Fig. 4, if the transient is strictly exponential and the final rise is known.

Time Constants Applied to Transient Temperatures of Dynamo Machines on Basis of Constant Losses During Transition

The following is a brief presentation of the well-known theory of transient temperatures in dynamos under steady load. It is assumed that the impressed speed is constant, in the case of a generator, impressed voltage in the case of a motor, impressed voltage and frequency in the case of a transformer. The machine is supposed to comprise a single thermal body, of perfect thermal conduction throughout. The machine starts at $t = 0$ hours, from an initial and constant ambient temperature T_a deg. cent., under continuous load, finally reaching a final temperature $T_m = T_a + \Theta_0$ deg. cent. The power losses in the machine remain constant at p_0 watts. The dissipation constant s of formula (2) is constant and also the thermal capacity k, in watthours absorbed per deg. cent. elevation of temperature. Then if θ is the instantaneous temperature of the machine at any time t, the heat generated in the machine during any short interval of time dt is $p_0\ dt$ watthours. During the same interval, the heat dissipated by the machine is $\theta\, s\, .\, dt$ watthours. If during the same, the temperature of the machine rises by $d\theta$ deg. cent. the heat absorbed in the machine will be $k\, .\, d\theta$ watthours. Equating the heat generated to the heat dissipated and absorbed,

$$p_0\, .\, dt = \theta\, s\, .\, dt + k\, .\, d\theta \quad \text{watthours} \quad (19)$$

Let

$$p_0 = \Theta_0\, s \quad \text{watts} \quad (20)$$

by (2). Then

$$(\Theta_0 - \theta)\, s\, .\, dt = k\, .\, d\theta \quad \text{watthours} \quad (21)$$

or

$$(\Theta_0 - \theta)\, .\, dt = \tau_\epsilon'\, .\, d\theta \quad \text{deg. cent hours} \quad (22)$$

where

$$\tau_\epsilon' = \frac{k}{s} \quad \text{hours} \quad (23)$$

τ_ϵ' is an exponential time constant. It may be called the *constant-loss time constant.*

Hence

$$\frac{d\theta}{\Theta_0 - \theta} = \frac{dt}{\tau_\epsilon'} \quad \text{numeric} \quad (24)$$

and

$$-\,\text{logh}\,(\Theta_0 - \theta) = \frac{t}{\tau_\epsilon'} - c \quad \text{numeric} \quad (25)$$

where logh signifies the hyperbolic or Napierian logarithm, and c is an integration constant.

Then

$$\Theta_0 - \theta = C\, \epsilon^{-\frac{t}{\tau_\epsilon'}} \quad \text{deg. cent.} \quad (26)$$

When $t = 0$, $\theta = 0$ and $C = \Theta_0$.

Thus

$$\theta = \Theta_0 - \Theta_0\, \epsilon^{-\frac{t}{\tau_\epsilon'}} \quad \text{deg. cent. rise} \quad (27)$$

$$= \Theta_0 - \Theta_0\, 2^{-\frac{t}{\tau_2'}} \quad \text{“ “ “} \quad (28)$$

$$= \Theta_0 - \Theta_0\, 10^{-\frac{t}{\tau_{10}}} \quad \text{“ “ “} \quad (29)$$

These results are in accordance with those obtained for the continuous-current transient of Figs. 2, 3 and 4, using the three time constants mentioned above.

The instantaneous temperature elevation θ will be completely specified if we know the ultimate temperature rise Θ_0, and any one of the three time constants. The easiest time constant to measure is probably τ_ϵ, from a tangent to the curve of initial heating, assuming that the ultimate rise Θ_0 is known or is measured. We do not need to know either k or s. The attainment at any time is θ / Θ_0, and the deficiency $(\Theta_0 - \theta)/\Theta_0$.

Cooling Transient

The curve of cooling of a machine will be identical with that of heating inverted (see Figs. 3 and 4), if the dissipation constant s remains the same. In the case of an air-cooled transformer, this may be expected; but in the case of a generator or motor, this can only be expected if the speed of rotation remains the same during both cooling and heating. It is evident that s will be greatly diminished if the machine is stopped while cooling.

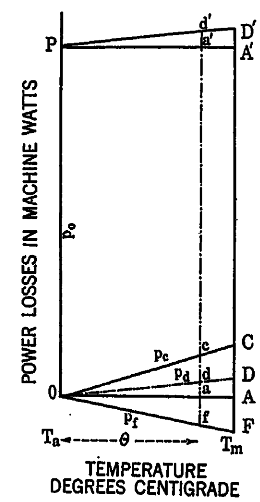

Fig. 6—Diagram of Assumed Straight Line Losses at Constant Output as Function of Temperature

Time Constants Applied to Straight-Line Change of Losses During Transition

Fig. 6 represents an ideal diagram of losses in a machine operated at a steady output, commencing at an initial and ambient temperature T_a and terminating at a final temperature T_m deg. cent. $O\,P$ represents the internal losses p_0 watts converted into heat. Of this amount, a certain part, not definitely known, is in the copper windings, another part in the steel frames of rotor and stator, while the remainder will be in frictions of various kinds. If p_0 were constant throughout the transition, the loss would reach $A\,A'$ at the final temperature. Suppose, however, that the copper losses increase by an amount $A\,C$ along the straight line $O\,C$. This would be true if the current strengths in the windings remained constant, and the copper resistances increased with temperature in the regular way. Actually, the currents may have to be re-adjusted as the temperature increases; while the electric resistance of

carbon brushes, if used, may diminish. It will be sufficient that the actual change in copper losses does not depart markedly from a straight line $O\,C$. Again, the iron losses are likely to diminish as the temperature rises, because the resistance of the iron to eddy currents will increase; while the hysteresis losses remain substantially unchanged. We may assume that the change in iron loss will amount, at the maximum temperature, to a reduction $A\,F$ watts, and that it will follow a straight line $O\,F$. Actually, the change will be more complex; but it will suffice for most practical purposes if the deviation from the assumed straight line $O\,F$ is not serious. The total change of power losses over the transition will then be say $A\,D$, plus or minus, according to the predominance of $A\,C$ or $A\,F$. The total change with temperature will then also occur along a straight line $O\,D$, so that the total losses will follow the straight line $P\,D'$.

Let p be the power liberated in the machine at temperature elevation θ deg. cent. Then

$$p = p_0 + p_c - p_f \qquad \text{watts} \quad (30)$$

$$= p_0 + c\,\theta - f\,\theta = p_0 + d\,.\,\theta \qquad \text{"} \quad (31)$$

where c is the ratio $A\,C : O\,A$ or $\tan A\,O\,C$,

and f " " " $A\,F : O\,A$ " $\tan A\,O\,F$

" d " " " $A\,D : O\,A$ " $\tan A\,O\,D$

Then at any temperature elevation θ, the power liberated in the machine being $p_0 + d\,.\,\theta$, the heat liberated in time dt is

$$p\,.\,dt = (p_0 + d\,.\,\theta)\,dt \qquad \text{watthours} \quad (32)$$

The heat dissipated in the same time will be $\theta\,s\,.\,dt$ watthours; while the heat absorbed in the machine by a simultaneous small rise of temperature $d\theta$, is $k\,.\,d\theta$ watthours. Equating the gain and loss of heat, as in (19)

$$(p_0 + d\,.\,\theta)\,dt = \theta\,s\,.\,dt + k\,.\,d\theta \qquad \text{watthours} \quad (33)$$

Let $p_0 = \Theta_0\,s$, as before.

Then $\{\Theta_0\,s - \theta\,(s-d)\}\,dt = k\,.\,d\theta$ watthours (34)

or

$$\text{or} \quad \left\{ \Theta_0\left(\frac{s}{s-d}\right) - \theta \right\} dt = \left(\frac{k}{s-d}\right) d\theta \qquad \text{deg. cent. hours} \quad (35)$$

$$\text{or} \quad (\Theta - \theta)\,dt = \tau_\epsilon\,.\,d\theta \qquad \text{deg. cent. hours} \quad (36)$$

$$\text{where} \quad \Theta = \Theta_0\left(\frac{s}{s-d}\right) \qquad \text{deg. cent.} \quad (37)$$

$$\text{and} \quad \tau_\epsilon = \frac{k}{s-d} = \tau_\epsilon'\left(\frac{s}{s-d}\right) \qquad \text{hours} \quad (38)$$

τ_ϵ may be called the straight-line variable-loss time constant, or simply the *variable-loss time constant.*

Equation (36) corresponds to (22), and its solution is

$$\theta = \Theta - \Theta\,\epsilon^{-\frac{t}{\tau_\epsilon}} \qquad \text{deg. cent. rise} \quad (39)$$

$$= \Theta - \Theta\,2^{-\frac{t}{\tau_2}} \qquad \text{deg. cent. rise} \quad (40)$$

$$= \Theta - \Theta\,10^{-\frac{t}{\tau_{10}}} \qquad \text{deg. cent. rise} \quad (41)$$

The effect of the variation of losses with temperature is to change both the ultimate rise and the time constant in the ratio $s/(s-d)$. If the losses are greater at the higher temperature d is positive; so that both Θ and τ are increased. The temperature elevation will remain a simple exponential transient, the curve of which will correspond to that of Fig. 3 for rises, and to that of Fig. 4 for falls. The exponential time constant of the curve, as obtainable from the tangent, will be τ_ϵ, and very nearly 70 per cent of this will be the binary time constant τ_2.

Cooling Curve with Normal Dissipation and Load Removed

If the load were cut off the machine and all excitation removed, while the normal dissipation was maintained by continued rotation, the power liberated in the machine would be zero. Equation (33) then becomes

$$0 = \theta\,s\,.\,dt + k\,.\,d\theta \qquad \text{watthours} \quad (42)$$

$$0 = \theta\,.\,dt + \tau_\epsilon'\,.\,d\theta \qquad \text{deg. cent. hours} \quad (43)$$

$$-\,\theta\,.\,dt = \tau_\epsilon'\,.\,d\theta \qquad \text{deg. cent. hours} \quad (44)$$

$$-\,\frac{dt}{\tau_\epsilon'} = \frac{d\theta}{\theta} \qquad \text{numeric} \quad (45)$$

the solution of which is

$$-\,\frac{t}{\tau_\epsilon'} = \text{logh}\,\theta + c \qquad \text{numeric} \quad (46)$$

$$\text{Hence} \quad \theta = \Theta\,\epsilon^{-\frac{t}{\tau_\epsilon'}} \qquad \text{deg. cent. rise} \quad (47)$$

The time constant of this falling transient is not τ_ϵ but τ_ϵ'. Consequently, if the losses vary with the temperature at constant output, the curves of transient temperature will be simply exponential, whether with load applied or with load removed; but the time constants will differ. But since it is very unusual to run a machine steadily without load or excitation, the constant-loss time constant τ_ϵ' does not present itself in practise, and only the variable-loss time constant τ_ϵ comes into operation.

Although, under the above assumptions, the transient temperature of a dynamo machine in continuous operation from one steady load to another is a time-constant transient, yet it will be found on examination of such temperature curves that they deviate somewhat from strict time-constant curves, although for many practical purposes the deviations may be ignored. A principal cause for deviation is that the windings of a machine, with their copper losses, form one thermal system, and the steel structures, with their iron losses, form another. Each system has its own k, s and time constant. If the two systems were thermally independent, they could be measured apart; or, if the two systems were united by perfect thermal conduction, they would blend into

one with a single time constant, as has been assumed above. But they are actually only semi-detached, being in mutual communication through thermal resistances; so that each tends to modify the behavior of the other, in a rather complicated way. The curves of transient temperature of the copper are affected by the influence of the associated steel structures, and reciprocally; so that neither can display a true time-constant curve.

By the courtesy of Mr. H. M. Hobart, a number of curves of transient temperature, in passing from one steady state to another, have been procured and examined for various types and sizes of machines. Two only of these are presented here, as examples.

Fig. 7 gives the observed hottest stator lamina temperature, as obtained by thermometer, on a particular 30-h. p., 3-phase, 6-pole induction motor, operated under steady load, at 500 rev. per min., from a 440-volt, 25 ~ circuit. The ambient temperature was 16 deg. cent. and remained within 1 deg. cent. of that value during the test. The small black circles, at half-hour intervals, indicate the observed temperature rise; while the curve $A\ B\ C - H$ shows a time constant computed on the basis of $\Theta = 37$ deg. cent. ultimate rise.

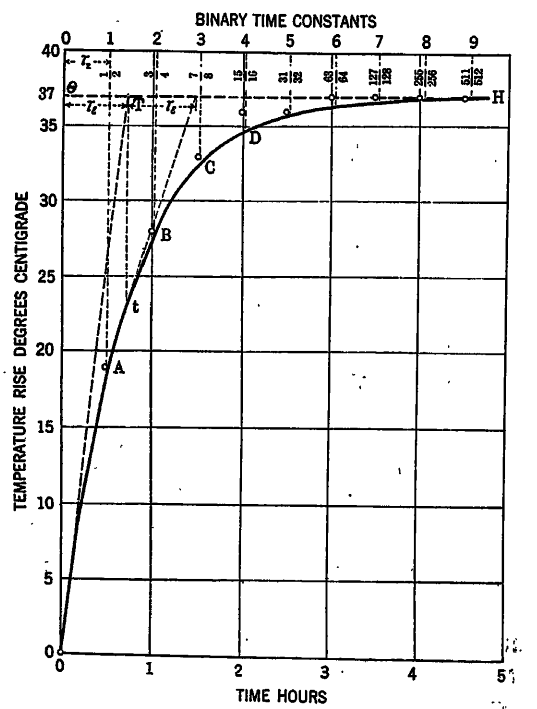

FIG. 7—TEMPERATURE RISE OF HOTTEST STATOR LAMINA IN INDUCTION MOTOR

The observations do not depart more than 1.5 deg. cent. from the computed curve at any point, but indicate a tendency to exceed the curve near the middle of the run. Two exponential time-constants of about 44 minutes each are marked off on the 37 deg. rise line $T\ H$, by tangents from the curve. The binary constant τ_2 of about 30.5 min., is obtained by taking 70 per cent of τ_ϵ. Nine of these binary time constants are marked off. At the last, the rise should be theoretically within 1/512 of the final value.

Fig. 8 gives the corresponding data for a particular 4-pole, 50-h. p., d-c. motor, operating at 1075 rev. per min., on a 230-volt circuit. The motor was operated for five and one-quarter hours steadily, at rated load, and then after 15 min. intermission, at 125 per cent of rated load, for two hours more. The black circles give

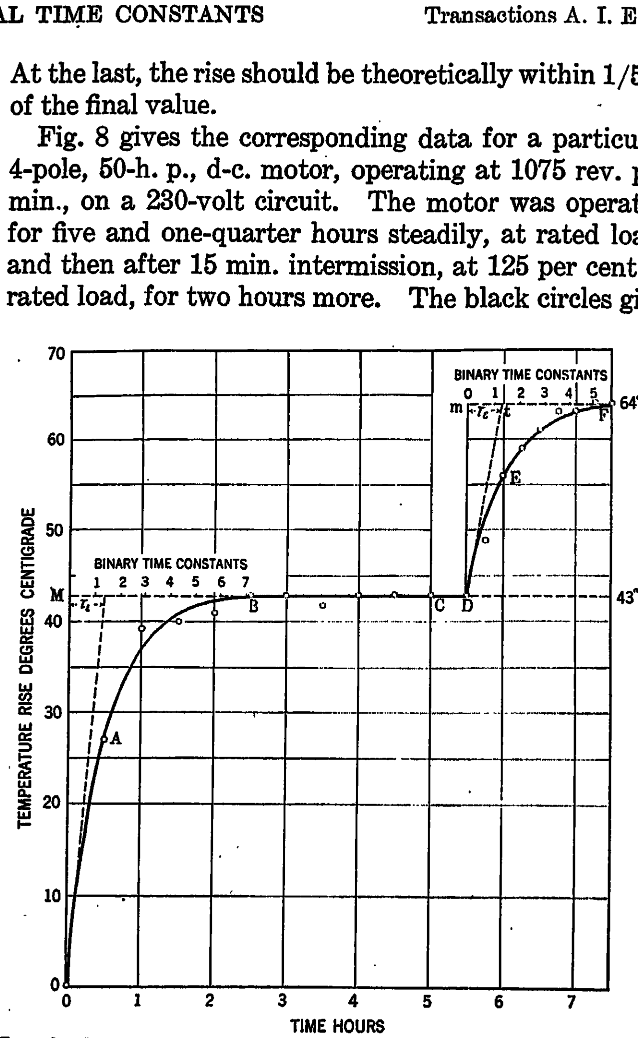

FIG. 8—TEMPERATURE RISE OF COMMUTATING FIELD WINDING IN D-C.-MOTOR

the observed temperature rise on the commutating field winding, by thermometer, above an ambient temperature of 15 deg. cent. at the beginning of the test. This ambient temperature rose steadily to 22 deg. cent. at the end of the run. The curve $O\ A\ B\ C$ is the computed time-constant curve, based upon an ultimate temperature rise of 43 deg. cent. The initial tangent $O\ T$ cuts this horizontal line at T, marking off an exponential time constant $M\ T = \tau_\epsilon$, of 30 min. The binary time constant was thus approximately 21 min. Seven binary time constants are marked off along $M\ B$, where the deficiency would be 1/128.

The overload-run temperature time-constant curve is $D\ E\ F$ based on a new ultimate rise Θ of 21 deg. cent. The initial tangent marks off an exponential time constant $m\ t = \tau_\epsilon$, of 30 min. as before, and five binary time constants are marked off along the ultimate-rise line $m\ F$. Half the ultimate rise should develop at 1, half the remainder at 2, and half the succeeding remainder at each successive binary time-constant interval.

It has recently been pointed out[5] that if after an

5. "The Temperature Rise of Electrical Machinery" by T. R. Rowlands, *The Electrical Review*, London, correspondence July 4th, 1924, page 11.

interval of t_1 hours from a starting point on an exponential heating curve like that of Fig. 3, the temperature elevation reached is θ_1, while after an interval of $t_2 = 2\,t_1$ hours, it has reached θ_2, then the ultimate rise should be

$$\Theta = \frac{\theta_1}{2 - \theta_2/\theta_1} \quad \text{deg. cent.} \quad \textbf{(47a)}$$

Correction for Change in Ambient Temperature During Run

If, as very frequently happens, the ambient temperature is observed to change during a run under steady load, some uncertainty develops as to the proper value to accept for the temperature rise Θ. The heat dis-

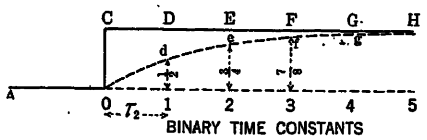

Fig. 9

sipated by the machine during the run tends to raise the ambient temperature. If the thermal time constant τ_2 were negligibly small, so that the temperature of the machine could follow impressed thermal forces without delay, the attained temperature elevation would always be equal to $T_m - T_a$; but there would be no need for carrying out a long continuous-load run, because such a machine would instantly reach its full temperature rise, on the application of the load. The longer the binary time constant, the greater the time needed for the machine to accommodate itself to a change in ambient temperature. Some correction of the observed temperature rise is therefore necessary for changes in ambient temperature. Such corrections should not require much computation, and should be

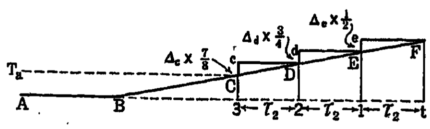

Fig. 10

easily applied; because with ordinary care, neither the change in ambient temperature nor the correction for it need be large.

In Fig. 9, the ambient temperature T_a, after pursuing the uniform stationary line $A\ B$, is supposed suddenly to rise by an amount Δ deg. cent. to C, and thereafter to continue unchanged with time, along the straight line $C\,D\,E\,F\,G\,H$. Commencing at O, the moment of change, binary time constants τ_2 are marked off along the time axis 1 2 3 4 5. After say three time constants have elapsed, the machine will theoretically have acquired at f, a thermal state corresponding to 7/8ths of the full change Δ, and no correction from the ambient temperature $T_a' = T_a + \Delta$ will ordinarily be required if Δ is small. The temperature elevation at any time after F will thus be

$$\theta = T_m - T_a' \quad \text{deg. cent. rise} \quad \textbf{(48)}$$

where T_m is the observed temperature of the machine. But immediately after the instant C Fig. 9, the ambient temperature should be reckoned as T_a and not T_a'; because the machine has not had time to respond. At D, after one time constant, the corrected value of T_a' would be $T_a + \Delta/2$. At E, it would be $T_a + 3\Delta/4$.

The conditions relating to Fig. 9 suggest the following simple approximate correction to be applied when the ambient temperature is changing. Suppose that the observed ambient temperature follows the lines $A\ B\ C\ D\ E\ F$ in Fig. 10, and that at the instant t, when the ambient is at F, and the temperature at some warm part of the machine under observation is then T_{mf}. Required the corrected ambient temperature T_{af}, so that the corrected temperature rise may be taken as

$$\theta_f = T_{mf} - T_{af} \quad \text{deg. cent. rise} \quad \textbf{(49)}$$

Find the variable-loss binary time constant τ_2 of the machine, as previously described. Measure off three of these time constants along the time axis, as at C, Fig. 10. Between C and D, the change was gradual; but assume that it occurred suddenly as $C\,c$. The corresponding sudden changes at D and E would have

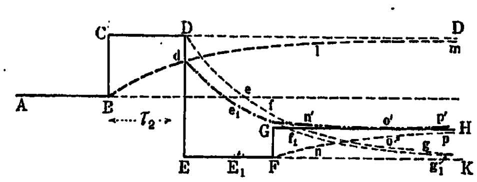

Fig. 11

been $D\,d$ and $E\,e$ deg. cent., respectively. Let the three disturbances be denoted as Δ_c, Δ_d and Δ_e, the signs of which are all the same in the case considered. Then

$$T_{af} = T_{ac} + \frac{7}{8}\,\Delta_c + \frac{3}{4}\,\Delta_d + \frac{1}{2}\,\Delta_e \ \text{deg. cent.} \quad \textbf{(50)}$$

In the case considered, with uniform ambient rise from C to F, the uncorrected ambient temperature would be $T_{ac} + 3\,\Delta_c$. The approximately corrected value would be, by **(50)**, $T_{ac} + 2\frac{1}{8}\,\Delta_c$.

In this approximate correction process, it is assumed that a change in ambient temperature which occurred 3 or more time constants back, has produced its full effect on the temperature of the machine.

Effects of Oppositely Directed Changes in Ambient Temperature

If the ambient temperature pursues in time the course $A\,B\,C\,D\,E\,F\,G\,H$, Fig. 11, changing its value suddenly at B, D and F, the effects successively produced in the inferred ambient temperature of the machine may be obtained by superposition. If the ambient temperature, after changing abruptly from B to C, were to

continue unchanged thereafter, it would follow the horizontal straight line $C\,D\,D'$, parallel to the time axis. The effective ambient temperature of the machine, with a binary time constant τ_2, would follow the time-constant curve $B\,d\,l\,m$, ultimately coinciding with $D\,D'$. Again, if the abrupt change from D to E in the minus direction, were followed by a stationary condition, the ambient temperature would pursue the straight line $E\,F\,K$. The effect of this negative change $D\,E$, acting alone, would be to produce the time-constant curve $D\,e\,f\,g$. The negative ordinates of this curve are now applied to the curve $d\,l\,m$, to produce the resultant curve $d\,e, f, g$. The third positive change $F\,G$, acting alone, would produce the time-constant curve $F\,n\,o\,p$. The positive ordinates of this curve, with respect to $F\,K$, are now applied to the previous resultant curve e, f, g, producing the final resultant $G\,n'\,o'\,p'$. The course of the effective ambient temperature is thus $B\,d\,e, G\,n'\,o'\,p'$, which happens to end close to the final actual ambient temperature H.

Approximate Correction of Ambient Temperature When Varying Oppositely

Applying the above principles to the general case of a slowly wandering ambient temperature, the changes of

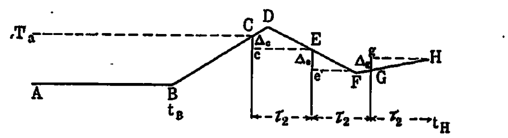

Fig. 12

which are kept relatively small, but have varying directions, we proceed as in Fig. 12; the method is the same as in Fig. 10, but the application is more general. Let $A\,B\,C\,D\,E\,F\,G\,H$ be the observed course of the ambient temperature with time. At the time t_H, corresponding to point H, it is required to find the approximate effective ambient temperature. Measure back three binary time constants along the curve, marking them off at G, E and C. It is assumed that T_{ac} the value at C, is the ambient temperature for correction. The changes in ambient $C\,c$, $E\,e$ and $G\,g$, occurring in each of the three time constants, are drawn. The hypothetical path of the ambient temperature is then $C\,c\,E\,e\,G\,g\,H$. It is assumed that the effects of these three sudden changes will be substantially the same as those of the wandering changes $C\,D\,F\,H$. Let the three hypothetical displacements be denoted by Δ_c, Δ_e and Δ_g, respectively. The first two have the $-$ sign and the last one the $+$ sign. Then

$$T_h = T_{ac} + \frac{7}{8}\,\Delta_c + \frac{3}{4}\,\Delta_e + \frac{1}{2}\,\Delta_g \text{ deg. cent.} \quad (51)$$

the proper signs of the Δ terms must be carefully followed.

In particular cases, a more elaborate correction formula may be called for. In such a case, the correction might be carried back to cover four binary time constants instead of three, and each time constant might be divided into two equal parts. There would then be eight perpendiculars of the type $C\,c$, $E\,e$ and $G\,g$, Fig. 12. Calling them $\Delta_a, \Delta_b \ldots \Delta_g, \Delta_h$, the factors to apply, with the proper sign in each case, may be taken as

$$\frac{15}{16}\,\Delta_a + \frac{9}{10}\,\Delta_b + \frac{7}{8}\,\Delta_c + \frac{4}{5}\,\Delta_d + \frac{3}{4}\,\Delta_e + \frac{13}{20}\,\Delta_f + \frac{1}{2}\,\Delta_g + \frac{3}{10}\,\Delta_h$$

Advantages and Disadvantages of a Long Time Constant in a Machine

A dynamo machine with a short time constant has the advantage that its temperature elevation follows closely upon the heels of impressed changes of load. The machine has a short thermal memory, and its previous history in service exerts a relatively small influence upon its instantaneous thermal state. If the ambient temperature changes, there is also less uncertainty as to the correction to be applied for the same, when measuring the temperature rise.

A machine with a long time constant has, however, one advantage in service. If the machine is called upon to supply a temporary overload, it may be able to do so without becoming overheated, by relying upon its heat storage capacity. If the duration of the overload is no more than one binary time constant, the overload will only be able, as we have seen, to develop half the ultimate temperature rise of that overload. Consequently, the duration that might be permitted to an overload increases with the time constant of the machine. It might readily happen that a central-station manager, desiring to purchase electric railway machines, under conditions where a certain overload period was expected, might decide in favor of a machine with a relatively long time constant, if in all other respects the machines submitted to his choice were substantially alike. It would be advantageous for him to utilize the longer time constant for carrying the overload, provided the proper maximum temperature limits were unexceeded. On the other hand, a long time-constant machine needs more careful supervision than a short-time-constant machine.

With equally effective ventilation, heavy machines tend to develop long time constants and light machines short time constants.

Complete Specification of Thermal Behavior in a Machine

Three quantities are theoretically necessary and sufficient for determining the thermal behavior of a machine under any assigned load schedule.

(1) The rated load temperature rise, or the maximum accessible temperature rise under continuous rated load.

(2) The corresponding temperature rise at some other steady load, such as 25 per cent below, or 25 per cent above, rated load. From this a chart like Fig. 1 can be prepared.

(3) The variable-loss time constant, and for practical purposes, preferably the variable-loss binary time constant.

No. 1, the rated-load temperature rise is regularly supplied by the manufacturer. No. 2 and No. 3 are not ordinarily stated for small machines. Indeed, it would be unreasonable to expect a maker to execute the tests on each machine for arriving at these two specifications. Nevertheless, the maker would probably know their numerical values approximately, from tests made on similar machines of the same type and size, so that there would probably be little difficulty in securing this information, within a degree of precision sufficient for operating purposes.

Summary of Deductions

(1) For operating purposes, it is requisite and desirable to have three specific thermal data concerning a machine, the rated load rise, another load rise, and the time constant.

(2) For practical purposes, the binary time constant is the best: but any one of the three time constants, exponential, binary or decimal, is readily convertible into the others.

(3) The binary time constant of a machine is the interval of time in which, when passing normally from one temperature to another under any steady load, the outstanding difference from the ultimate temperature is reduced by 50 per cent, or to one half.

(4) The curve of temperature of a machine under steady load, working from a steady ambient temperature, is approximately a time-constant curve.

(5) The true time-constant curve of temperature change against time makes a straight line on inverted arith-log paper when the final temperature is known.

(6) Changes in the ambient temperature observed during any steady-load run may be corrected for, in estimating the temperature rise, by a simple approximate process.

(7) A common value for the binary time constant of an ordinary generator or motor is less than one hour. In particular cases, however, and especially in air-cooled transformers, it may be several hours.

Discussion

V. Karapetoff: The use of exponential expressions for heating and cooling curves of machinery is quite old. I published a complete theory of such curves in my Laboratory Notes in 1906. See also my "Experimental Electrical Engineering," second edition, Vol. II, pp. 69 to 74. For a number of years we had at Cornell a student experiment on temperature rise in transformers using and checking exponential curves. However, the discrepancy with the observed results was so considerable that we dropped the theory and left only the measurements. As a result of study of various Institute papers on temperature rise in electrical machinery, I have come to the conclusion that the exponential theory, in the simple form used by the author, is inadequate to represent the observed facts even in simple stationary apparatus, not to speak of revolving machinery. I am therefore omitting this theory from the third edition of my laboratory book.

Some attempts have been made of late to differentiate among the various surfaces of a machine in their heat emission. See in particular G. E. Luke, A. I. E. E. Transactions, 1922, Vol. 41, p. 172; a bibliography is on p. 173. With two coefficients proposed by Mr. Luke, it is probably easier to approximate an experimental curve than with one time constant, only I would keep two separate expressions, with a finite difference of temperature between two parts of the machine, and not bunch them together.

It would hardly be wise to introduce the concept of an "over-all" thermal time-constant of a machine into our Standards, or even to encourage its use, thereby creating an impression that heating and cooling curves of machines follow a simple exponential law with any accuracy, until we have more assurance of this fact. It is desirable to continue both theoretical and experimental researches with a view to finding out discrepancies with the simple exponential law for different kinds of electrical apparatus, from a simple wire to a big turbo generator with forced draft. A somewhat more complicated law, with two or more parameters, will probably be necessary.

The value of the paper lies in (a) bringing the phenomena of temperature rise to the attention of the profession at large, in a clear and interesting manner; (b) showing the possibility of using a time constant to a base different from that of natural logs; (c) extending the previous treatment of the subject to the case when the losses in the machine are functions of the temperature; (d) calling attention to the desirability of including certain thermal constants among other characteristics of the machine.

I recently developed a theory of heating and cooling curves on the assumption of a finite variable temperature difference between the winding and the core, and hope to present it later before the Institute. It leads to a sum of two exponential terms with different parameters.

V. M. Montsinger: While I suspect that this paper, according to the subject, is intended to apply principally to dynamo electric machines, yet in several places, reference is made to air-cooled transformers and the inference is that oil-immersed self-cooled transformers are included in the subject under discussion, namely, that the manufacturer give to the operating engineer the thermal time constant as a part of the regular specification, and that this constant can be determined by the methods shown in the paper, and that the binary instead of the exponential time constant be used.

Now, let us see how the various methods of determining the time constant compare and apply to air-cooled transformers.

The author has, correctly, pointed out that when the copper and iron systems are thermally independent, it would not be necessary to resort to the graphical method of determining the time constant by drawing a tangent to the tested time-temperature line as shown in Fig. 3, or by plotting the deficiency temperature rise values against time on semi-log or arith-log paper as illustrated in Fig. 5.

Most oil-immersed transformers, with the exception of small units, where the windings are sometimes wound directly on the iron core, come within this class of apparatus in which the copper and iron parts are thermally independent. It has been my experience that when the weight of the materials, the losses and the final temperature rises are known, it is a simple matter to calculate the time constant and consequently be able to predict the temperature rise at any time during the change from one steady thermal state to another. If the final rise is known—and it usually is—for some given load, the final rise for any other load

can be estimated by any one who is experienced in this line of work as accurately as it can be determined by test.

Before giving the method or formula which I have used, I would like to point out the conditions under which the method of plotting the deficiency in temperature rise against time and the graphical method of drawing a tangent to the tested time-temperature line hold, and where they do not hold.

In order to analyze correctly the thermal conditions in a transformer it is well to remember that the temperature rise of the windings above the cooling medium is composed of two steps which are: (1) top oil temperature rise above room; and (2) winding temperature rise above top oil. Each of these steps must be dealt with separately. I have found that if the deficiency in temperature rise of the maximum or top oil is plotted against time on semi-log paper, the points fall in a straight line, regardless of the size of the transformer and amount of oil. This method, therefore, can be used to determine either the decimal, the exponential or the binary time constants for any given load. Likewise, the deficiency of the winding temperature rise over the top oil against time can be plotted as a straight line on semi-log paper. The winding rise over the ambient, however, does not lend itself to this method unless we neglect the time it requires the winding oil to become constant. But after the temperature rise of the windings over the oil becomes constant, which usually requires from 20 to 30 min. for the average transformer the points naturally fall in a straight line which line is parallel to the oil-rise curve. The line, therefore, naturally does not go through the point of zero time. For this reason, I do not believe that this method would be entirely satisfactory when applied to the winding rise over the room temperature.

The graphical method illustrated in his Fig. 3 is really not satisfactory for either the oil rise or the winding rise over the room temperature. The temperature of a large body of oil when loss is first liberated in it does not immediately start to rise but seems to have a certain time lag. This slight displacement of the curve at the beginning is enough to prevent the drawing of a tangent to the line with any reasonable degree of accuracy. Furthermore, I do not believe that this method will give entirely satisfactory results for any type of apparatus because so much depends on the first few readings being absolutely accurate, and again, even if the first test points were right it is rather difficult for one to know just where to draw the tangent. When applied to the temperature rise of the windings over the room the method falls down completely, for the reason that, as pointed out before, the winding rise increases very rapidly at first and becomes constant within 25 or 30 min. whereas the oil required approximately the same number of hours, *i. e.*, about 25 hours to become constant. Consequently, the tangent line is too nearly vertical and gives a very much smaller time constant than the correct one. And then, there is the further objection or disadvantage to both the graphical and deficiency methods as applied to the oil rise of transformers that the time constant for a given transformer has different values for different loads. The reason for this is that the temperature rise for constant conditions is never proportional to the loss but to the loss raised to some power less than unity, generally around 0.8. This means, therefore, that it would be necessary to make a test under all the possible loading conditions which is an impractical thing to do. The same objection holds for horizontal coil rises over oil, but not to vertical coil rises over oil, because in the latter case, the rise is approximately proportional to the loss.

I believe Dr. Kennelly will agree with me that where the thermal conditions are simplified as they are in a transformer and where temperature rise is not proportional to the loss, the most satisfactory method of determining the thermal time constants is by calculating them. At least, he gives this intimation in his paper at the bottom of page 143 and top of page 144.

The formula which I have used for several years with satisfactory results is similar to equation (27). The formula and the definition of the various factors in it are as follows:

$$\theta = \theta_f \left(1 - \epsilon^{-\frac{t}{B}}\right)$$

in which

θ = temperature rise at time t.

θ_f = final temperature rise with the resulting loss (*i. e.*, considering the increased copper loss due to increased temperature) for constant conditions.

B = Time constant

$$= \frac{C\,\theta_f}{L}$$

L = initial loss in watts

C = thermal capacity of mass being heated.

When calculating top oil temperature rise, and time t is expressed in hours:

$C = (2.96\,c + 3.5\,i + 105\,a\,G)/60$

where

c = lb. copper

i = lb. (core + 2/3 tank wt.)

G = gallons (U. S.) oil

a = ratio of average to max. vertical temperature gradient of tank (which ranges from about 0.75 to 0.95, depending on the design).

When calculating winding temperature rise above top oil, and expressing time t in minutes.

$$C = 2.96\left(\frac{A + a}{2\,a}\right) \times \text{lb. bare copper.}$$

where A and a are the insulated and bare cross sections, respectively, of the conductor in the winding.

No attempt will be made here to compare calculated and tested results as space does not permit. However, a paper giving a more complete discussion of this subject will be published in the near future by Mr. W. H. Cooney, who is associated with me in my work.

Dr. Kennelly strongly recommends that we discard the exponential time constant and use the binary time constant. I am in accord with the author in everything he says regarding the advantages of the binary over the exponential time constant, and would be glad to see the binary constant used.

In reference to the theoretical formula, that is, equation (47), which he gives for the cooling after load is removed, I would like to point out that it has been found that this formula cannot be used to calculate the cooling of the windings of oil-immersed transformers after shut-down. The reason seems to be that the temperature of the cooling medium for the windings, which, of course, is the oil circulating around and through the windings is undergoing a change in temperature at the same time the windings are cooling down. This subject was discussed fully in my paper on "Cooling of Oil-Immersed Transformer Windings after Shut-down," see TRANSACTIONS, A. I. E. E., 1917, p. 117. It was shown in this paper that the cooling of the windings was approximately a function of the watts per pound in the copper and of the time after shut-down. Even the insulation on the conductors, etc., does not have to be considered, consequently the problem is very much simplified. The rule for cooling after shut-down given in the present A. I. E. E. Standards was based on the data given in the above referred to paper. The formula is of the form:

$$\theta = 1.95\,W_c^{.7}\,(1 - \epsilon^{-at})$$

in which

θ = cooling in deg. cent.

W_c = Watts per lb. of bare copper

$a = 0.106\,W_c^{0.3}$

t = time in minutes.

With reference to the proposed method of correcting for a change in ambient temperature, during heat run, while I have

not tried it out, I feel that the most satisfactory means of doing this for a transformer is by the use of an idle unit having approximately the same amount of material as the unit under test. While the idle unit may not always give ideal results, it appears to be the most practical at present and it is recommended that it be used wherever possible.

In closing I would like to urge that we give serious consideration to the author's plea for the adoption of the binary time constant. There is no question but that it is preferable to the exponential constant. The fact that I advocate the method of calculating the constant for transformers does not affect in the least the question of the merits of the binary constant.

W. B. Kouwenhoven: Dr. Kennelly's paper on "Thermal Time Constants" is a valuable one, and his introduction of the "binary time constant" simplifies to some extent the use of temperature data.

I have had occasion to make quite a number of heat tests during the past several years, and I have found that the use of the theoretical temperature curves and thermal constants will often save considerable time in determining the rating of a piece of equipment. There are three principal uses to which a knowledge of these curves may be applied.

1. By means of the curve plotted from the readings secured in the first two to three hours of an eight-hour heat run, we can predict fairly closely the end temperature or maximum temperature rise that will be reached at the end of the test period.

2. By means of the same curve secured in the early part of the heat run we can determine whether we are applying the proper load for the eight-hour rating; and whether the machine will reach the specified temperature rise in the specified time.

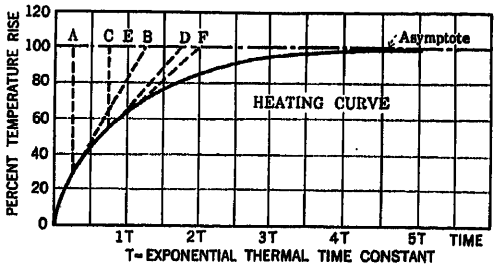

Fig. 1

3. We can determine the thermal constant of the machine, and as shown by Dr. Kennelly, use this in estimating what the machine will do under intermittent load or under some other load conditions.

Before discussing these applications it will be necessary to refer to the heating curve shown in the accompanying Fig. 1. The maximum or end temperature is the asymptote to this curve. It can easily be shown that the subtangents *A B*, *C D* and *E F* of the heating curve, referred to its asymptote as an axis, are equal.

In the actual heat run the desired load is applied, conditions being kept as nearly constant as possible, temperature readings are taken at frequent intervals and the temperature-rise curve is plotted. As soon as a sufficient length of curve has been obtained, a number of tangents to this curve are drawn and as nearly as possible, the height of the horizontal line that will give equal subtangents is determined. The point where this cuts through the Y axis gives the end temperature.

As Dr. Kennelly has shown, these subtangents are also equal to what is known as the exponential thermal time constant of the apparatus and in a length of time equal to five exponential thermal time constants the machine will reach 99.4 per cent of its maximum temperature rise. As soon as the constant is known we can not only predict the end temperature but also the duration of the heat run necessary to reach this final temperature. By this means we can tell whether the proper load is being applied for a given rating.

In using this theory in practise there are many cases where the heat curve is of such irregular shape that it is impossible to draw tangents and to obtain any idea of the constants of the apparatus under test. In other cases the early part of the curve is useless, but the middle portion may be of value and may permit us to obtain an idea of the end conditions.

My experience, however, has been that it is always worth while to attempt to apply the theoretical curve in making a heat run.

C. M. Laffoon: The simple exponential relation between temperature rise and time during the transient temperature period for any given constant-load condition is correct on the basis of the simplifying assumptions which were made. As a matter of fact, this exponential relation has been well known for a number of years. Designing engineers of electrical machinery have used similarly shaped curves as obtained from test or by calculation to determine the temperature rise of machines when operating under different load conditions.

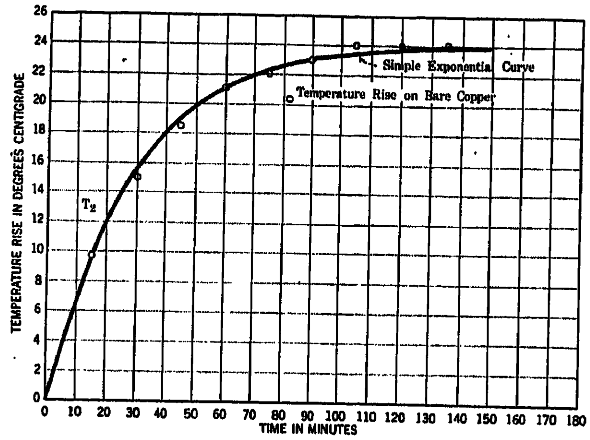

Fig. 2—Temperature Rise of 35,000 Kv-a. Turbo Generator

Generator rating—12,000 volts, three-phase, 60-cycles; operating at 75 per cent load, starting from 50 per cent load at constant temperature.

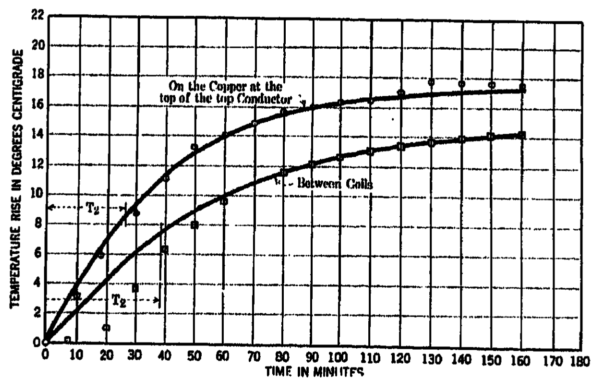

Fig. 3—Temperature Rise of 25,900 Kv-a. Turbo Generator

Generator rating—8000 volts, three-phase, 60-cycles; temperature rise under 75.3 per cent load, starting from constant temperature and 45 per cent load. Simple exponential curves used to fit experimental data.

At the present time, there is insufficient experimental data available on actual machines to determine definitely how far it is necessary to extend the analysis in order to obtain a satisfactory solution. If no simplifying assumptions are made and the analysis is based on the actual distribution of the losses, and

the losses are considered to be dissipated principally by conduction and convection, the solution becomes very complicated and involved. Fairly complete mathematical solutions have been worked out for the case of transformers and considerable progress is being made in determining a more complete solution for rotating machines.

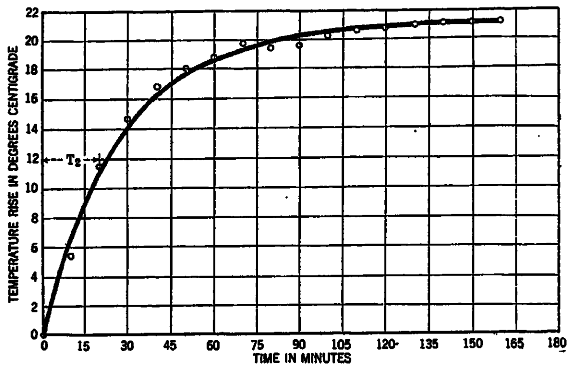

FIG. 4

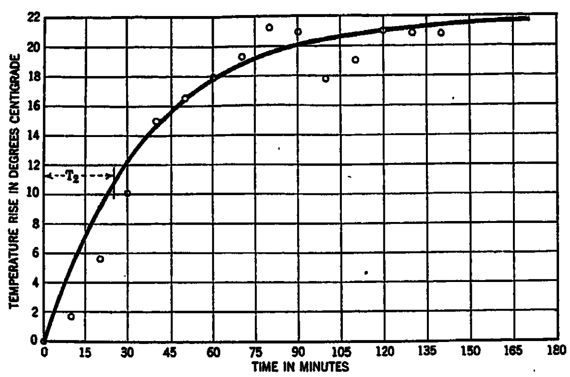

FIG. 5

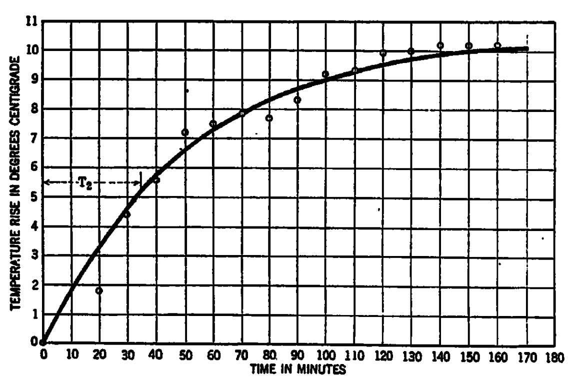

FIG. 6

FIGS. 4—5—6—TEMPERATURE RISE ON VARIOUS PARTS OF 25,000-KV-A. TURBO GENERATOR

Generator rating—66,000 volts, three-phase, 25 cycles; temperature rise under full load from constant temperature under 74.5-per cent load. Simple exponential curves are used to fit the experimental data.

Fig. 4 shows temperature at surface of top conductor as measured by thermo-couple

Fig. 5 shows temperature between coils

Fig. 6 shows temperature of field-winding, calculated from the resistance rise

The accompanying curves in Figs. 2 to 7 show the measured temperature rises of several large turbo generators at definite time intervals when operating under constant load conditions. The temperatures of the armature windings were obtained by imbedded temperature detectors which were placed in contact with the bare copper, as well as between coil sides. The temperatures of the field windings were obtained by the increase-in-resistance method. Simple exponential curves are superimposed on the test points. It is interesting to note that the simple exponential curves practically coincide with the test points for the case of the temperatures on the bare copper. In the case of the temperature detectors placed between the coil sides, the exponential curves fit the test points reasonably closely, as the temperatures approach sustained values, but during the early part of the transient state the test points drop appreciably below the exponential curves. This temperature dip or lag is due to the fact that there is an appreciable volume of insulation through which the heat, caused by the copper loss, must flow and its coefficient of specific heat is relatively large, as compared to that of copper.

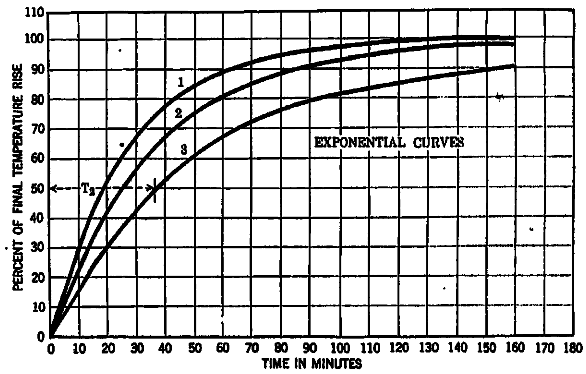

FIG. 7—TEMPERATURE RISE OF DIFFERENT PARTS OF 25,000 KV-A. TURBO GENERATOR

Generator rating—6600 volts, three-phase, 25 cycles, operating at 100-per cent load starting from constant temperature at 75 per cent load.
Curve 1 is temperature on bare copper
Curve 2 is temperature between coil sides of armature winding
Curve 3 is temperature of field winding

Another interesting and practical point to note for the last set of curves (Fig. 7) is that the thermal time constants are widely different for the different elements of a given generator. In the case of the 25,000-kv-a. turbo generator, a 50-per cent change in temperature rise corresponds to a binary time constant of approximately 20 min. for the bare copper of the armature winding, 26 min. for the temperature detectors between coil sides, and 38 min. for the field winding. (The values are based on the exponential curves.) Hence, in order to determine the rating of an electrical generator when operating under overload conditions, it is necessary to know the thermal time constants for both the armature and field windings. If exponential curves are to be used in determining the temperatures, the curves must be based on measured values obtained near the final or sustained values.

G. E. Luke: It is of special interest to electrical engineers to be able to visualize problems such as transient heating phenomena in terms of similar electrical problems. The similarity can be seen even down to the constants of the equation. Thus, the time constant in the electrical circuit is L/R and in the thermal circuit it is k/s; (L) and (k) are similar in that both represent constants of the circuit which are proportional to the stored energy. Likewise (R) and (s) both are factors proportional to the loss in the circuit.

In a previous paper[2] presented to the Institute on a similar subject, an equation of the same form as Dr. Kennelly's equation was derived, also this equation was shown in the form:

$$t = 2.3\,\tau_e \operatorname{Log}_{10} \frac{\theta_0 - \theta_a}{\theta_0 - \theta} \tag{27}$$

This is the general form where θ_a is the temperature rise at

2. Heating of Railway Motors in Service and on Test-Floor Runs, by G. E. Luke. TRANSACTIONS, A. I. E. E, 1922, p. 165.

start, the other constants being the same as in Dr. Kennelly's paper. This equation will satisfy any heating or cooling condition and can be easily solved with the aid of an ordinary slide rule. This equation can also be solved graphically with the use of special nomographic charts.

An interesting application of these heating equations is in the solution of the heating problem where a continuously applied heating and cooling cycle is found. Such a cycle is common in elevators, hoists, street cars, etc. Thus the curve in Fig. 8 herewith gives a typical cycle where one load is applied at alternate intervals of (t_1 – hrs.) and another load for the other (t_2) intervals. θ_0' would be the continuous temperature rise if the first load should be applied continuously and θ_0'' the rise on the basis of a continuous application of the second load. The

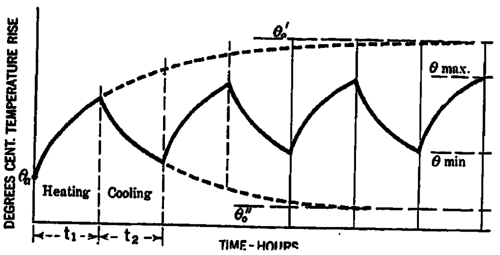

FIG. 8—TEMPERATURE CYCLE OF MOTOR ON VARIABLE LOAD

two points of interest on such a load are the maximum steady rise θ_{max} and the minimum rise θ_{min}.

It can be shown that

$$\theta_{max} = \frac{\theta_0'\,(1 - e^{a_1}) + \theta_0''\,(e^{a_1} - e^{a_1 + a_2})}{1 - e^{a_1 + a_2}}$$

$$\theta_{min} = \frac{\theta_0''\,(1 - e^{a_2}) + \theta_0'\,(e^{a_2} - e^{a_1 + a_2})}{1 - e^{a_1 + a_2}}$$

where

$$a_1 = -\frac{t_1}{T_e'} \text{ and } a_2 = -\frac{t_2}{T_e''}$$

if

$$a_1 = a_2 \text{ and } \theta_0'' = 0$$

Then

$$\theta_{max} = \frac{\theta_0'}{1 + e^{a_1}} \text{ and } \theta_{min} = \frac{\theta_0'\,e^{a_1}}{1 + e^{a_1}}$$

As mentioned in the paper, the heating of various parts of an electric machine is not uniform, and much of a machine's masses absorb very little heat. Thus in Figs. 7 and 8 of the paper if the time constant is calculated on the basis of the total weight of the motor, its value will be over twice the tested value. On the other hand, if the heating curve for the d-c. motor armature copper is calculated its time constant will be considerably less than that shown on Fig. 8. Hence the use of such heating curves and formulas for industrial motor applications may be dangerous unless they are based upon that part of the machine that has the smallest time constant, that is, heats up the quickest.

A good example of the way various parts of a motor increase in temperature is shown on in the accompanying Fig. 9. This is the tested heating curve of a typical d-c. railway motor. Thermocouples were placed in the windings, both field and armature (with slip rings). The approximate exponential time constants based upon the tangent to the curves at the origin are 0.9, 2.1 and 2.2 hours for the armature copper, field copper, and surface respectively. The same constants based upon the time corresponding to the 63.2 per cent temperature rise are 1.1, 1.8 and 2.0 hours respectively. Thus the initial rate of heating of the armature copper is over twice the rate of the field copper. This is primarily a question of ventilation and heat flow. The time constant of the copper alone imbedded in the slots is very small, being considerably less than the values given on the author's Fig. 7 and Fig. 8. This influences the "hottest spot" and when short overload of 125 to 150 per cent of full load are found the permissible time of loading should be based upon the time constant of the "hottest spot" and not upon the average heating of the motor as found by thermometers. This point was explained in greater detail in the paper previously mentioned.

It is believed that there is some error in the last sentence on page 141, since the curve referred to, in Fig. 4, is not a straight line. The equation

$$\theta = \frac{\theta_1}{2 - \theta_2/\theta_1} \qquad \textbf{(47a)}$$

holds true only if the origin is taken at the time of start ($\theta_a = 0$) and hence will not be true in general when $\theta = \theta_a$ for $t = 0$, similar to curve Fig. 3.

In the summary in the last sentence on page 147, it is assumed that air-cooled transformers means oil-insulated, self-cooled, instead of air blast transformers, since the latter usually have a small time constant.

E. B. Paxton: I believe that information based on the thermal time constant as proposed by Dr. Kennelly would be very useful if it could be made available in such simple form as to be readily used and understood, not as a rating but as information supplementary to a rating.

Electrical machines could often be applied to better advantage if there were some simple means available of knowing, if only approximately, their operating capabilities under various service conditions such as, for example, low ambient temperatures or short-time operation. An understanding of what might be expected of a machine under such conditions would often result in the installation of a smaller machine.

A criticism has been made that each different part theoretically has its own time constant and that, due to the heat of each part affecting the others, the effect is much more complicated than indicated by the simple logarithmic relation. However, test results show, as pointed out in the discussion of Mr. Laffoon, that the temperature rises of individual parts often follow quite closely a law based on a single time constant and it is only necessary, as a basis for information to serve as a guide in operation, to regard the limiting or hottest part.

O. E. Shirley: The binary heating constant gives a very

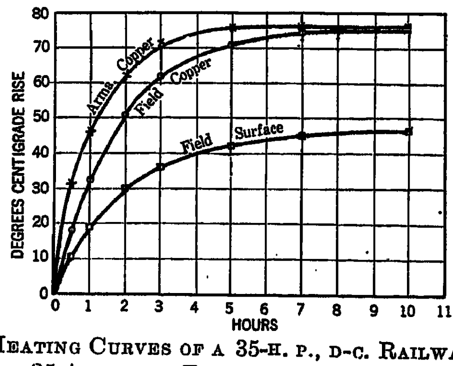

FIG. 9—HEATING CURVES OF A 35-H. P., D-C. RAILWAY MOTOR 300 VOLTS, 35 AMPERES; TEMPERATURE BY THERMO COUPLES

convenient method of determining to a practical degree of accuracy the heating of a rotating machine under a considerable number of varying conditions. I agree with the view brought out in some of the previous discussions that the results may vary from the actual tests under many conditions, but the method may be used to considerable advantage where approximate heating is required for machines operating on duty cycles.

A number of machines, for which heating curves are available, have been checked to obtain an idea of typical values of the

binary constant. The constants for several machines are as follows:

Cycles	Kv-a.	Volts	Binary Constant (Minutes) Thermometer	Temp. Detector
25	1250	6400	30	29
25	2450	13200	38	39
25	2450	6600	23	20
50	2500	11000	25	19
60	1250	2300	15	16
60	2500	4000	20	12

The agreement between results for thermometer and temperature detector is very good except for the last machine which shows a considerable difference between the constants by thermometer and by temperature detector.

In determining the constants from the test heating curves there were some appreciable variations in the time for the different intervals, but by taking the average values for the higher increments, (*i. e.*, from ½ to ¾ rise, and from ¾ to ⅞ rise) constants could be obtained that would give curves checking the tests to a very good degree of accuracy.

The binary time constant as proposed in the paper appears to increase with the size of the machine, and also with the thickness of insulation.

The machines, which have been checked, indicate that the range of values for the usual design is 15 to 45 min., but this maximum value would very likely be exceeded in very large units and with high voltages.

As I see it, the principal advantage of the proposed constant is to give an easily remembered way of approximating the effect of a varying load from the curve of final temperature and load and the time constant which can be obtained from one test heating curve. The binary constant is very much easier to apply than the exponential constant and the accuracy of the results is the same.

A. M. MacCutcheon: This subject has a tremendous interest if we intend to use our knowledge of the time constant in connection with design and test. If it is to be given to the user of electrical apparatus for assistance in applying electrical machinery, I think it is exceedingly dangerous for the reasons that Prof. Karapetoff and others have pointed out. It is difficult to determine accurately, and it is likely to vary, I believe, even for duplicate machines. We have known duplicate machines to vary 15 degrees in measurable temperature under continuous full-load operation. If there are differences like that in machines which are intended to be identical, how can a man in the field applying electrical apparatus intelligently use a time constant if he makes its application general?

I believe that successful application of electrical machinery will result to a much greater degree if more study is given on the application problem, which is a very difficult one, and I think it would be dangerous to mislead power-apparatus users into thinking that something we can give them on a time constant is going to solve all of their difficulties. I am referring particularly to smaller sizes of power apparatus, from 250 h. p. down. When a large installation goes in possibly a time constant could be well used, because on such an installation as that, the company putting it in has high-grade engineers probably to consider the time constant and to make absolutely certain that they are applying it well. But for general applications of power motors, it seems to me extremely dangerous to attempt to give to the user a time constant which we aren't sure we can accurately predict; we aren't sure that we will not have to divide it into ten parts, as Professor Karapetoff has said, and we aren't sure that it will always be the same constant for duplicate machines.

F. D. Newbury: A possible inference from Dr. Kennelly's paper is that this mathematical relationship between temperature and time affords a practicable method of defining the rating of a rotating machine for any combination of loads and times of loading. If a machine can be given, as one of its characteristics, a single time constant, then its rating can be completely and exactly defined by stating its temperature rise at one loading, applied continuously, in combination with this time constant.

Mr. Laffoon in his discussion points out two important facts that greatly complicate this practical application: the agreement between the exponential curve and the test results is close only when it is possible to measure temperatures at or near the seat of the loss; and each machine has a time constant for each major loss-producing element. In a motor, for example, a time constant, determined from externally-applied thermometer readings, would be safe to use only when the test is continued long enough for the motor to approximate its final temperature; for short times the measured temperature is considerably lower than the temperature obtained from the correct exponential curve. In all machines of any size, and notably in turbine generators, the time constant of the armature windings and field windings will be quite different. Finally, the several time constants of each size of each type of machinery will vary depending on design proportions affecting distribution of losses, heat storage capacity, and ventilation constants.

The application of this matter to the rating of electrical machinery is not as simple as it might seem from the paper under discussion, and a word of caution in connection with the practical use of the exponential relationship for the application of motors and other machinery to service conditions may not be out of place.

M. L. Keller: (by letter): Although I agree with Professor Kennelly that the binary time constant as suggested by him is the much more practical term for a simple explanation, the exponential time constant has nevertheless some importance from the practical standpoint. Instead of saying that after the lapse of one exponential time constant the deficiency is $1/2 \times 0.7182$, which for practical purposes is meaningless, we may define the exponential time constant as the time necessary to reach the maximum temperature if no heat is dissipated during the period of observation (See Fig. 10 herewith).

This definition is very simple and has also other advantages. For instance: we are able to determine the tangent of the temperature curve at the start without reference to the later period of the temperature rise.

The differential equation as set forth, is:

$$p \, . \, d\,t = G \, . \, c \, . \, d\,\theta \tag{1}$$

p = watt; G = weight (gramm), c = specific heat

Considering the temperature-rise in degrees centigrade per second of a conductor with the conductivity (ρ), specific weight (γ) and specific heat (c), at a current-density (i) amp/mm², we find

$$\theta\,^\circ/\text{sec} = i^2 \frac{\rho}{\gamma \, . \, c} \tag{2}$$

Therefore, knowing the ultimate temperature-rise to be $\theta_0 = \frac{p_0}{s}$ [Prof. Kennelly's equations (20) also (3)], the exponential time constant is:

$$\tau = \frac{\theta_0}{i^2 \dfrac{\rho}{\gamma \, . \, c}} \tag{3}$$

This means that if we know the conductor and ultimate temperature-rise at a given current density, the value of the time constant can be easily obtained.

Applying equation (3) to electrical machines, it will be found that the time constant thus determined is in most cases too small. The reason for this lies in the fact that we must take into account the thermal effect of the materials surrounding the conductor. It is apparent that the insulation around the conductor increases the time constant of the same, acting as a means of

storage of heat energy produced by the conductor. It may be added that with the increase in the heat-absorption qualities and conductivity of the insulating material, the active time constant also increases. As it takes time for the surrounding materials of the conductor to absorb heat, it is evident that the increasing influence of the insulation, etc., upon the conductor depends on the rapidity of the temperature rise, which in turn depends on the load. (For load periods the duration of which is greater than about 3/5 times the full-load time constant this need not be considered.) In other words: the time constant of electrical machines is not only a function of material and construction, but indirectly also of load periods and load variations as well.

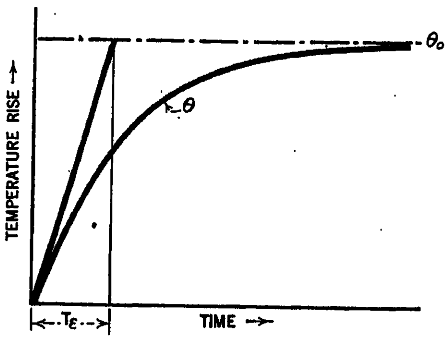

FIG. 10

This fact is of extraordinary importance where sudden load changes in quantity and duration occur and where the total time constant of the machine is large in respect to the inherent time constant of the heat producing conductors (for instance, transformers).

The above conclusions explain Prof. Kennelly's statement, why with reference to Fig. 7 in his paper "the computed curve has the tendency to exceed the temperature curve near the middle of the run." The inherent time constant of the motor analyzed by this curve—judged by its size—will probably be half (or even less) the given full-load time constant. For a general rule, it may be said that the full-load time constant of a motor depends on the conductor plus about 50 per cent on the insulation in the slot.

Prof. Kennelly mentions as a main reason causing deviation of the temperature curve from a strict time-constant curve "that the windings of a machine with their copper losses form one thermal system and the steel structures with their iron losses, form another and that each tends to modify the behavior of the other."

This conclusion is of much importance and brings forth the question: How do these different thermal systems affect the hottest—*i. e.* critical spot—of the machine and how are we able to consider them in a simple manner? As the critical spot—which is the main point of interest to us—lies at the inner surface of the insulation next to the conductor, the simplest way seems to be, to take as a basis for any temperature consideration the time constant of the conductor which is identical with that of the critical spot and to consider the other heating sources, iron losses and adjacent conductors, as distributing factors.

Recapitulating, we may say, the smallest time constant of an electrical machine is the inherent time constant of the conductor. It increases through the thermal influence of the surrounding materials (insulation, etc.). The amount of this influence depends on the rapidity of heat changes in the conductor, this means that the time constant is also a function of the load. The heating influence of the iron losses and adjacent conductors are to be considered as disturbing factors in respect to the critical spot.

F. Wenner (by letter): In the analysis of this problem Prof. Kennelly points out the similarity between it and the variation of an electric current in an inductive circuit. This procedure enables us to handle certain parts of these two problems practically as if they were the same problem, and to apply information we may have concerning one to the other. To those who are required to work with both problems this results in a real saving of mental effort.

As this subject is one of considerable importance and the method of analysis is new it may not be out of place to point a little more in detail the way in which thermal time constants may be used to advantage in the solution of a particular problem. It will be conceded without question, I think, that an exact mathematical solution is too complicated for general use. Further, nothing is gained by carrying the computations to four or five significant figures, since the data is reliable to a few significant figures only and the fundamental assumptions which must be made are only approximately correct. What is wanted is a simple procedure by which calculations can be made to two or at most three significant figures.

In the consideration of a similar though somewhat more complicated problem in electromechanics, it was observed that a considerable simplification could be made by using what, for the lack of a more appropriate designation, we have called a "weight" curve. This is the response and recovery curve with the time scale reversed and with all ordinates multiplied by such a factor as to make the area under the curve unity.

In a dynamoelectric machine heat is developed within the material of the machine simultaneously with the energy output and is dissipated slowly. If a load is applied for an instant only, the mean temperature increases suddenly and then decreases very slowly following approximately a curve similar to that shown in Fig. 4 of the paper. The variation in mean temperature, therefore, may be considered to follow the curve shown here in Fig. 11. The instantaneous rise shows the response and the part beyond the peak shows the recovery. The weight curve corresponding to this response and recovery curve is of the form shown in Fig. 12. In the latter the origin of time is taken at the end. Any convenient unit of time such as the minute or the hour may be used. However, there is a very considerable advantage in taking one of the time constants of the machine under consideration as the unit of time. When this is done both the response and recovery curve, and the weight curve are independent of the constants of any particular machine. In fact all responses and recoveries of whatever nature, which take place according to the laws assumed to apply here have the same weight curve.

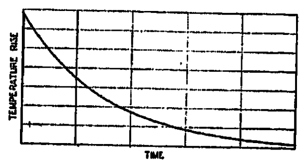

FIG. 11—TEMPERATURE RESPONSE AND RECOVERY
Load applied for an instant only

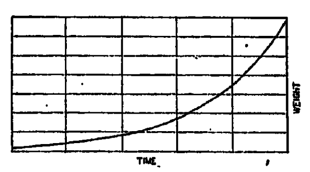

FIG. 12—WEIGHT CURVE CORRESPONDING TO RESPONSE AND RECOVERY FIG. 11

If the unit of time is taken as the binary time constant then the weight at any time t is equal to $\text{Log}_e 2\ t^3$. This gives the following data which may be used in constructing a weight curve.

Time	Weight
0	0.693
−¼	0.583
−½	0.490
−1	0.347
−2	0.173
−4	0.043
−8	0 003

Such a curve is shown drawn to scale in Fig. 13.

Now let us see how we may proceed to predict the temperature rise for a particular machine when subjected to a particular assumed load. Let this load be as shown in the curve of Fig. 14, and let the problem be the determination of the temperature rise at the end of 4¼ hours. As Prof. Kennelly has pointed out, three specific thermal data are required. These are the ultimate temperature rise for two different constant loads and the time instant. The former give two points from which a straight line curve similar to that shown in Fig. 1 of the paper may be plotted and the latter serves to convert the time scale of the assumed load to the time scale of the weight curve. We then have three curves for use in making the calculations, namely: 1. The assumed load curve with a proper time scale, 2. The ultimate rise in temperature curve of the type shown in Fig. 1 of the paper, and 3, the weight curve as shown in Fig. 13 herewith. With these three curves, a slide rule, and pencil and paper, the calculation is carried out as follows: First, read from the load curve the average load from $-\frac{1}{4}$ to 0. Second, from the ultimate temperature rise curve read the rise in temperature corresponding to this load. Third, read from the weight curve the mean weight from $-\frac{1}{4}$ to 0. The ultimate rise in temperature, times the time (in this case ¼) gives the temperature rise at the time 0 which would result from the assumed load if applied only from $-\frac{1}{4}$ to 0. This figure is the first of a series to be added. Proceeding in the same way the temperature rise which would result at the time 0 from the assumed load if applied only from $-\frac{1}{2}$ to $-\frac{1}{4}$ is obtained. This constitutes the second term of the series to be added. Third, Fourth, etc., terms of the series are obtained in the same way, except, as the weight becomes smaller, an interval of time equal to a half, a full, or even two time constants may be used. The series is extended back so as to include the time at which the load came on, or to a time previous to which the load does not appreciably affect the temperature at the time 0. The addition of the series gives the temperature rise to be expected at the time 0 (in this case at the end of 4¼ hours) for the assumed load. The calculation is simple, straightforward, and readily gives an accuracy comparable with the accuracy of the fundamental assumptions and data based upon these assumptions.

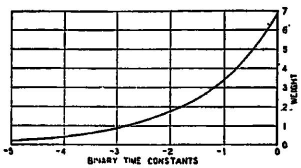

FIG. 13—WEIGHT CURVE CORRESPONDING TO RESPONSE AND RECOVERY SHOWN IN FIG. 11
Time expressed in binary time constants

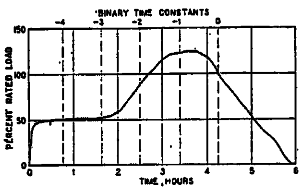

FIG. 14—ASSUMED LOAD IN TERMS OF RATED LOAD

In this discussion I have tried to show how the technique acquired in work upon a more complicated problem in electromechanics may be used in computing the temperature rise in a dynamoelectric machine, when subjected to a variable load. Fundamentally the procedure followed is the same as that outlined in the paper. It is, however, given in more detail with the hope that this may lead to a fuller appreciation of the advantages to be gained by the use of time constants, whether thermal, electrical, or mechanical, depending upon the nature of the problem under consideration.

A. E. Kennelly: The discussion has brought out many interesting and valuable points, including new mathematical material by Messrs. Luke and Wenner.

It has been pointed out that while the graphs of temperature elevations in different parts of dynamo machines may deviate considerably from exponential or time-constant curves, yet in many cases, under certain restrictions, they approximate to true time-constant curves sufficiently closely for many practical purposes. Valuable graphical data to this end have been contributed by the speakers. Moreover, it seems to be unanimously agreed that whenever a time constant can be used in practise, it should be a binary time constant.

It has been well shown that in view of deviations of heating curves from strict time-constant curves, it is unsafe to assign a time constant to a heating curve by means of a tangent drawn through the origin. Perhaps the most practical way to determine the mean binary time constant from a curve of observed steady-load heating against time, is to measure the temperature elevation θ, at successive uniform time intervals t_1. Then if θ_1 is the temperature rise in one such interval, and this has reached θ_2 by the end of the second interval, we have as the binary constant τ_2 on the assumption of exponential rise during these two intervals ($2\, t_2$)

$$\tau_2 = \frac{0.30103\, t_1}{\log \dfrac{\theta_1}{\theta_2 - \theta_1}} \quad \text{time}$$

Thus, if the chosen time interval t_1 happened to be equal to τ_2, the rise θ_1 in one such interval would be just double the further rise $\theta_2 - \theta_1$ in the second interval, and $\log \left(\dfrac{\theta_1}{\theta_2 - \theta_1}\right) = \log 2 = 0.30103$. By repeating the computation over several such successive pairs of intervals, we can easily ascertain whether τ_2 is nearly constant throughout, or whether a mean value of τ_2 can be accepted.

Squirrel-Cage Induction-Motor Core Losses

BY T. SPOONER[1]
Member, A. I. E. E.

Synopsis.—An experimental method is presented for segregating the various no-load losses of a squirrel-cage induction motor. It is shown that for insulated rotor bars the losses consist principally of stator fundamental-frequency losses, rotor surface losses and eddy-current losses in the rotor bars due to radial and tangential slot-leakage fluxes in the rotor slots caused by reluctance pulsations in the air-gap between stator and rotor teeth. The pulsation losses vary about as the square of the air-gap induction and about as the 1.2 power of the frequency. The surface losses for the particular slots described are from ¼ to 1/3 of the total pulsation losses. The pulsation losses are approximately the same whether or not the rotor bars are connected by end rings, and are approximately equal to the stator fundamental-frequency losses.

Introduction

In a recent edition of Behrend's "The Induction Motor," it is stated that certain assumptions with reference to induction-motor core losses are "justifiable only on account of a profound ignorance of the causes of core losses and the magnitude of these losses." This may be true to a degree in connection with the core losses of this type of machine, particularly concerning the high-frequency pulsation losses due to the pulsations in the tooth flux as the rotor teeth pass by the stator teeth. Some experimental work has been done to segregate these high-frequency losses for wound-rotor induction motors, but so far as we know no data have been published showing a segregation of the various types of core loss for squirrel-cage induction motors. In this paper we propose to give such data for a special experimental machine.

Types of Core Loss

Squirrel-cage induction-motor no-load core losses may be classified as follows:

1. Fundamental-Frequency Losses
   a. *Stator*
      1. Yoke hysteresis
      2. Yoke eddy current
      3. Tooth hysteresis
      4. Tooth eddy current
   b. *Rotor*
      1. Core hysteresis (Slip frequency)
      2. Core eddy current (Slip frequency)
      3. Tooth hysteresis " "
      4. Tooth eddy current " "
2. High-Frequency Pulsation Losses
   a. *Stator*
      1. Surface
      2. Tooth pulsation
      3. Copper eddy current
   b. *Rotor*
      1. Surface
      2. Tooth pulsation
      3. Rotor bar eddy current
      4. High-frequency damping current in secondary winding.

In the squirrel-cage construction some of these losses will be negligible. For instance, there will be no appreciable fundamental-frequency losses in the rotor under ordinary no-load conditions due to the very small slip. High-frequency damping currents in the rotor bars may exist not only to damp out the tooth pulsations but also to give more nearly a sine-wave distribution of flux in the air-gap. The value of these latter currents will depend upon the number of slots and type of stator winding used. The relative magnitude of these various losses will be discussed later in connection with the test results.

Test Apparatus

The induction motor used in this investigation was a special 3-phase, 4-pole, 60-cycle, 440-volt machine of about 35-h. p. capacity. The stator and rotor punchings had the following dimensions:

Stator
Punchings O. D. 19 in. I. D. 13-19/32 in.
Length 6 inches
No. Slots (open) 60
Air-gap 0.047 in.

Rotor
Punchings O. D. 13½ in. I. D. 4 in.
Length 6 inches
No. Slots (nearly closed) 78
See Fig. 1 for slot dimensions
The rotor bars were 0.484 in. by 0.3 in. by 9.25 in.

The rotor was direct-connected to a 3-h. p. d-c. motor, the set being supplied with 3 ball bearings. The induction-motor, stator and rotor punchings were made of enameled 0.0172 in. one per cent silicon sheet steel. Special pains were taken to remove the burrs before enameling the punchings. The induction-motor stator was supplied from a 440-volt 3-phase generator direct-connected to a d-c. drive motor, the set having a considerably larger capacity than the special motor under test. The d-c. motor of the special set was supplied from a storage battery.

Test Methods

Three sets of tests were made: (1) with no windings on the rotor, (2) with rotor bars in position but no end-rings, (3) squirrel-cage winding complete with brass end-rings. In order to eliminate the uncertain variations due to laminations being short-circuited by the rotor bars, as is the condition for the standard construction, slightly smaller bars than normal were used and insulated by means of 3-mil fish paper.

1. Research Engineer, Westinghouse Electric & Mfg. Co., East Pittsburgh, Pa.

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 9-12, 1925.

For the first two tests the results were obtained by the method described in the appendix of a previous paper.[1] The method consisted in measuring the a-c. input to the induction-motor stator and the d-c. input to the drive motor, subtracting the friction and windage, brush and $I^2 R$ losses from the inputs and plotting the curves as indicated by Fig. 2 for a given a-c. voltage and frequency and various rotor speeds. a, b, c, d, e, is the a-c. input and o, f, g, h, i, is the corresponding d-c. input. c is the midpoint of b, d, and g is the midpoint of h, f. $O - c'$ is the stator fundamental-frequency loss for the given conditions.

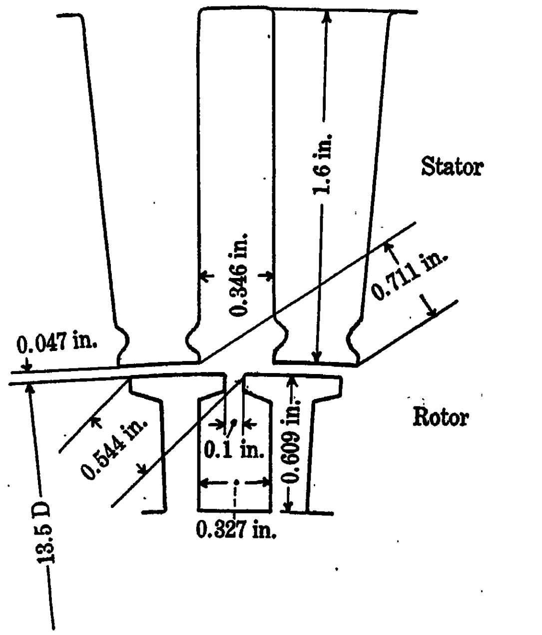

FIG. 1—DIMENSIONS OF STATOR AND ROTOR PUNCHINGS

$O - g'$ is the high-frequency pulsation loss. O, g, j, is the pulsation-loss curve for various rotor speeds and the given applied stator frequency and voltage. For a theoretical discussion of this method see Alger and Eksergian.[2]

Due to voltage limitations of the supply generator an average air-gap induction of 22 kilolines per sq. in. only was obtainable by this method. In order to extend the range direct current was applied to the stator and the input to the drive motor noted for various speeds and stator fields, as described in the previously-mentioned paper on Surface Losses. The fundamental-frequency rotor losses as obtained from the test with alternating current on the stator were extrapolated and subtracted from the total, giving the pulsation losses. Results up to 32 kilolines, air-gap induction, were obtained.

For the third set of tests with the complete squirrel-cage winding we had to resort to a slightly different method of procedure. Due to the large torque produced by the rotor windings, speeds only slightly different from synchronism could be used. Therefore tests were made with rotor speeds varying in general not more than 0.2 of a cycle from synchronism. Two points above synchronism and two below were measured

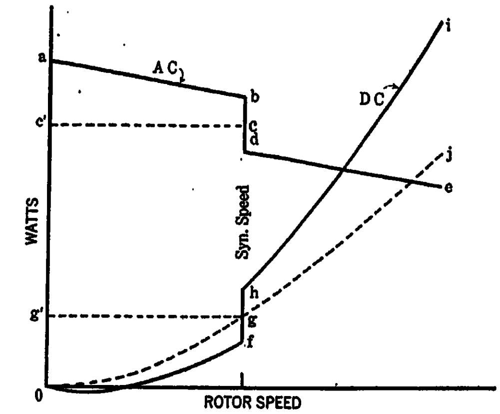

FIG. 2—INPUTS TO MOTOR-GENERATOR SET, SHOWING METHOD OF SEGREGATING LOSSES

and the results plotted as indicated by the typical results of Fig. 3. It will be noted that even for the very slight departure from synchronism of 0.1 of a cycle, the inputs and outputs are considerable. The very greatest care was necessary in measuring these

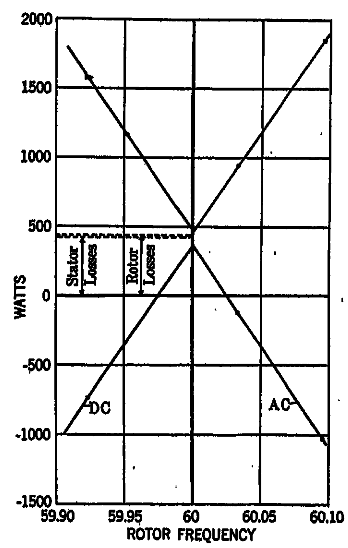

FIG. 3—A-C. AND D-C. INPUTS TO MOTOR-GENERATOR SET WITH SQUIRREL CAGE ROTOR 60 CYCLES

inputs and outputs in order to obtain reliable results, and without a very steady d-c. and a-c. supply such tests are impossible. Three synchronous speeds were used, namely, 20 cycles, 40 cycles and 60 cycles, and as wide a range of voltages as possible. It may be noted that with the scale of abscissas used for Fig. 2 the lines for Fig. 3 would be nearly vertical.

1. Surface Iron Losses with Reference to Laminated Materials, by T. Spooner and I. F. Kinnard, presented before the A. I. E. E. in Philadelphia, Feb., 1924.

2. Induction Motor Core Losses. JOUR. A. I. E. E., Oct., 1920, p. 906.

In order to measure the slip frequency, use was made of a coil which was placed around a single rotor tooth for the purpose of measuring the tooth-flux pulsations. This was connected to a d-c. galvanometer through slip rings. Whenever the d-c. galvanometer completed a cycle of oscillation, the rotor completed a cycle of slip. The time was measured by means of a stop watch.

Test Results

Fig. 4 gives the pulsation losses for a synchronous frequency of 20 cycles and the three conditions,

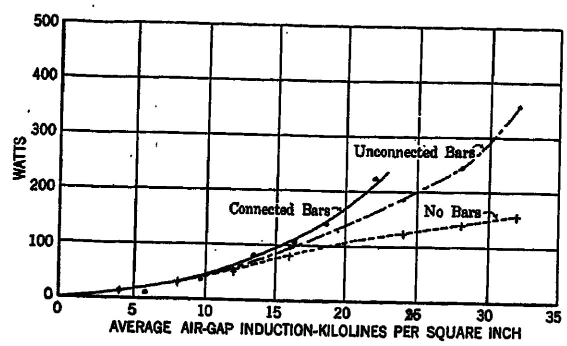

Fig. 4—Pulsation Losses—20 Cycles

namely, no rotor bars, bars unconnected and bars connected. With no bars it will be seen that the rate of increase of pulsation losses decreases for the higher air-gap inductions. This is due to saturation of the teeth and consequent reduction of the tooth pulsations as explained in a previous paper.[3] The difference between these results and the losses with the unconnected bars is due to high-frequency slot leakage fluxes caused by saturation of the teeth which produced eddy-current losses in the bars. These fluxes are

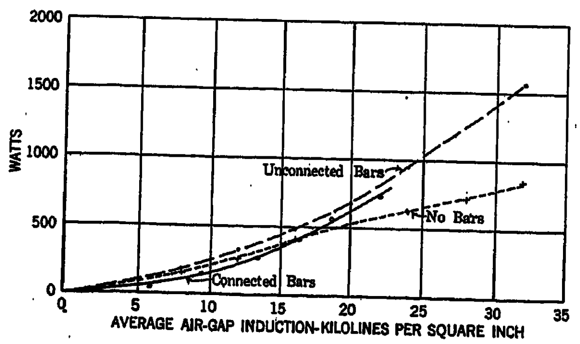

Fig. 5—Pulsation Losses—60 Cycles

both tangential and radial and while the density is only a few hundred lines per square inch, the frequency is so high that the losses become considerable.

With the bars connected, the high-frequency tooth pulsations produced currents in the bars which tended to damp out the tooth-pulsation fluxes. In fact, they do this so effectively that at 60 cycles no tooth-pulsation voltages could be detected by any a-c. indicator available when connected to the previously-mentioned coil surrounding a rotor tooth. With no rotor bars this voltage was of the order of 3 volts and with the bars connected was less than 0.1 volts. It will be noted that in spite of this damping out of the high-

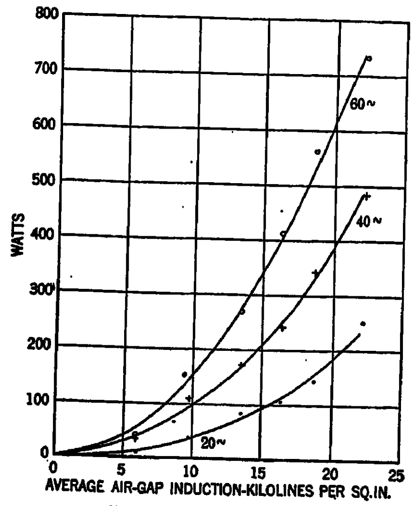

Fig. 6—Pulsation Losses—Insulated Bars Connected

frequency fluxes, the pulsation losses are not much changed. This will be discussed later.

Fig. 5 shows the corresponding 60-cycle pulsation losses. 40-cycle losses are intermediate.

Fig. 6 shows a comparison of the pulsation losses for

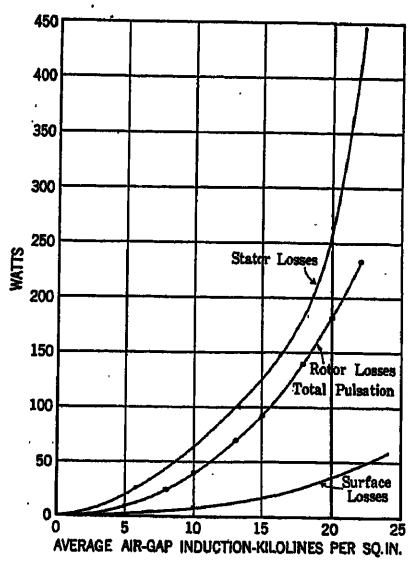

Fig. 7—Insulated Bars—Connected—20 Cycles

the three fundamental frequencies, 20, 40 and 60 cycles with the bars connected. It will be noted that in spite of the difficulties of test the points line up fairly well.

Fig. 7 shows the no-load losses for 20 cycles applied to the stator with the bars connected. It will be seen that the pulsation losses are nearly as great as the fundamental-frequency stator losses. These pulsa-

3. Tooth Pulsation in Rotating Machines, by T. Spooner. Jour. A. I. E. E., July, 1924, p. 646.

tion losses include the surface losses, which are given by the lower curve and were plotted from the results previously obtained on smooth core rotors.[1] Since the rotor slots are nearly closed, it is assumed as a first approximation that the surface losses for the rotor are the same as for a smooth-core rotor. Also due to the nearly closed rotor slots it is assumed that

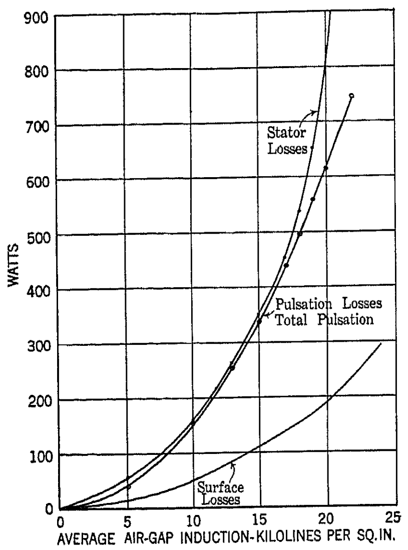

Fig. 8—Insulated Bars—Connected—60 Cycles

the stator tooth-pulsation and surface losses are negligible. The rapid increase of stator losses at high inductions is due to the fact that the stator yoke was rather narrow and began to saturate, thus forcing flux into the solid frame and hence rapidly increasing the stator losses.

Fig. 8 gives the motor core losses corresponding to an applied frequency of 60 cycles. The relative losses

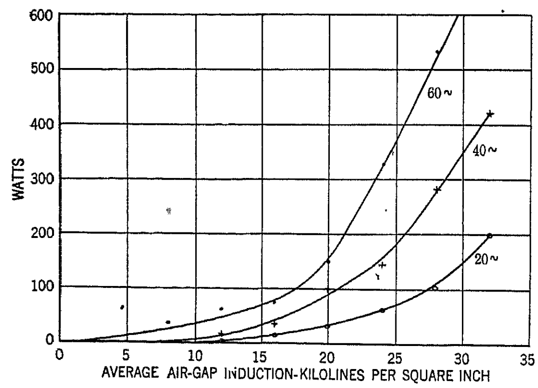

Fig. 9—Rotor Copper Eddy-Current Losses. Bars Insulated and not Connected

are much the same as for 20 cycles. The 40-cycle results lie in between the 20- and 60-cycle losses.

Fig. 9 gives the eddy-current losses in the unconnected copper bars as obtained by subtracting the test values of set No. 2 from set No. 1, namely, the difference between the losses with the unconnected bars and no bars.

Fig. 10 gives the stator losses with the connected bars and with no bars on the rotor. The increased losses in the former case should be noted.

Discussion of Results

The fundamental-frequency stator losses can be calculated in the ordinary way from the known fundamental magnetic characteristics of the material. If appreciable burrs are present or the enamel on the punchings is not in good condition, eddy losses will be

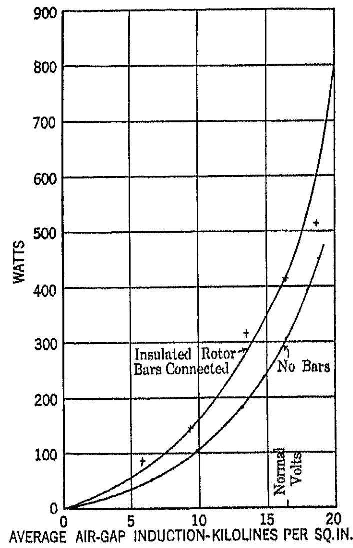

Fig. 10—Stator Losses—60 Cycles

present which are not subject to accurate calculation. Also, if it is desired to go to such a refinement, the additional losses in the yoke material due to the elliptical field may be calculated by the method developed by Alger & Eksergian.[2] This correction is fairly small in this case.

Since we are dealing only with synchronous speeds

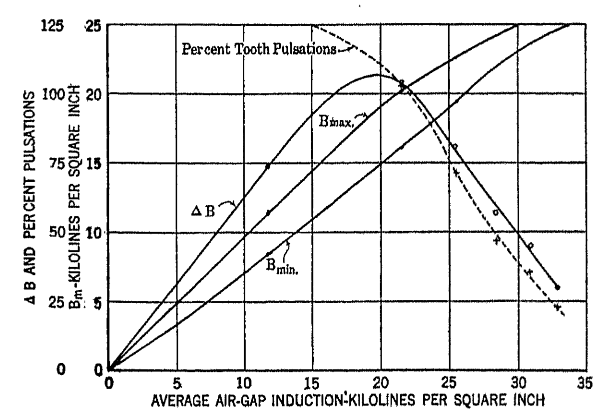

Fig. 11—Maximum Tooth Inductions (B Min.) and Tooth Pulsations

the rotor slip-frequency losses are zero. In any case they would be fairly small except under starting conditions. They may be calculated in the ordinary way for any desired slip.

As previously mentioned, for the nearly-closed slots

it is assumed that the stator surface and tooth-pulsation losses are negligible. We have left then only the rotor high-frequency losses. The method of calculating the surface losses has been described previously.

Referring now to the rotor tooth-pulsation losses, we shall give only brief attention to the condition with no rotor bars, since the losses do not correspond to working conditions though the results are of interest in connection with other types of machines having wound rotors. These tooth-pulsation losses are the result of high-frequency pulsations which penetrate the whole length of the rotor teeth and are caused by variations in the reluctance between the individual stator and rotor teeth at the air-gap. The method of calculating these pulsations has been given previously.[3] The actual magnitude of the tooth pulsations was measured ballistically with direct current applied to the stator as shown by Fig. 11. The effect of saturation in reducing the flux pulsations should be particularly noted. Inductions are expressed in net section of iron and correspond to the position of maximum air-gap flux. Remembering that for a 60-cycle fundamental frequency the tooth pulsations have a frequency of 1800 cycles, it can easily be seen how these high-frequency fluxes produce the hysteresis and eddy losses which were observed. Referring to Figs. 4 and 5, the effect of saturation on the tooth-pulsation losses for no bars should be compared with the tooth-pulsation data of Fig. 11.

For the second case with the unconnected bars we have in addition to tooth-pulsation losses, eddy-current losses in the bars due to radial and tangential slot leakage fluxes. As the teeth begin to saturate, high-frequency flux pulsations pass down the rotor slots and produce eddy currents in the rotor bars. Also, when a rotor tooth is opposite a stator tooth and therefore in position of minimum air-gap reluctance, the adjacent teeth are in a position of greater air-gap reluctance, therefore at a lower magnetic potential. Due to the saturation of the first tooth flux crosses the air-gaps to the teeth at lower magnetic potential, thus giving rise to tangential leakage fluxes of the same high frequency as the radial fluxes. When a tooth is in a position of maximum air-gap reluctance the tangential leakage fluxes flow in the opposite direction across the slots.

The magnitude of these slot-leakage fluxes was measured ballistically and found to be only from one to two hundred lines per square inch, even at fairly high tooth inductions. Nevertheless, due to the large section of the copper bars and high frequency, losses of several kilowatts would have been produced at the higher inductions with 60 cycles applied to the stator if there were no skin effect. Due, however, to skin effect, these eddy losses were much reduced, giving the values actually observed. The magnitude of these leakage fluxes can be calculated roughly from the permeability of the tooth material and the variations in tooth air-gap reluctance but the details will have to be reserved until a later date.

For the third case with the rotor bars connected we arrive at further complications. As it has been shown experimentally that the tooth pulsations are reduced to small values, it might at first be assumed that since the pulsation losses remain nearly the same, the high-frequency circulating currents in the copper bars give rise to losses which are approximately equal to the decreased iron losses in the teeth.

The magnitude of these high-frequency currents was calculated for an average air-gap induction of 22 kilolines and found to be about 100 root-mean-square amperes maximum. The corresponding losses were calculated using Field's Method[4] of calculating the effective resistance and it was found that this would account for only a comparatively small percentage of the observed losses. It was therefore concluded that these losses were the result of the eddy-current losses in the copper due to increased tangential slot-leakage fluxes, due to the increased magnetomotive force between adjacent bars. Since pulsating flux can no longer flow down the teeth to compensate for the varying tooth air-gap reluctance, a higher magnetomotive force exists between the adjacent teeth and as a consequence more leakage flux passes tangentially across the upper part of the slots, producing higher eddy losses than existed with the open-circuited rotor bars and thus compensating for the decreased iron losses in the teeth. Moreover, these tangential slot-leakage fluxes will be of considerable magnitude at lower tooth inductions since we would have the same effect produced by the short-circuited bars as would be produced by saturation of the teeth. The radial slot-leakage fluxes probably would not be greatly altered by the short-circuited bars.

The rate of increase of these losses with induction and frequency is interesting. As previously reported,[1] the surface losses increase about as the square of the air-gap induction and as the 1.5 power of the frequency. For the closed-bar rotor, the pulsation losses increase about as the square of the induction (a little less at the lower inductions and a little greater at the higher). The pulsation losses increase about as the 1.2 power of the frequency and if the surface losses are subtracted, the pulsation losses increase about as the first power of the frequency.

The increase in fundamental-frequency stator losses with closed rotor bars (Fig. 10) is probably due to the following cause. With no rotor bars the field form at the air gap is rather flat. In the presence of the squirrel-cage rotor at synchronous speed there is no fundamental frequency current in the rotor bars, but there are higher frequency currents which circulate and tend to give a sine wave distribution of flux in the air-gap, thus increasing the maximum stator-tooth

4. A. B. Field, Proc. A. I. E. E., Vol. 24, 1905, p. 659.

inductions and probably accounting partly at least for the increased fundamental-frequency stator losses.

Conclusions

The important no-load losses for a squirrel-cage induction motor having open stator slots and nearly closed rotor slots are, then, the fundamental frequency stator hysteresis and eddy-current losses in the teeth and yoke. (These may be altered somewhat due to change in field form resulting from harmonic currents in the squirrel-cage winding). There are also, of course, $I^2 R$ losses in the stator windings due to the magnetizing current.

In the rotor we have surface losses, eddy losses in rotor bars due to tangential and radial slot leakage fluxes and $I^2 R$ losses in the rotor bars due to high-frequency damping currents. The varying magnetomotive force due to the air-gap tooth-reluctance pulsations produces tangential slot-leakage fluxes which give large eddy losses in the bars but under conditions of large skin effect, namely, the eddy currents are concentrated near the surface of the bars. There are also, of course, certain losses in the iron due to high-frequency leakage fluxes which can be estimated only very roughly.

When the rotor bars are not insulated from the core new conditions arise which we hope to consider at a later date. Uninsulated bars are, of course, the standard practise.

In conclusion, we may say that for the ordinary squirrel-cage induction-motor the rotor pulsation losses are of the same order of magnitude as the stator fundamental-frequency losses and that the pulsation losses are approximately the same whether or not the rotor bars are connected.

Discussion

P. L. Alger: Mr. Spooner's paper extends by one step our knowledge of the various kinds of core losses which we have been considering for several years in Institute papers. First, we described the line-frequency losses; then, recently, Mr. Spooner described the surface losses; and now the pulsation losses are being attacked. These last losses, though, are the most complicated and the most difficult to understand of all those that occur at no load, and, consequently, it is worth while to point out some of the things that are not mentioned in Mr. Spooner's paper; which, nevertheless, are very important in this connection.

The first point I have in mind is an explanation of Mr. Spooner's statement that he finds more loss with the bars short-circuited than he can account for. I believe the reason is that when the bars are short-circuited in the rotor, the induced squirrel-cage currents shove the pulsation of flux back into the stator. That is to say, with the bars open the rotor flux pulsates; when the bars are closed the rotor flux is held constant and, consequently, the flux is forced to pulsate in the stator. Thus, losses of high frequency are produced in the stator in addition to those occurring in the rotor, and these extra iron losses account, in my mind, for the additional losses occurring beside the losses calculated to be in the copper itself.

In the second place, I will describe a convenient means of measuring the tooth-frequency losses applicable to completed machines, which Mr. Spooner has not mentioned. By measuring the running-light slip of an induction motor, the total torque developed by the flux is determined. For, the torque of the motor is proportional to the slip at light loads, and the design data give a reasonably accurate value of the torque per rev. per min. of slip. When the motor is running light, the total torque developed is absorbed in overcoming the friction and windage losses and tooth-frequency losses. The tooth-frequency losses, which are due to the passage of the rotor past the stator teeth, are precisely analogous to friction losses in their manner of origin. Like all friction losses, they must be supplied from the source of power that causes the motion, which, in this case, is the fundamental electromagnetic torque of the motor. From this, it is evident that by subtracting the friction and windage watts from the synchronous torque developed by the motor when running light, as indicated by the observed value of slip, there is obtained the value of the part of the core loss due to the tooth pulsations and surface losses. The value of tooth-frequency loss so obtained must be increased by the amount of power supplied by the rotor hysteresis torque, as obtained by calculation.

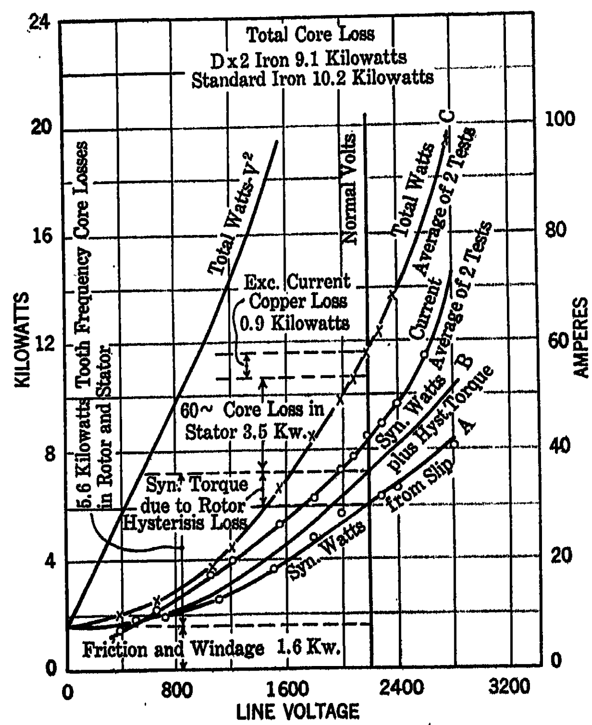

Fig. 1

The advantage of this method of measuring tooth-frequency losses is that it forms a means of segregating core loss into its two major portions as a routine part of the commercial testing. To illustrate the results obtained by the method and to make clear my third and last point, there are shown herewith three diagrams illustrating the test results on three dissimilar motors. Fig. 1 shows the total core loss as a function of line voltage on a 400-h. p., 60-cycle, slip-ring motor. There are also shown curves of the synchronous watts obtained from slip measurements, and of the synchronous watts corrected by adding the hysteresis torque. With these data available, the separation of the total loss into its components is easily made, as indicated in the figure. In this particular motor, the line-frequency core loss was only 3.5 kw. out of a total core loss of 9.1 kw., showing the motor to have an exceptionally large percentage of tooth-frequency losses.

The remaining two figures, Figs. 2 and 3, illustrate my third and last point, which is the possibility of varying the tooth-pulsation losses without affecting the major electrical character-

istics of the machine, by varying the ratio of primary to secondary numbers of teeth. When the numbers of teeth on the two sides of the air-gap are nearly equal and when the rotor slots are partly closed, each rotor tooth always spans approximately one stator tooth and one stator slot, so that its flux remains practically constant. However, when the number of rotor teeth becomes large, each rotor tooth first embraces the flux from a

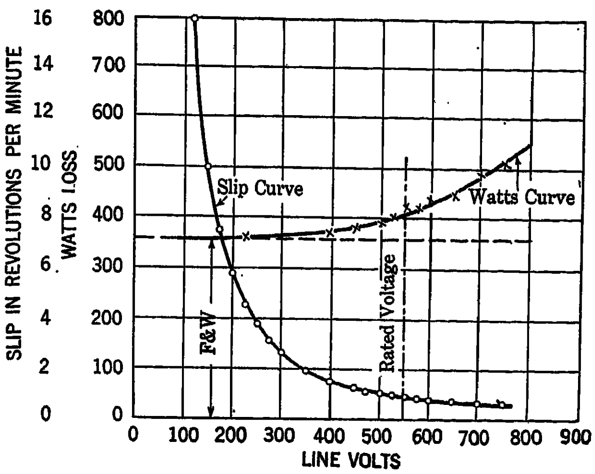

FIG. 2

stator tooth, and then that of a stator slot, and so on, so that the flux pulsates very considerably. The relations to be expected between the flux pulsations and the tooth ratios are given at some length by Chapman in the *London Electrician* for August, 1916. Here it need only be said that with a large tooth ratio the pulsation losses are high, and with a nearly one-to-one ratio the losses are small.

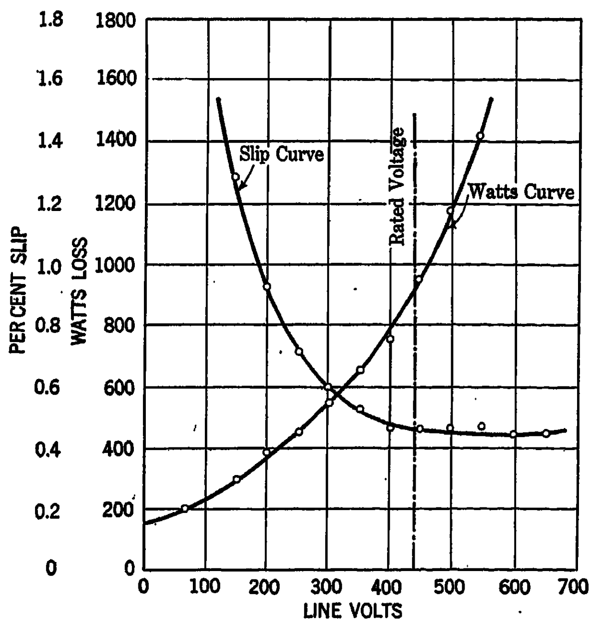

FIG. 3

Fig. 2 shows the running-light slip and the synchronous-watts curve on a 30-h. p. motor with 72 and 69 slots. It will be seen that the ratio of the tooth-frequency losses to the friction and windage is very small, indicating a very low total core loss. Fig. 3 shows a similar pair of curves on a 20-h. p. motor with a comparatively large ratio of teeth, and with magnetic wedges in the rotor. This motor has a tooth-frequency core loss of five times as much as its friction and windage, corresponding to a very high total core loss.

The obvious reason for not designing squirrel-cage motors with nearly one-to-one ratios of slots and, consequently, with low core losses, is that such a design makes the machine noisy. When a combination of slots that avoids both noise and core loss is obtained, it will be found that standstill locking or synchronous crawling will occur, so that as yet no means of solving the problem other than a good old-fashioned compromise has been discovered.

H. Weichsel: Any designer of electrical machines will

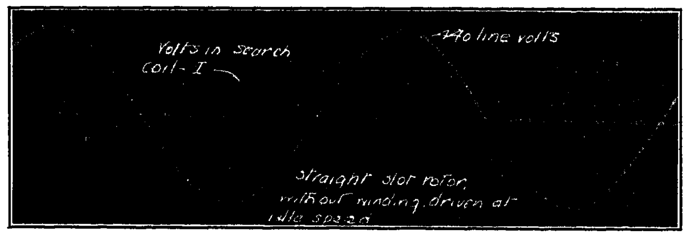

FIG. 4

welcome and appreciate the valuable contributions which Mr. Spooner has given to the engineering fraternity upon several occasions on the subject of iron losses. The phenemona which are responsible for the so-called iron losses in electrical machines are extremely complicated and are the result of a large number of factors entering into this problem. Mr. Spooner has described in various articles some of the most important factors. May I take this opportunity to point out some conditions which have not received general attention.

If a search coil is placed over a stator tooth of an induction motor and the induced voltage in this coil is recorded by an oscillogram, the following phenomena will be observed:

If the rotor is driven at approximately synchronous speed from an outside source, while the stator winding is connected to the supply line and the rotor is not provided with a winding, then certain high-frequency oscillations will be recorded, such as are shown in Fig. 4. If the rotor is then provided with a squirrel-

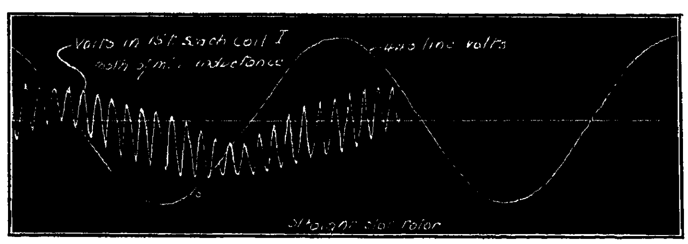

FIG. 5

cage winding and the machine is allowed to operate idle under its own power, it will be noticed that the fluctuations of the voltage in the search-coil have greatly increased, as shown by oscillogram Fig. 5. This increase of the oscillations is the result of the damping currents flowing in the squirrel-cage windings.

These damping currents, as pointed out by Mr. Spooner, attempt to reduce the fluctuation in the rotor teeth. But these currents not only react on the rotor teeth but also on the stator teeth and in this latter member the fluctuations are increased. The oscillograms Figs. 4 and 5 were taken on a machine with semi-closed slots in the stator and rotor and no skew in either member.

Figs. 6A to 6C, inclusive, represent a rotor and stator punching. The stator is assumed to have open slots and the rotor is shown

with semi-closed slots. In Fig. 6A the maximum possible flux will pass through the rotor tooth No. 1. In the position pictured in Fig. 6B, the number of lines passing through rotor tooth No. 1 have decreased and in the position represented by Fig. 6c, the number of lines passing through the rotor tooth No. 1 are a maximum.

A voltage will be set up in a loop of the squirrel-cage winding surrounding the tooth No. 1. The frequency of this voltage will be such that one cycle is completed during the time required for the rotor tooth to move one stator slot pitch. The current which is caused by this voltage to flow through the loop surrounding the rotor tooth No. 1 will be 90 electrical degrees displaced from its voltage. This current is a maximum when the rotor and stator tooth coincide and is zero when rotor tooth is in position *B*. (See Figs. 5 and 6.) The current is a maximum again when the rotor tooth has reached position *C*. All stator teeth which at a certain moment lie in the region of maximum induction of the main field, have the same magnetic polarity and are of practically the same field strength. During the short time required for the rotor to move one rotor slot pitch, the magnetomotive forces acting on adjacent stator teeth due to the stator winding can be considered as constant and of equal polarity and strength.

The whole arrangement pictured in Fig. 6 may be considered as a short-circuited high-frequency induction generator, where the stator forms the exciting member and the rotor coils represent the short-circuited induced winding.

At the first thought it might appear to be advisable to design the rotor punching of an induction motor with an open slot stator in such a manner that the fluctuations in the rotor teeth become zero. Such a condition can readily be obtained when the relation exists as shown in Fig. 7.

An arrangement as per Fig. 7 gives less losses than an arrangement corresponding to Fig. 8 on basis of equal induction and equal dimensions of the magnetic circuit. However, a machine built in accordance with Fig. 8 requires for the same maximum horse power less magnetic lines than a machine of equal dimensions built in accordance with Fig. 7.

As the losses decrease roughly with the square of the number of lines under otherwise equal conditions, it can be readily seen that in spite of the less favorable relations from the fluctuation point of view in Fig. 8 the total losses of the machine built according to Fig. 8 may be less than the total losses in a machine built according to Fig. 7. The general tendencies of the laws governing the relative changes between the necessary magnetic lines and the relative changes of the losses are approximately represented in Fig. 9. Experience has shown that generally the minimum iron losses for a given machine are obtained when the ratio of rotor tooth crown to stator slot pitch is 70 to 75 per cent, while the stator tooth crown is about 40 to 50 per cent of the stator slot pitch.

It may also appear that skewing the rotor member would have a beneficial effect on the losses of a machine. It is quite readily seen that when the fluctuations in a stator tooth are of a symmetrical nature, when the rotor is not skewed, it is possible to eliminate the fluctuation in a stator tooth by skewing the rotor one rotor slot pitch. Experience has shown that a machine with skewed rotor shows a reduced fluctuation in the voltage induced in the search coil of a stator tooth. Nevertheless the idle losses of this machine are practically unchanged. This can probably be explained by the fact that the skewing of the rotor does not influence the fluctuation of the individual stator laminations but only produces a steady flow of the total magnetic lines passing through one stator tooth. The skewing of the rotor member has further the effect of increased leakage and, therefore, for equal strength of the machine the number of lines must be increased. The only real beneficial effect obtainable by skewing the rotor is a decrease of noise and perhaps more uniform torque during starting.

The additional losses in a machine, especially the surface losses, are greatly influenced by machining operations on the magnetic circuits. Cases are known to the writer where careful reassembling of the same iron decreased the losses very materially. Other instances are known in which turning or grinding the rotor surfaces effected the losses noticeably, but it was also found that

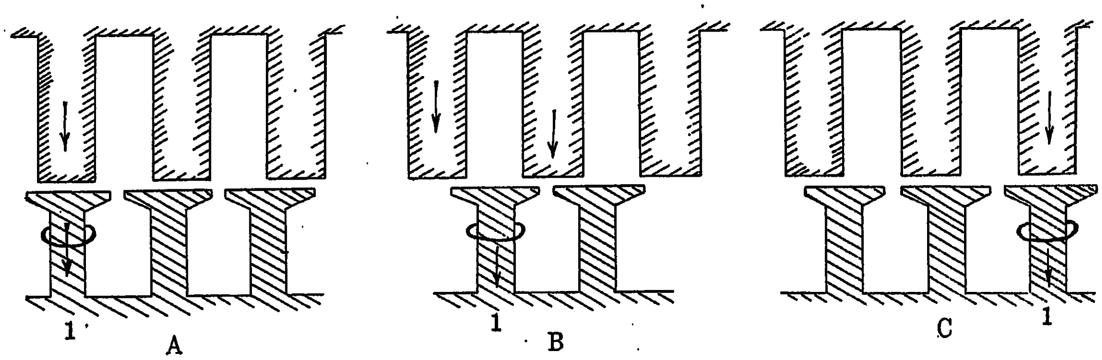

FIG. 6

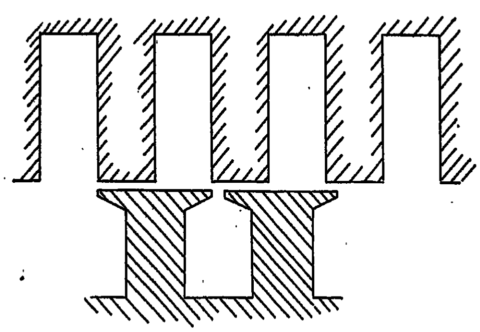

FIG. 7

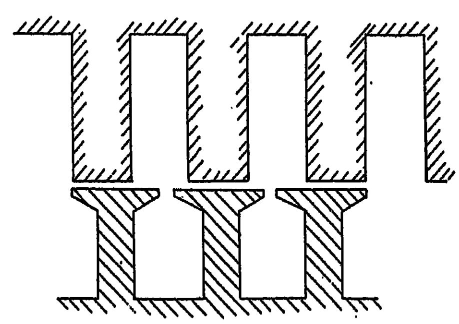

FIG. 8

when the grinding of the rotor surface is done properly the increase in losses is negligible. The magnitude of the additional losses in open-slot motors is often very large and it is not uncommon that under otherwise equal conditions open-slot motors have 1½ to 3 times the losses of semi-closed slot motors. That a large percentage of these additional losses are located in the rotor iron

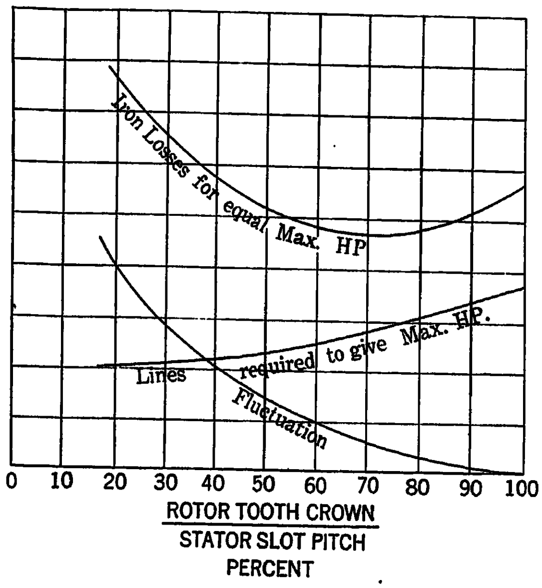

Fig. 9

can readily be demonstrated by using different grades of iron for the rotor circuit. The writer is familiar with cases where a change in the grade of rotor iron has decreased the losses in an open slot machine 25 per cent and more.

Another loss which is not negligible will be found in the end

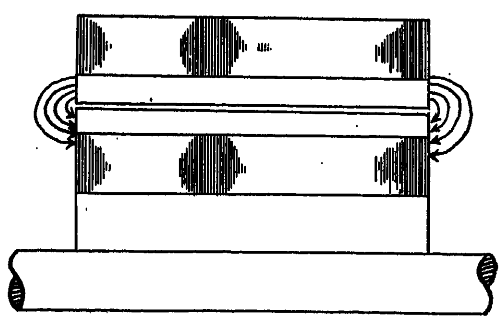

Fig. 10

punchings. There is a certain number of magnetic lines which pass from the stator, not through the air-gap into the rotor but which pass out of the end punchings of the stator into the end punchings of the rotor, as indicated in Fig. 10. These lines penetrate the end punchings at right angles to the plane of the punching and, therefore, are most favorably located to produce heavy eddy currents. Similar conditions exist in regard to the end rings holding the punchings.

That these losses are not negligible has been frequently observed by the writer by comparing the iron losses of machines built with exactly the same punchings but with different lengths of iron. Invariably the machine with longer iron showed a smaller loss per inch of iron length than the shorter machine, the comparison being made for equal induction. This clearly indicates that quite appreciable additional losses must take place in the end punchings.

Thomas Spooner: Mr. Alger and Mr. Weichsel have undoubtedly given the correct explanation for the fact that the pulsation losses are approximately the same with and without the squirrel-cage bars connected by end rings, namely, in the former case the pulsations are set up in the stator teeth as a result of the high-frequency m. m. f. due to the currents in the rotor bars and these pulsations produce stator-tooth pulsation losses which are approximately equal to the rotor-tooth pulsation losses which existed with the rotor bars unconnected. This point was overlooked by us, consequently no measurements were made of the stator-tooth pulsations.

The method which Mr. Alger describes for obtaining pulsation losses in commercial machines should be very useful due to its simplicity. It was not applicable, however, to a large proportion of the tests which we made on the experimental machines which were described in the paper because much of the time the rotor windings were either not operative or not present at all.

As pointed out by Messrs. Alger and Weischel, there seems to be no way of eliminating pulsation losses in induction motors without producing other even worse effects, such as noise, dead points, etc. A further knowledge of the factors which govern pulsation losses and these other undesirable allied effects should, however, make possible better compromise designs than often have resulted in the past when insufficient consideration has been given to tooth pulsations.

Mr. Weichsel states that the minimum iron losses occur when the ratio of the rotor-tooth crown to the stator slot pitch is 70 to 75 per cent while the stator tooth crown is about 40 to 45 per cent of the stator slot pitch. We have no specific data to show whether or not this is correct. In general, however, our experience indicates that for open stator slots, other things being equal, the tooth-pulsation losses alone are less for a given per cent difference between the number of stator and rotor teeth when the rotor teeth are less in number than the stator teeth. There are some advantages, however, not connected directly with iron losses in having the rotor slots greater in number than the stator slots.

Referring to Mr. Weichsel's comments on the effects of end punchings, these extra losses due to these punchings are partly caused by the fact that these punchings are much thicker than the ordinary material and are often made of steel which is inferior magnetically. Under these circumstances the end punchings will frequently have several times the hysteresis and eddy losses which would occur in an equal volume of ordinary thin laminated material. The increased losses for the short armatures noted by Mr. Weichsel are undoubtedly also due in part to the axial components of leakage flux and consequent large eddy currents as explained by him.

Complete Synchronous Motor Excitation Characteristics

BY JOHN F. H. DOUGLAS,[1] ERIC D. ENGESET[2] and ROBERT H. JONES[2]
Associate, A. I. E. E. Enrolled Students of A. I. E. E.

Synopsis.—*Synchronous motor excitation characteristics published hitherto have been incomplete. If theoretically determined, while forming closed loops, some doubt as to their accuracy has been entertained. When determined experimentally, thay have not been complete, in that the so-called unstable portions of the curves have not been obtained, and generally speaking, the upper portions of the characteristics have been missing.*

This paper shows complete synchronous motor characteristics, experimentally determined, differing materially from published curves determined by theory. These differences are discussed, and their cause attributed to variations in synchronous impedance.

Experimental data is included showing the factors on which synchronous impedance depends, and how it varies with current, saturation and power-factor.

THE excitation characteristics of a synchronous motor, more familiarly known as the *V* curves are well known. As determined from test they are incomplete, *i. e.* lacking portion corresponding to the larger armature current values. In Fig. 1 is reproduced a set of complete excitation characteristics, calculated by Dr. C. P. Steinmetz and shown in his "Alternating Current Phenomena", page 434. These curves are closed loops. Quoting from page 437, we read, "The upper parts of these curves, however, I have never been able to observe completely and consider it probable that they correspond to a condition of synchronous motor running which is unstable. The experimental observations usually extend about the lower portion of the curves, and in trying to extend the curves further to each side the motor is thrown out of synchronism." The writers know of no published experimental data covering the unstable portion of these curves.

Dr. Steinmetz did not regard these curves as accurate for he says, "It must be understood, however, that these power characteristics can be considered as approximations only, since a number of assumptions are made which are not, or only partly, fulfilled in practise." For instance Fig. 1 indicated that a synchronous motor will not carry any load with the field circuit open. Dr. Steinmetz says "So by decreasing gradually the excitation, and thereby the e. m. f., the curves, at light load, occasionally are extended below zero, into negative values of voltage, while the power still remains constant and positive as a synchronous motor. In other words, the motor keeps in step even if the field excitation is reversed; the lagging component of the armature reaction magnetizes the field, in opposition to the demagnetizing action of the reversed field." We do not recall any experimental data published which shows the distortion actually occuring in the left hand corner of the curves in Fig. 1.

The object of our experiments was to obtain the complete excitation characteristics of a synchronous motor, unstable as well as stable portions, and the complete closed loops if possible, and to observe the manner in which the curves are distorted for small and reversed excitations. We hoped that the instability was of a purely mechanical nature, for then we might succeed in stabilizing the motor by coupling it to another synchronous motor. We had, fortunately, in our laboratory, a 15 kv-a., 6 pole, 1200 r. p. m., synchronous set consisting of two identical machines, made by the Westinghouse Company for educational institutions. One of the machines had a stator that could be rotated around the shaft as an axis, either by a hand wheel, or freely within limits. The stator of this machine carried a two foot arm for weighing the

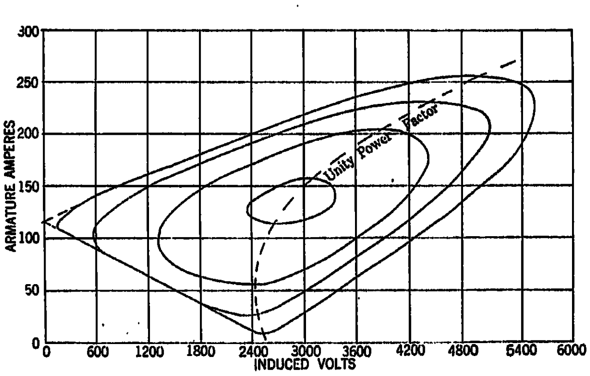

FIG. 1—SYNCHRONOUS MOTOR CHARACTERISTICS AFTER STEINMETZ

torque by the reaction method. We connected the machine according to Fig. 2. The projecting arm of the movable stator was supported on a jack-screw, which was in turn supported on small platform scales.

In Fig. 2 the motor at the right was the one tested. Although connected for 3 ϕ, *Y*, and 230 volts, it was run at reduced voltage by a bank of auto-transformers. It was run first at 115 volts, later at 55 volts, and finally at 20 volts, impressed voltage. The motor at the left was run at 230 volts, and was successful in all cases in keeping the other machine from falling out of step. When supplied with current the movable stator tended to rotate, and we were able to measure the reaction

torque successfully. The left hand motor was first started. The right hand machine was then excited to transformer voltage. S_2 was then closed. Before closing S_1 the movable stator was swung into such

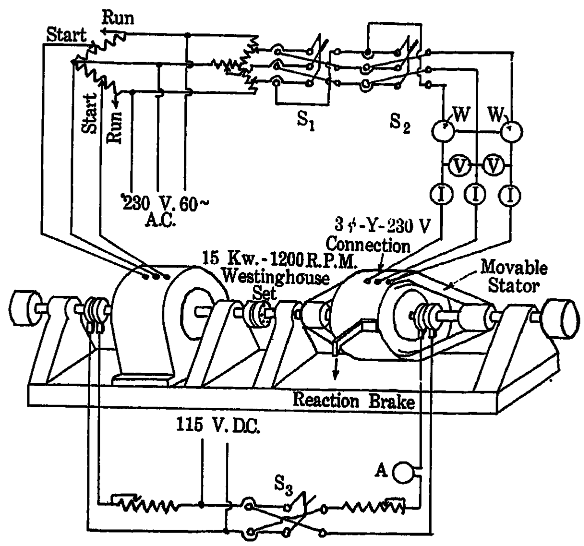

FIG. 2—CONNECTIONS FOR TEST ON COMPLETE SYNCHRONOUS MOTOR CHARACTERISTICS

a position that the phase of the induced voltage was the same as that of the line when a voltmeter across switch S_1 indicated no voltage. Then switch S_1 was closed,

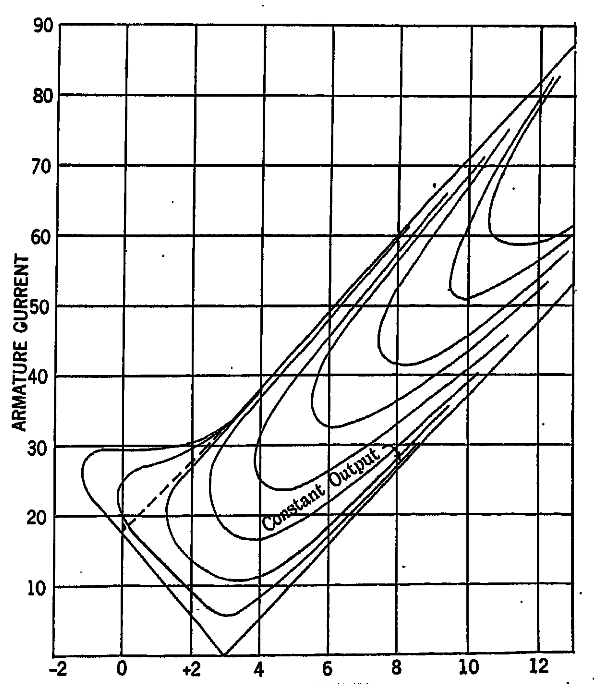

FIG. 3—COMPLETE EXCITATION CHARACTERISTICS OF 15 KV-A., 1200 R. P. M., WESTINGHOUSE SYNCHRONOUS MOTOR AT HALF NORMAL VOLTAGE

and as might be expected practically no current flow resulted, and no torque was produced.

When a synchronous motor is loaded, the rotor drops back in phase, this in turn, causes the motor to draw an increased current, and usually a larger torque is produced enabling the motor to carry its load. However, when the increased current gives a smaller torque, the motor will stop. In place of allowing the rotor to fall back in phase, we advanced the stator with the jack screw. We found that advancing the stator in the direction of rotation, the current and watts increased continuously. At first the torque also increased, but it reached a maximum, and then an advance of the stator phase resulted in a lower reading on the scales. We were able to reduce the torque again to zero in this way, in every case. This shows conclusively that we were observing points on the so-called unstable portions of the characteristics.

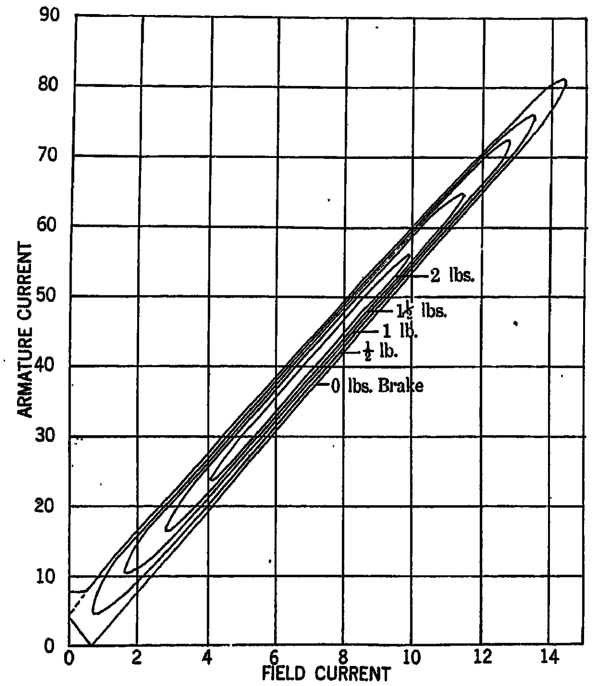

FIG. 4—COMPLETE EXCITATION CHARACTERISTICS OF 15 KV-A., 1200 R. P. M., WESTINGHOUSE SYNCHRONOUS MOTOR AT 20 VOLTS

We were able to shift the phase of the stator sixty electrical degrees by the jack-screw. By reversing switch S_1 or S_2 we were able to advance or retard the phase 120 deg., by reversing S_3 and either S_2 or S_1 we were able to advance or retard the phase 60 deg. We made a number of runs at each voltage. Most often we held the field current constant for a given run, and varied the phase reading, phase angle, torque, volts, watts, and armature current. The readings were then corrected and reduced to a standard voltage and plotted.

The characteristics obtained at 115 volts (and at 55 volts adjusted to 115 volts) are shown in Fig. 3. The nose-shaped protuberance on the curves for reversed excitation is to be noted. The upper portion or unstable portion of the curves seems to have been obtained, however, no evidence of the curves forming loops is shown.

In an endeavor to obtain closed loops, tests were made at an impressed voltage of 20 volts. The results of these tests are shown in Fig. 4. The loops are now closed. The maximum torque occurred at 7 amperes in the field, and 40 amperes in the armature, and was 2.13 lb. Fig. 4 is somewhat surprising, in that the loops are very long and narrow, and with practically straight sides. No evidence of a saturated condition is observed with large field currents. Dr. Steinmetz, in the place quoted, expressed a fear that saturation would affect the shape of the curves, which does not seem to be realized.

The peculiarities in the shape of the characteristics here shown, may be attributed possibly to the following assumptions used by Dr. Steinmetz, and acknowledged by him to be inaccurate. "While the reactance of the line is practically constant, that of the motor is not but varies more or less with the saturation, decreasing for higher values." "Furthermore, this synchronous reactance usually is not a constant quantity, even at constant induced e. m. f., but varies with the position of the armature with regard to the field; that

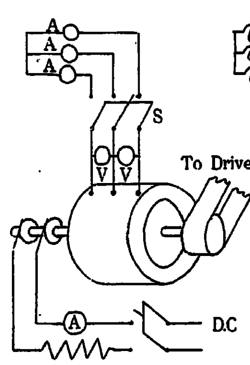

Fig. 5

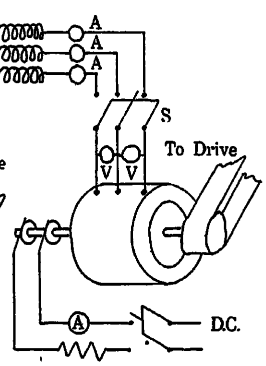

Fig. 6

Synchronous Impedance Tests

is, varies with the current and its phase angle. While in most cases the synchronous reactance can be assumed constant, with sufficient approximation, sometimes a more complete investigation is necessary, consisting in the resolution of the synchronous impedance into two components, in phase and in quadrature, respectively, with the field poles. Especially is this the case at low power factors." He here mentions the example of a synchronous motor remaining in step with light loads and reversed excitations as coming under this case, and which Fig. 3 verifies.

We draw from the above data the following conclusions:

1. The unstable portions of the synchronous motor characteristics can be obtained by directly connecting the motor to another rated at the same speed.

2. The torque can be conveniently measured by the reaction method if the stator is swung from bearings and free to turn about the shaft.

3. Complete characteristics (closed curves) can be observed if the motor is tested at a greatly reduced voltage. The curves for one voltage are similar to those obtained at another except for scale.

4. Anomalies in the shape of the characteristics have been observed at light loads, with small and with reversed field excitations.

5. Further tests to determine the amount of variation in the synchronous impedance, with saturation, current, and phase angle, were thought desirable, in view of the anamolies observed, and the attributing of variations in shape from Fig. 1 to this quantity by Dr. Steinmetz.

Variations in the Impedance of a Synchronous Motor at Synchronous Speed

A common method of measuring the synchronous impedance of a motor or generator is shown in Fig. 5. The voltage induced in the machine is measured with the switch S open, the motor being driven at synchronous speed, and separately excited. The current on short circuit is measured with the switch S closed, the field current being unchanged. The synchronous impedance is taken as the ratio of cause to effect, of open circuit voltage to short circuit current. The impedance obtained in this way is much too large. Since the armature reaction destroys the saturation of the machine, this test does not give the equivalent impedance at higher values of saturation.

Another method of finding the synchronous impedance is shown in Fig. 6. The voltage with S open is called E_o, that with the switch closed, E_1, the current being I. The impedance may be taken as the ratio of cause to effect, but the cause of current flow is the unbalanced voltage $(E_o - E_1)$. The impedance is $Z = (E_o - E_1)/I$. This method is superior to that in Fig. 5, in that we have two controls, the field resistance and the choke coils. We are thus able to obtain the synchronous impedance at different saturations, and, if we desire, at different currents as well. This is the method on which the A. I. E. E. standard is based. This method gives no clue as to how the impedance varies with power factor, since the current is always at very low power factor.

In order to determine the variation of synchronous impedance with current, saturation and power factor, three controls should be available, and these were available in the Westinghouse set, in the two field rheostats, and in the phase displacement hand wheel attached to the machine with the movable stator. The two machines were coupled together and driven by a d-c. motor at 1200 rev. per min., and connected as in Fig. 7. First both machines were excited equally, then the adjusting handwheel was turned until the voltmeter $D E$ indicated no voltage, The angular position of the movable stator was then noted on a degree scale mounted on its frame.

If either the phase position of the movable stator,

or the relative field excitations were changed, the voltmeter across the switch indicated a resultant voltage $D\,E$, which was taken as the cause of the flow of current resulting when the switch was closed. The reactions of this current equalized the fluxes in the two machines and the terminal voltage E when the switch S was closed was taken as the measure of the saturation. The synchronous impedance was taken as the ratio of cause to effect, or $Z = (D\,E/I)$. By unbalancing the voltages more and more different circulating currents could

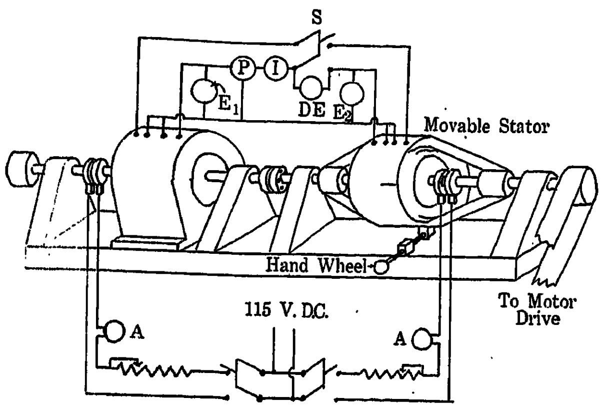

Fig. 7—Improved Synchronous Impedance Test.

be obtained. By increasing both fields together different saturations could be obtained. By controlling the phase relation of the circulating voltage through the combined use of the hand wheel and the field rheostats, currents of any power factor could be circulated. The power factor was taken as the ratio of the wattmeter reading P to the product $E\,I$. When the voltage was unbalanced by field excitation only, (the stators being in phase) the resulting current had a very low power factor, 8-10 per cent. When the

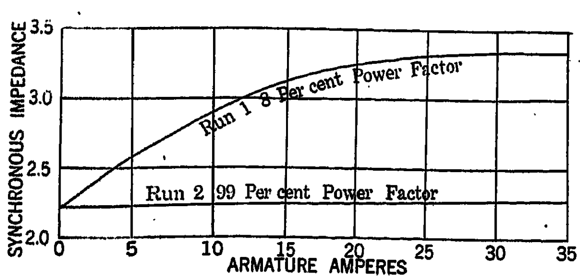

Fig. 8—Synchronous Impedance at Constant P. F. and Terminal Volts, Varying Current

voltages were unbalanced by the hand wheel only, the fields being equal, the resultant current had a very high power factor from 99-100 per cent. Six readings were taken for each point of data, the voltage E_1, E_2 and $D\,E$, with S open and E, I and P with S closed.

In the first two runs the terminal voltage on closed circuit E was held constant at rated value 180 volts, but the voltages were unbalanced more and more, circulating different currents. In one run this was done by the field rheostats, the phase displacement between the stators being zero, and resulting in an 8 per cent power factor. In the other, this was done by the hand wheel, the machines being excited equally, resulting in a 100 per cent power factor. The results of these two runs are shown in Fig. 8. An increase of

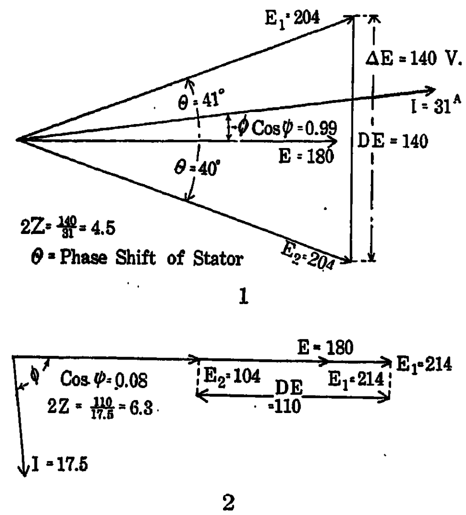

Fig. 9—Vector Diagrams Runs 1 and 2

impedance with current at low power factors is indicated. A considerably lower impedance is shown for 100 per cent power factor than for low power factors. The impedance at 100 per cent power factor seemed to be independent of the current strength. Two points are shown, one on each curve for which vector diagrams are given in Fig. 9. One curious result shown in this figure is that the terminal voltage on closed circuit E is greater than the average of E_1 and E_2 for low power

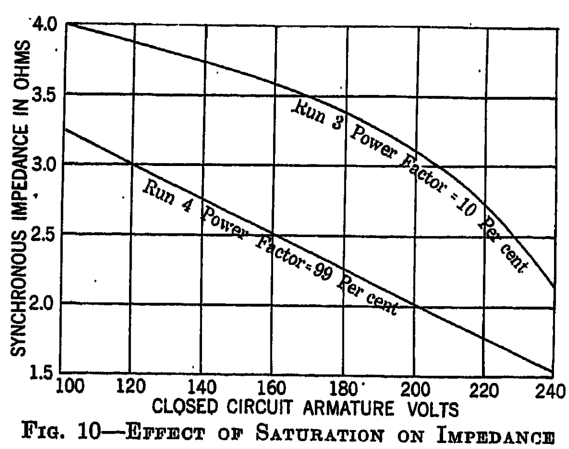

Fig. 10—Effect of Saturation on Impedance

factors, but less than the vectorial average of E_1 and E_2 for high power factors. This indicates that our test gives simply an average impedance of the two machines.

In the next two runs the power factor was again kept constant, but the saturation of the machines was varied. In the third run the two machines were kept at zero relative phase, the power factor was 10 per cent, and the circulating current was kept at rated

value on the name plate of the machine. In the fourth run the phase displacement of the machines was kept constant at 41 deg., and the power factor was 99 per cent. The results of these two runs is given in Fig. 10. A decrease in impedance with saturation is indicated, as well as a lower impedance at 100 per cent than at low power factors. The decrease in the impedance with saturation at 100 per cent power factors

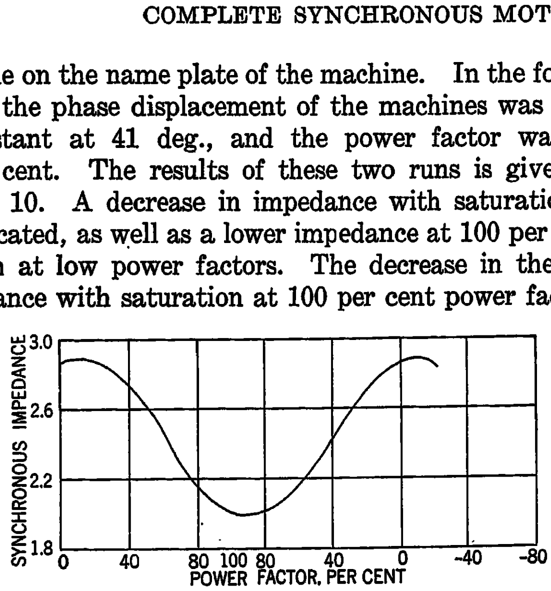

FIG. 11—EFFECT OF POWER FACTOR ON IMPEDANCE-CURRENT AND SATURATION CONSTANT

is believed to be a novel result. The ratio of impedance at normal voltage namely impedance at 100 per cent power factor to impedance at zero power factor is as 2 as to 3. This ratio is considerably higher than that obtained by purely mathematical calculation as for example in Karapetoff's "Magnetic Circuit" pages 150 and following.

In the fifth run the saturation was kept constant at a terminal voltage of 180 volts, the circulating current

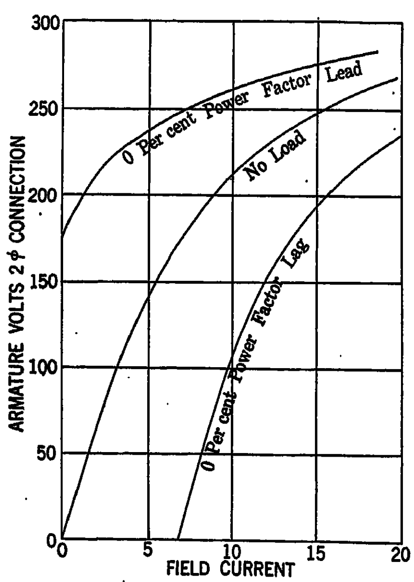

FIG. 12—SATURATION CURVES

was kept constant at (2/3) of name plate rating, but the power factor was varied from 90 deg. lag to 90 deg. leading current. The results are shown in Fig. 11. A variation of very considerable amount with power factor is indicated. The saturation curves of the machine at no load, and full load zero power factor both leading and lagging are given in Fig. 12 as a matter of interest.

The variation in synchronous reactance with saturation is satisfactorily allowed for in the magnetomotive force method, and in the A. I. E. E. method of figuring synchronous machine performance as well. The Blondel method of computing performance, explained by Professor Karapetoff in his "Magnetic Circuit" pages 150-157, provides a satisfactory method of allowing for the effects of saturation, and also power factor, with two exceptions. First, as noted above, impedances at 100 per cent power factor seem to be larger than those indicated by the "Magnetic Circuit." Secondly, according to Professor Karapetoff, the impedance at 100 per cent power factor, should be independent of of saturation. This is conclusively disproved by our experiments.

We do not have any theory to propound that will harmonize the variations here noted, but we believe that the Blondel method can be improved so as to allow for the effects of saturation with high power factor currents. Furthermore, we hope, that when such a theory is found it will completely explain the queer nose we have observed and recorded in our Fig. 3.

Discussion

Q. Graham; (communicated): To those who are familiar with synchronous motor *V* curves in the normal working region only, the shape of the curves in their remote upper portions may seem to be of little importance. Yet they do form a fascinating study and they have a certain practical importance.

A synchronous machine having negligible resistance in the armature winding and negligible saturation could be made to furnish armature current in proportion to its field current through an unlimited range. As soon as armature resistance is introduced this relation is changed and an upper limit for armature current is reached. The curves then take the shape which the authors show in their Fig. 4.

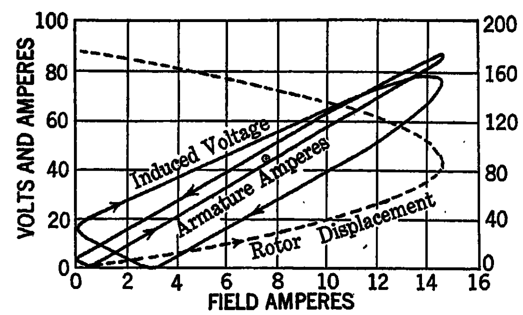

FIG. 1—THE POINT OF MAXIMUM TORQUE IS SHOWN BY THE SMALL CIRCLE

In order to point out some of the interesting relations that exist I have calculated the curve of zero torque for the authors' machine, having had access to the manufacturer's records. This calculated curve along with the corresponding curves of induced voltage and angular position of the rotor are shown in Fig. 1. The corresponding branches of the three curves are shown by the arrows. The calculated curve agrees fairly well with the test curve shown in the paper.

If we proceed from the point of zero armature current an increase in field current gives an increase in armature current until the point of maximum field current is reached. Here the displacement of the rotor is nearly 90 deg. A slight reduction of field current and an increase in displacement brings the armature current to a maximum as the displacement reaches 90 deg. At this point the power factor of the machine is unity and the resistance drop in the winding is just equal to the line voltage. A

further reduction in excitation accompanied by a greater phase displacement of the rotor reduced the armature current again. The next point of interest occurs where the induced voltage is zero. That is, the impedance drop in the winding is equal to the line voltage and the field and armature ampere turns across the air-gap are neutralized. From this point the curves proceed to the position of zero field current. To continue the increasing displacement of the rotor after zero field current is reached the excitation must be reversed. An increase of field in the reversed direction will then bring the armature current back to zero and the complete path will have been traversed. It will be noted that the rotor displacement has reached 180 deg. but since the excitation has been reversed a condition of stability exists. In

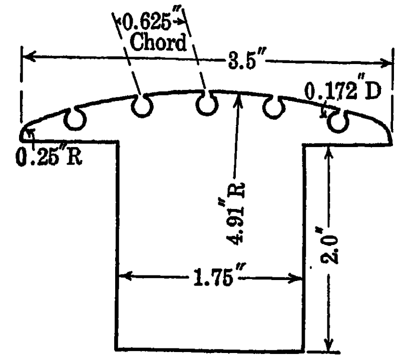

Fig. 2

passing through the point of zero excitation it would have been satisfactory to consider the rotor as going through an instantaneous shift in position of 180 deg. and the excitation as remaining positive.

It is interesting to consider these curves from the standpoint of power input and output and thereby examine the region beyond the point of maximum excitation. Under any condition the power input is divided between the $I^2 R$ loss in the winding and the output which appears as torque at the shaft. For pure condenser operation, or zero torque, the input is entirely absorbed as loss in the winding. The following conclusions may be drawn at once:

1. For any torque curve, including the zero torque curve, the power factor is unity at the point of maximum armature current.

2. The maximum torque point occurs with an armature current which is half of the maximum current on the zero torque curve. The input is then equally divided between loss and output.

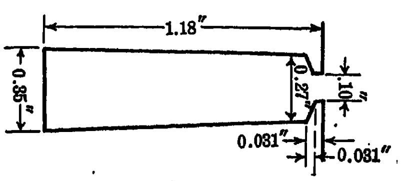

Fig. 3

3. For armature and field currents beyond the range shown by the curves the loss exceeds the electrical input and torque must be supplied to the shaft. The machine then becomes a generator loaded on its own windings.

A study of the complete excitation characteristics of synchronous motors has proved worthwhile in connection with applications requiring extremely low frequency operation. If the authors are inclined to make further experiments they might operate their machine at 25 cycles or even lower and thus have the equivalent of a higher resistance armature with its concomitant effects.

The following design data on the authors' machine may be of interest.

Stator:

15 in. outside diameter, effective (punching is not circular.)
10 in. inside diameter.
5 in. axial length.
72 slots. See Fig. 3 for dimensions.
22 conductors per slot. Each conductor consisting of two 0.57 in. diam. wires in parallel.
Winding in three parallel groups, star-connected, for 220 volts.
Throw of coils from slot No. 1 to slot No. 10 or a pitch of 9 slots.
Single air-gap 0.094 in.

Rotor:

Six poles. See Fig. 2 for dimensions.
Damper winding; 5 bars per pole, each 0.162 in. diam. copper.
End ring 0.156 in. $\times$ 0.75 in. copper.
Field winding: 185 turns per pole of 0.057 in. $\times$ 0.081 in. copper ribbon.

R. W. Wieseman: The unstable portion of the excitation curve or phase characteristic of a synchronous motor has never been obtained experimentally, so far as we know, and therefore the authors of this paper are to be commended for obtaining the complete synchronous motor excitation curve. However, these curves are apparently more valuable from the academic standpoint than from the practical standpoint because a synchronous motor can not be operated in practise at the unstable part of its excitation characteristic.

The authors state that in Fig. 4 no evidence of a saturated condition is observed in the excitation curves at large field currents. I wish to point out that practically no saturation could exist in a machine which is operated at one-eleventh voltage and consequently one-eleventh of its normal magnetic flux density. Saturation will only occur and affect the shape of the curves when the motor is operated near normal flux densities. No effects of saturation are noted in Fig. 3, which shows the excitation characteristics at one-half normal densities.

In the description of the method of finding the synchronous impedance shown by Fig. 6, it is stated that this method gives no clue as to how the impedance will vary with power factor, and that to obtain this variation an arrangement shown by Fig. 7 is necessary. The variation of impedance with power factor can be obtained very easily with the arrangement shown by Fig. 6 if resistance is connected in series or in parallel with the inductance.

This paper states that the synchronous impedance of a synchronous motor varies with the several conditions of load. It is easier and also more practical to consider the synchronous impedance made up of two components: armature leakage reactance and armature reaction. The armature resistance can be neglected. In a salient pole machine the armature reactance is maximum with unity power factor currents and minimum at zero power factor, whereas the effect of armature reaction is minimum at unity power factor and maximum at zero power factor. Therefore, the manner in which the synchronous impedance varies depends upon the inherent design of the machine as well as the load conditions.

V. Karapetoff (communicated): The authors deserve much credit for having shown that the so-called unstable portions of load characteristics of a synchronous machine may be obtained experimentally, by coupling two machines mechanically at an adjustable angle[2]. The instability is purely mechanical, and is due to the fact that in regular operation the machine (whether a generator or a motor) is allowed to change its torque angle with the load. When two synchronous machines are coupled mechanically and also connected electrically, this angle is entirely under the observer's control, and the stability is that of the set and not of the individual machines. While the practical application of the method is somewhat limited because two mechanically and adjustably coupled machines are but seldom available, the method should prove of interest in experimental studies of armature reaction and reactance, and in checking various proposed theories and performance diagrams of synchronous

machines. Just now, the stability limit in the generator range is of considerable practical importance in superpower plants in which the generator characteristics limit the amount of power which can be transmitted over a given line. Possibly, the range near and beyond the generator stability limit can also be conveniently studied by means of two adjustably coupled machines. Then, if the observed performance, on small machines checks with that predicted by theory, the designer may compute the power limit of his superpower generators with much more confidence.

The value of the paper would be much enhanced if complete design data of the machines were available. It is to be hoped that the maker of the machines will be generous enough to contribute these data to this discussion, in order that the observed curves may be checked with theoretical diagrams. Perhaps with the theory of two reactions, when properly applied, the observed hump in Fig. 3 could be interpreted or predicted. In the range under consideration, the machine is unsaturated, and Blondel's theory should apply with considerable accuracy.

I am at a loss to understand the latter part of the paper, purporting to analyze the effect of the current, saturation, and power factor upon the magnitude of synchronous impedance. The concept of synchronous reactance was introduced in the early days of a-c. engineering, and served its useful purpose in those days, but it is almost unbelievable that any one should now attempt to interpret the observed performance characteristics of a synchronous machine with salient poles in terms of a variable synchronous reactance. The authors should have separated the direct armature reaction from the leakage reactance, using the zero-power-factor load curve,[3] and then estimated the transverse armature reaction from the performance at unity power factor and the observed torque angle. This would have given them a rational basis for an interpretation of the other observed curves and for a judgement about the accuracy of the method of two armature reactions. Having instead bunched together all these heterogeneous factors into a physically irrational concept of "synchronous impedance," they have reached conclusions apt to befog rather than to clear up the issue.

Equally incomprehensible to me are their references to my "Magnetic Circuit." They speak of the observed ratio (2 to 3) of the synchronous impedance at unity power factor to that at zero power factor and state that it is considerably higher than that computed by me. My formulas and computations refer to the direct and transverse components of the armature reaction, and not to synchronous impedance, which latter I have used in my writings only in order to show its limitations and inadequacy. My values could be checked with the experimental results only by computations involving the design constants of the machines, and there is nothing in the paper to indicate that the authors have used the design data in their conclusions. The authors also ascribe to me the statement (without giving the page) that the impedance at 100 per cent power factor should be independent of saturation. Since I do not use the concept of synchronous impedance in the "Magnetic Circuit" at all, it is not clear how and where I could have made such a statement. At unity power factor at the terminals, there is not an inconsiderable internal phase angle and a corresponding direct reaction. With higher saturation, the effect of this direct reaction upon the net flux is of course less. The transverse reaction and the leakage coefficient are also affected by the saturation of the pole tips, although these factors are difficult to take into account theoretically.

Within the last six or seven years, Prof. Blondel has published in various French periodicals a number of excellent articles, further explaining and extending the application of his theory of two armature reactions of the synchronous machine. In the light of these painstaking researches, the interpretation of the results by the authors is quite out of date. They could render real service to the profession if they would further experiment with the same machines, and use their results to build up, step by step, a consistent and accurate theory of synchronous machines, and also critically check various modifications of the present theories.

J. F. H. Douglas: We wish to concur in what Mr. Wieseman has said on saturation, and on the armature leakage reactance probably being larger at high power factors. We wish to thank Professor Karatpetoff for suggestions for future tests, and for bibliographic references. We find the comment and calculations of Mr. Graham of interest and his discussion of stability illuminating. The design data furnished will be valuable. We wish to call attention to fact that Mr. Graham's and Mr. Wieseman's statements as to whether armature resistance is negligible can be harmonized. The armature resistance is negligible at normal frequency and impressed voltage, if the motor is not greatly over excited it must be taken into account otherwise.

We wish to express a doubt whether a simple load test using resistance as well as reactance, will give the synchronous reactance. For illustration, in Fig. 1, if E_o is measured at no load, one might think the synchronous reactance drop to be perpendicular to the current and might get an erroneous value for the same. Fig. 9 in our paper, indicates that the $I\,X_s$ drop is not perpendicular

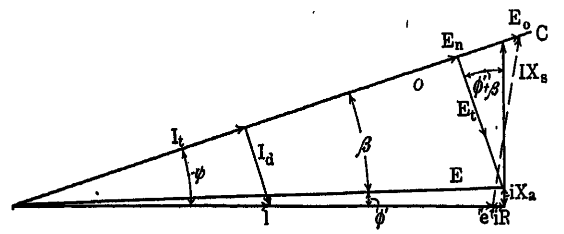

FIG. 4—VECTOR DIAGRAM COMPARING BLONDEL METHOD WITH SYNCHRONOUS IMPEDANCE

to the current in all cases. Professor Karapetoff's remark is quite to the point here that considerably more experiment is needed.

We are criticized by Professor Karapetoff for the use of synchronous impedance on various grounds. We consider the term too firmly entranced in the texts, and by implication in the A. I. E. E. rule for regulation, to be ignored. We consider it useful as a concept for the very fact that it gathers up a number of components. (1) In qualitative explanations it affords a simple way of speaking of the effects of changing the excitation of a synchronous motor, or of putting a load upon it. (2) For approximate calculations it affords a quick method of computation. (3) When allowance is made for the fact that at high power factors the measured impedance is less, (and the reason why is easily explained), it affords a simple basis for calculating period of hunting and synchronizing torque, and a simple basis for discussing the accuracy of the A. I. E. E. method for regulation at high power factors.

Defined as the ratio of cause to effect, of antecedent to consequent, as voltage across as witch to current flowing after closing it, it is in accord in reasoning with many of Professor Karapetoff's own explanations. To term it a collection of heterogeneous factors is not quite just. The distortion of flux and the drop in voltage resulting from it has only one "genesis" or origin—the armature m. m. f. We may, if we wish, divide the cause into components parallel to and perpendicular to the poles. We may divide the effect into components, those fluxes, and e. m. fs. strictly proportional to armature current and those which, owing to saturation, are not so proportional,—reactances, and reactions. This is a question of accuracy and convenience for the purposes in hand.

Synchronous impedance is criticised as physically irrational. It is empirical, while the Blondel method is highly theoretical.

2. Testing of alternators by means of two identical machines rigidly coupled at an angle was suggested by A. Blondel in 1892 and more fully described by him before the International Electrical Congress in St. Louis, 1904; TRANS. Vol. 1, p. 620.

3. V. Karapetoff, Experimental Electrical Engineering, Vol. I, Third edition, Chap. 20.

However, all theories contain irrational elements in the sense of items which are approximations of the physical reality. In this sense, the Blondel theory is also irrational. To mention one point, in the "Magnetic Circuit" it is assumed that armature leakage reactance is an absolute constant. This is the basis of the criticism that we should have worked up our data in a certain way, but if we had done that we would have come under Mr. Wieseman's criticism," in salient pole machines, the armature reactance is a maximum with unity power factor, and a minimum with zero power factor," a statement, which we think may be correct. To mention another point, the coefficient of cross reaction or relation between the voltage induced to the current, is assumed as a constant. This relation is derived in Karapetoff's Magnetic Circuit by the analogy of "fictitious poles," which show no saturation. This is an irrational element, that only brings home the point that all our theories are approximations. We have no objection to using the Blondel theory as a second approximation, until a better is found, but we think of synchronous impedance as a first approximation.

That the Blondel theory does need improvement, we feel most strongly. Our data will not agree with Professor Karapetoff's formulas. When we try to get synchronous impedance from his diagrams at 100 per cent power factor and at low saturations the result is less than that shown by our tests. The value taken off his diagrams is independent of saturation, contrary to our experiments. We did not mean to imply that he used or calculated synchronous impedance himself. However, to be specific, we take the synchronous impedance at unity power factor to be approximately equal to

$$X_{s(100)} = X_a + (E_t'/i) = X_a + (0.3\ K_b mnv)$$

the quantities appearing in part in his equation (**84**), page 156.

The Fig. 4 herewith is Fig. 40 of page 150 of the Magnetic Circuit, drawn for 100 per cent power factor with three vectors added. The solid line $O\ E_o$ is the no-load voltage along the polar axis $O\ C$, the dotted line $E\ t'$ from equation (**84**) is drawn in its proper phase position, perpendicular to the current, and terminating on the line $O\ E_o$. The dotted line joining e and E_o is what we call, and what is usually called the synchronous impedance drop. There is nothing in the Magnetic Circuit to indicate that E_t' even has a position, but by reference to the equation after Eq. (**186**), namely,

$$E_t' \operatorname{Sin}(\phi + \beta) = E \operatorname{Sin}(\beta)$$

we see that the line E_t' of our diagram does meet these conditions. In the above diagram $I\ Z_s$ is numerically very close to $I\ X_a + E_t'$.

Numerically we note that X_a may be taken from our Fig. 12 as also may the direct reaction, given by Eq. (**79**) in the Magnetic Circuit. We find from our Fig. 12 that the value of (Xa) is too small to measure. We attribute then the whole effect to reaction. We find that an armature current of 35 amperes in Fig. 12 neutralizes a field current of 7 amperes. Comparing equations (**79**) and (**84**) in the Magnetic Circuit we note the constant in one is 40 per cent of that in the other, with V the slope of the saturation curve included. We compute the slope to be 31 volts per ampere. We compute $X_{s100} = 0.4(7/35)\ 31 = 2.5$ ohms.

When we refer to our Fig. 10 we see that this value is much too small when the machine is not saturated, and that the value of the reactance is not a constant, as indicated by the above interpretation of the Theory in the Magnetic Circuit, but actually a variable affected by saturation of the machine. Fig. 4 shows clearly that the direct reaction can not be a major item being nearly horizontal but that the saturation of pole tips affects the transverse reaction. As Professor Karapetoff admits, this factor is difficult to take into account theoretically but the variation of values in Fig. 10 of our paper at unity power factor from 3.2 to 1.6 ohms indicates that the reluctance of the transverse flux path is approximately doubled, by saturation. This change is so large that it is difficult to see how one can avoid the conclusion that the theory of transverse reaction needs considerable improvement.

With the data now available from the manufacturers it would be easy to follow the suggestion made to check the shape of the hump in our curves by the Blondel theory. The following calculation was made before this data was supplied, but checks so well in a general way, that on this point Professor Karapetoff may consider himself well vindicated. Let us assume that resistance may be neglected, and that we have only to consider two reactances X_t for cross-magnetizing current, and X_d for direct reaction component of the current. This is a rather crude simplification of the Blondel theory that will hold fairly well with

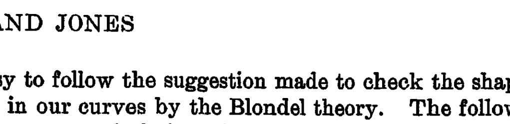

Fig. 5—Simplified Blondel Diagram

small saturation. Fig. 5 gives the vector diagram. The impressed voltage is E, the induced voltage at no load E_o, shows by its magnitude the field current, and by its phase the angle the pole has fallen behind. The current I may be resolved into components I_d and I_t in quadrature and in phase with the pole centers. By assumption I_d is caused by voltage component $E_o - E \cos\psi$ and is governed by X_d, while I_t is due to $E \sin\psi$ and is governed by X_t. Thus

$$I_t = E \sin(\psi)/X_t; \qquad I_d = (E_o - E\cos(\psi))/X_d \qquad (1)\ \&\ (2)$$

The ordinates Y of a set of V curves may be taken as the ratio the armature current to any current such as $(E/X_d) = I_o$ as a basis. The abscissas may be taken as the ratio of field currents of induced

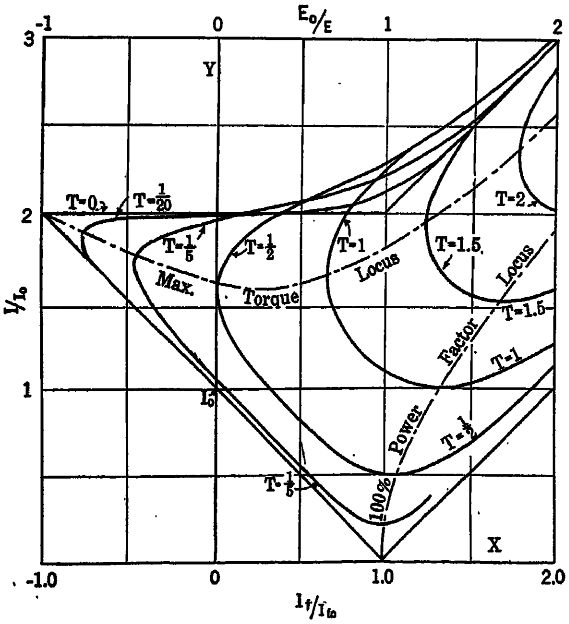

Fig. 6

no-load volts E_o/E. If we call $X_d/X_t = K$, I_p the power, and I_{qw} the wattless components of the current, we have the following:

$$I_t = I_o K \sin(\psi); \qquad I_d = I_o(X - \cos(\psi)) \qquad (3)\ \&\ (4)$$

$$T = I/I_o\, 2\sin(\psi)\ (\ (K-1)\cos(\psi) + X) \qquad (5)$$

$$I_w = I_o\,(X\cos(\phi) - K + (K-1)\cos^2\psi) \qquad (6)$$

$$I = \gamma\ (I_p^2 + I_w^2) \qquad (7)$$

We assumed $K = 2$, $T = 0.05$, 0.02, 0.5, 1.0, 1.5, and 2.0; we assumed values of $\psi = 2°$, 5°, 10°, 20°, 30°, ...170°, and solved Eq. (**5**) for X. We then solved Eq. (**6**) for I_w and Eq. (**7**) for I. We have plotted the values of I thus computed against X in Fig. 6. These curves in the main agree with our experiments, and certainly bear out the contention that the Blondel theory applies quite accurately at low flux densities.

Factors Affecting the Design of D-C. Motors for Locomotives

BY RALPH E. FERRIS[1]
Associate, A. I. E. E.

Synopsis.—The designer of motors for locomotive service is confronted with at least two limitations; space and weight. For large locomotives, the second limitation may not be of prime importance, but the first must be constantly in the mind of the designer.

The paper gives a comparison between different types of motor mounting as regards the amount of power which may be developed in the available space with direct current motors. The comparisons are largely qualitative but within reasonable limits are also quantitative.

The available space between wheels or locomotive side frames is divided into two parts. One of these parts is made up of units which are assumed to be constant within the range considered, while the other part is made up of variables. Expressions for the variables are derived, generally in terms of armature diameter, and constants and variables are then combined into a complete expression for motor output.

The voltage applied to motor commutator, voltage-to-ground, number of poles, peripheral speed and track gage, as well as type of motor mounting are considered in the comparison.

THE object of the following discussion is to develop the proportions of d-c. motors in relation to the available space between wheels or side frames of locomotives.

Two voltages only have been considered, viz., 3000 and 1000 volts, this, not because other voltages, either higher or lower, are not possible or desirable, but simply to give a basis of comparison and eliminate the almost endless number of combinations.

The results should be considered as largely qualitative, but it is believed that the effect of various factors will be shown and in a measure the results are also quantitative. Actual numerical values have been used in most cases with the full realization that exceptions could be taken to these values for special cases, or perhaps even for average conditions, but an honest attempt has been made to place all results on a basis as nearly comparable as possible. The nominal, or one-hour rating, of motors has been used as the physical dimensions conform more nearly with this rating than with the continuous rating where the type of ventilation is a determining factor.

The paper has been divided into three general sections: first 3000-volt motors; second, 1000-volt motors; and third, discussion of curves and conclusions.

3000-Volt Motors

For purposes of this paper the following classification has been chosen for the 3000-volt motors. It should be understood that the voltage given in the tables refers to the voltage across the commutator and not the voltage to ground which as before stated is in all cases either 3000 or 1000 volts.

1. Axle-hung Gear Drive

a. 750 Volts	*b.* 1000 Volts	*c.* 1500 Volts
1. four-pole	1. four-pole	1. four-pole
2. six-pole	2. six-pole	

2. Frame-mounted, Quill and Gear Drive

a. 750 Volts	*b.* 1000 Volts	*c.* 1500 Volts
1. four-pole	1. four-pole	1. four-pole
2. six-pole	2. six-pole	

3. Frame-mounted, Gear and Side-Rod Drive

a. 750 Volt	*b.* 1000 Volts	*c.* 1500
1. four-pole	1. four-pole	1. four-pole
2. six-pole	2. six-pole	2. six-pole
3. eight-pole	3. eight-pole	
4. 10 pole		

4. Gearless

a. 750 Volts	*b.* 1000 Volts	*c.* 1500 Volts
1. two-pole	1. two-pole	1. two-pole
2. four-pole	2. four-pole	2. four-pole
3. six-pole	3. six-pole	

To illustrate the method of analysis, all the cases for the axle-hung motors, 1 *a*, 1 *b*, and 1 *c*, are worked out in some detail, especially for the 750-volt four-pole motor. The first and second cases, under 4 *b* for the 1000-volt, gearless motor, will also be given in more or less detail. Of the remainder, curves will be shown for all four cases under 3 *a* and first case under 3 *b*, 3 *c*, 4 *a*, and 4 *c*.

Proportion of Space for 3000-Volt Motors, Axle-Mounted

The space between wheel flanges may be divided as follows:

L_t = Total space between wheels or between locomotive side frames

L_c = Length of commutator

L_e = Length of coil extension on ends not including cell extension.

L_g = Length of gear-face

L = Length of armature core iron

L_k = A constant which is made up of the following items:

1. Clearance between gear-case and wheel, front and rear .... 2.00 in.
2. Gear-case walls and clearance to gear, wheel side, front and rear .... 1.75 in.

---

[1] Westinghouse Electric & Mfg. Co., East Pittsburgh, Pa.

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 9-12, 1925.

3.	Gear-case walls and clearance to gear, motor side front and rear	1.50 in.
4.	Gear-case to end-housing, front and rear	0.75 in.
5.	Housing walls, front and rear	2.00 in.
6.	Clearance between front-end housing and commutator V-ring	0.75 in.
7.	Creepage on V-ring	2.50 in.
8.	Commutator groove and clearance between brushes	0.75 in.
9.	Coil extension, both ends	2.00 in.
10.	Clearance between coil and rear-end housing	1.25 in.
	Total	15.25 in.

In order that the foregoing variables and constants may be understood, they are indicated in the diagrammatic long section shown in Fig. 1.

It is realized that the constants as given may be open to question in any particular case, but it is believed they are not far from average conditions, and will at least give, as before stated, a basis for comparison.

Output Equations

It can be shown that the output of a motor may be expressed as follows:

$$\text{k-w.} = C\,D^2 L\,S \tag{1}$$

where

C = A so-called output constant
D = Armature diameter
L = Length of armature iron
S = Speed in rev. per min.

Substituting values given in preceding section in equation (1), gives

$$\text{k-w.} = (L_t - L_c - L_e - L_g - L_k)\,D^2 C\,S \tag{2}$$

But

$$L_c = \text{kw.} \times C_c \tag{3}$$

Where C_c is a constant depending on brush width, voltage, number of brush arms, and current density in brush.

$$L_g = \text{kw.} \times C_g + C_2 \tag{4*}$$

$$L_e = C_e D \tag{5}$$

Where C_g, C_2 and C_e are constants. The derivations of equations 3, 4 and 5, which are a means to an end, will be shown in more detail under the special case of the four-pole, 750-volts per commutator motor.

Substituting equations 3, 4 and 5 in 2, and solving for kw. gives

*Equation (4) is only approximate, the following being more nearly correct.

$$L_g = \frac{\text{kw.} \times C_p \times P_t}{s \times N_t}$$

where
P_t = Diametral pitch of gear
S = speed of motor in rev. per min.
N_t = Number of teeth in pinion
C_p = Constant depending on P_t

A value of C_p which will give a fairly conservative gear-face width is as follows:

$$C_p = \frac{32\,P_t}{1 - 0.19\,P_t}$$

$$\text{kw.} = \frac{D^2 S\,C\,(L_t - C_e D - C_2 - L_k)}{1 + D^2 S\,C\,(C_c + C_g)} \tag{6}$$

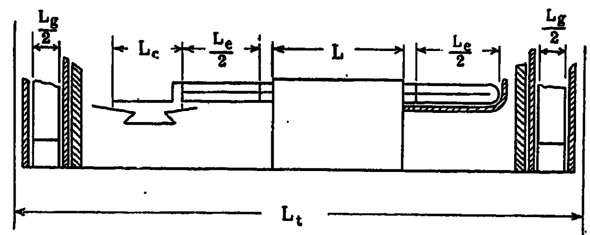
If $L_h = L_t - L_k$

Then

$$\text{kw.} = \frac{D^2 S\,C\,(L_h - C_e D - C_2)}{1 + D^2 S\,C\,(C_c + C_g)} \tag{7}$$

In order to obtain a comparison, a constant peripheral speed in feet per minute of C_s is taken, in which case,

$$S = \frac{3.82\,C_s}{D} \tag{8}$$



$L_k = L_t - L_g - L_c - L_e - L$

Fig. 1

By substitution, a final expression for kw. in terms of D is as follows:

$$\text{kw.} = \frac{3.82\,C_s\,D\,C\,(L_1 - C_e D - C_2)}{1 + 3.82\,D\,C_s\,C\,(C_c + C_g)} \tag{9}$$

General Discussion of Output Constant C

Very often in engineering literature a so-called constant is not a constant at all but is merely a convenient way of combining a number of factors which are difficult to evaluate. Such is the case with the output constant C. This constant C is affected by a number of factors, the principal being as follows:

a. Slot-space factor. The slot-space factor is the ratio of cross-section of copper in slot to cross-section of slot, and therefore with a given wall thickness of insulation to ground, this factor varies as some direct function of the cross-section of copper in the slot. For a given voltage and peripheral speed, the diameter of armature will increase with increase of total copper cross-section, or stated inversely, the slot-space factor increases with increase of armature diameter.

It can be shown that for a constant number of slots, the slot-space factor is given approximately by the following expression:[2]

$$f = \frac{K_1 D^2 - K_2 D + K_3}{K_1 D^2}$$

where f = Slot-space factor
K_1, K_2, K_3 = constants

b. Iron loss. For a given density in the teeth and core of the armature the iron loss will vary as some

2. Effect of Insulation on Design by R. E. Ferris, "*The Electric Journal*," October, 1923.

direct function of the speed. For a given peripheral speed, the iron loss per cubic inch of iron for a constant density and a constant number of poles will decrease with increase of armature diameter, or for constant iron loss per cubic inch, the density in teeth and core and therefore in the air-gap may be increased with increase of armature diameter. As the air-gap density is one of the factors which enters into the output-constant, it follows that this factor also causes the output-constant to increase with the armature diameter.

c. Pole constant. The pole constant as defined in this paper is the ratio of total pole-face bore to periphery of armature core. It is, of course, evident that the larger the pole constant, the larger will be the output constant, other things being equal.

In general, the space between main pole tips will remain approximately constant for a given number of poles within a reasonable range of armature diameters. With this assumption, therefore, if we let

a = space between pole tips
C_p = pole constant
D = armature diameter,

then

$$C_p = \frac{\pi D - a}{\pi D} = 1 - \frac{a}{\pi D}$$

This expression shows that the pole constant, and therefore the output constant, increases with armature diameter.

d. Watts copper-loss per sq. in. of armature surface. This factor in the output constant is governed largely by the method of heat dissipation and is not affected

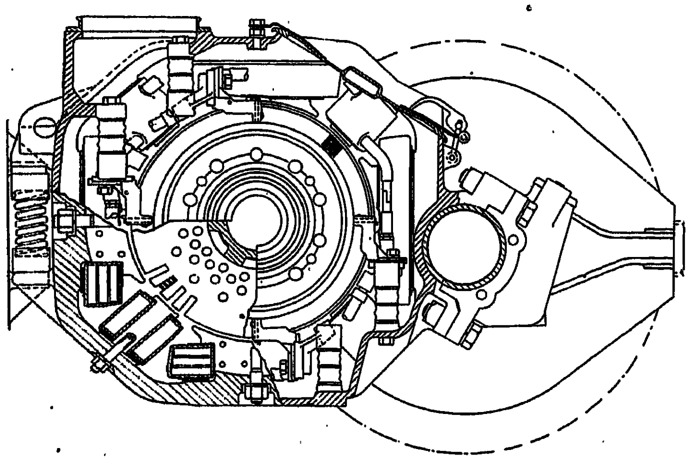


Fig. 2

materially by the armature diameter except as the armature diameter affects method of ventilation.

In general, therefore, the output constant increases with increase of armature diameter. It is, of course, practically impossible to give an expression for the output-constant in terms of armature diameter, which will more than approximate the results for any given design. The following imperical expression, however, is used as coming within the limits of accuracy of this article:

$$C = K \log (a D - b)$$

FOUR-POLE AXLE-HUNG MOTOR, 750 VOLTS PER COMMUTATOR

The axle-hung type of mounting and drive are so common that little or no description is necessary. Briefly, one side of the motor is supported by either a nose or bar suspension on the truck transom, while the other side is supported directly on the axle, through axle caps and bearings. With this mounting, a certain percentage of the motor weight is carried directly on the axle with no intervening spring.

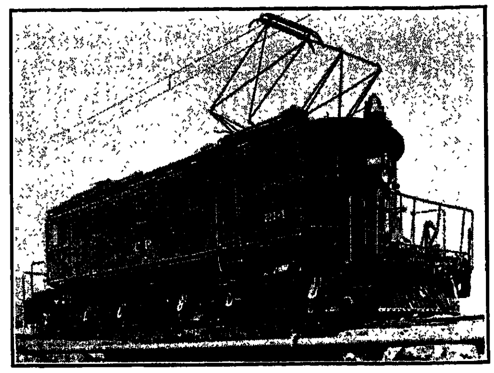

Fig. 3—Complete Locomotive with Axle-Hung Motors

A cross section of this type of motor mounting is shown in Fig. 2, and a complete locomotive with axle-hung motors in Fig. 3.

The output constant for a four-pole, 3000-volt, 750-volt-per-commutator motor may be expressed imperically by the following equation:

$$C = \log (0.385 D - 1.31) 7.65 \times 10^{-5} \qquad \mathbf{(11)}$$

Length of commutator. The length of commutator, L_c, for 750 volts per commutator and four brush-holder arms, may be derived as follows:

If

I_t = total amperes to armature
E = volts at motor terminals
f = efficiency

$$I_t = \frac{1000 \times \text{kw.}}{E F} \qquad \mathbf{(12)}$$

and, if,

$E = 750$
$f = 0.88$
$I_t = 1.52$ kw. **(13)**

The length of commutator neck cannot be expressed in terms of kilowatt unless the number of parallel circuits are taken into account; but as this introduces a further complication, such a factor will be omitted and the length of neck expressed as

$$\text{Neck} = 0.0024 \text{ kw.} \qquad \mathbf{(14)}$$

At 60 amperes per sq. in. in the brush and 5/8 in.

brush width, the expression for commutator face, including allowance for brush-stagger, is,

$$\text{Face} = \frac{I_t}{120 \times 0.625} = 0.0203 \text{ kw.} \quad (15)$$

or L_c = Neck + face = 0.0227 kw. (16)

Width of Gear-Face. As an imperical approximation of the gear-face

$$L_g = 0.0134 \text{ kw.} + 3.5 \quad (17)$$

This, for the larger sized motors, will give a gear-face

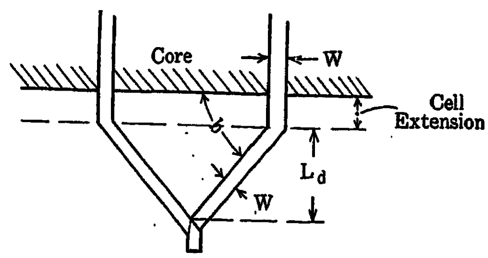

Fig. 4

which is somewhat low, and for the smaller sizes, somewhat high.

Coil Extension L_e. In general, the armature slot-depth will vary as some function of the armature diameter. For the present discussion the following relation will be used:

$$D_s = 0.1\, D \quad (18)$$

where

D_s = Slot-depth

Let

P = ½ the arc of coil-pitch at diameter $(D - 0.1\, D)$

Then for a four-pole machine

$$P = \frac{\pi\,(D - 0.1\, D)}{8}\, 0.95 \quad (19)$$

The factor 0.95 is introduced to take care of a slight amount of chording.

Referring to Fig. 4, with slot-width W equal to tooth-width at one-half depth of slot and with the coil on the diamond part of the end portion equal to slot-width, the sin of angle b, between iron and coil, will be,

$$\text{Sin } b = \frac{\dfrac{\pi\,(D - 0.1\, D)}{2}}{\pi\,(D - 0.1\, D)} = 0.5 \quad (21)$$

Tan b = 0.577

Therefore, referring to Fig. 4, (22)

$$L_d = P \times 0.577$$

But

$$P = 0.335\, D$$

and

$$L_d = 0.194\, D \quad (23)$$

If turn at end of diamond part of coil is considered as six per cent of armature diameter and both ends of the winding are included, then

$$L_e = 0.448\, D \quad (24)$$

TABLE OF CONSTANTS

The following values are, therefore, either constants or assumed constants, at the one-hour rating for a four-pole 750-volts-per-commutator axle-mounted motor:

C_c = 0.0226
C_g = 0.0134
C_2 = 3.5
C_e = 0.448
L_k = 15.25
L_t = 53.25
L_h = 38
C_s = 3500

Substituting equation No. **11** and constants given above in equation No. **9**,

$$\text{kw.} = \frac{(35.4\, D - 0.46\, D^2) \log (0.385\, D - 1.31)}{1 + 0.037\, D \log (0.385\, D - 1.31)} \quad (25)$$

Equation (**25**) gives the kw.-output of a four-pole 750-volts-per-commutator motor with double gears. The case for single-end gears will not be considered, as the only difference would be more available space between wheels for active material. In any case, as limitations are being considered, the motor sizes under consideration would, in general, have double gears.

Curve A of Fig. 5, is the graph of equation (**25**), and shows the kw.-output plotted against the armature diameter for axle-mounted motors, 750-volts per commutator, at a constant peripheral speed of 3500 ft. per min.

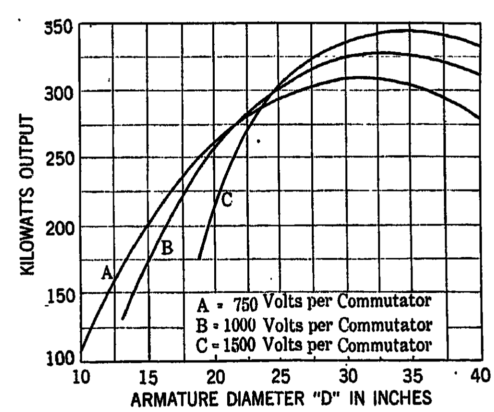

Fig. 5—Axle-Mounted 3000-Volt, Four-Pole Motors, 3500 Ft. per Min. Peripheral Speed 53.25 In. Track Gage

Effect of Track Gage. To show the effect of track-gage on maximum output, the following equation was derived from equation (**25**); assuming a constant armature diameter of 30 in. and a constant peripheral speed of 3500 ft. per min.;

$$\text{kw.} = 14.6\, L_t - 470 \quad (26)$$

Where L_t is distance between wheel flanges.

The graph of this straight line equation is shown in Fig. 6, and brings out strikingly the advantage to be gained by wide track gage.

Variable Peripheral Speed. In order to show the effect of change in peripheral speed, the armature

diameter was assumed a constant at 30 in. in which case, equation (27) was derived from the general equation to show this relation;

$$\text{kw.} = \frac{0.186\, C_s}{1 + 0.000318\, C_s} \tag{27}$$

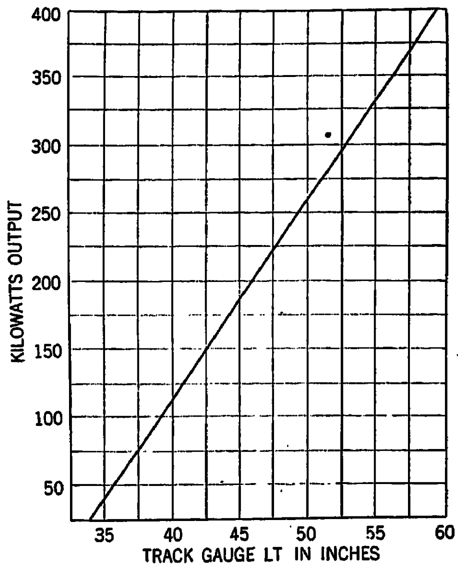

FIG. 6—AXLE-MOUNTED, 3000-VOLT, FOUR-POLE MOTOR, 3500 FT. PER MIN. PERIPHERAL SPEED, 30 IN. ARMATURE DIAMETER

The graph of equation (27) is shown in Fig. 7.

Depth of Field. It will be necessary at this point to digress somewhat from the specific consideration of

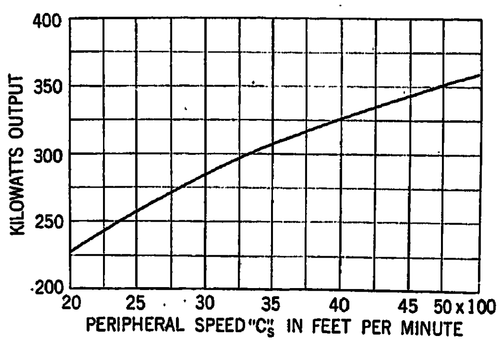

FIG. 7—AXLE-MOUNTED, 3000-VOLT, FOUR-POLE MOTOR 750 VOLTS PER COMMUTATOR, 30 IN. ARMATURE DIAMETER, 53.25 IN. TRACK GAGE

the 750-volt-per-commutator motor, to the more general discussion of the field design.

The amount of copper in the field-winding of a railway motor does not, in general, increase in direct proportion to the diameter of motor armature, mainly because the air-gap which absorbs a large share of the ampere-turns, is not increased in direct proportion to the motor diameter; for example, a 30-in. diameter armature would not, in general, have an air-gap twice the length of a 15-in. diameter armature. Furthermore, the available space for field copper increases with increase in armature diameter, assuming a constant depth of field, or, inversely, the depth of field may be less for a given amount of copper, the larger the diameter of armature. With the foregoing in mind, Figs. 8 and 9 will be understood. Fig. 8 shows roughly the ampere-turns per pole in relation to armature diameter, and Fig. 9, the depth of motor from armature surface to outside of frame at the bottom.

Wheel Diameter. From the curve shown in Fig. 9, and, assuming that the motor is raised above the center line of axle 1½ in., and with clearance-to-rail of 4½ in.,

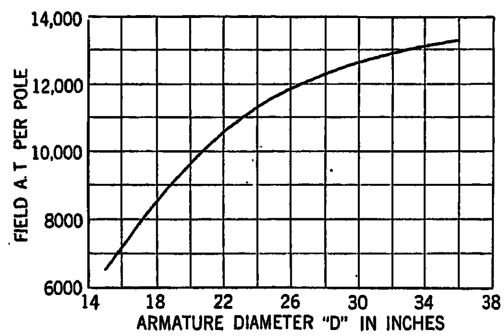

FIG. 8—FIELD AMPERE-TURNS PER POLE FOR A FOUR-POLE, AXLE-MOUNTED MOTOR

the wheel-size is plotted against armature diameter in Fig. 10.

Diameter of Gear. After the wheel diameter is determined, the pitch-line diameter of maximum size gear is approximately fixed, if a given clearance under the gear case is assumed. With 4½ in. clearance from the pitch-line of gear to rail, the pitch-line diameter of gear is plotted against armature diameter in Fig. 11.

For the size of motors under consideration, perhaps the minimum-size pinion would be 16 teeth 2 diametral

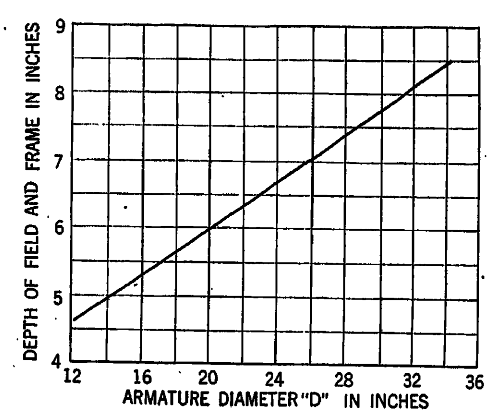

FIG. 9—APPROXIMATE DEPTH OF FIELD AND FRAME

pitch, which would give a minimum pitch-line diameter of pinion of 8 in.

With the diameter of gears and pinions given, by the foregoing assumptions the gear center distance of the motor is fixed, but this gear-center distance checks approximately with the gear-center distance derived from armature diameter, depth of field and frame, thickness of axle bearing and diameter of axle.

Minimum Miles per Hour. With a constant peripheral speed, the rev. per min. of armature may be derived for each diameter, and this, with the maximum gear reduction as given above, gives the minimum mi. per hr. at the one-hour rating for any sized armature under the conditions assumed. This is shown in Fig. 12.

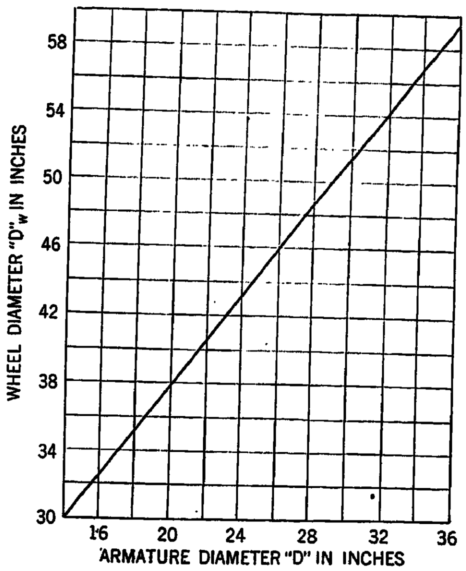

FIG. 10—AXLE-MOUNTED, FOUR-POLE MOTORS—WHEEL DIAMETER

FOUR-POLE AXLE-MOUNTED MOTOR, 1000 VOLTS PER COMMUTATOR

The constants included in L_k will be the same, for a 3000-volt motor with 1000 volts across the commutator,

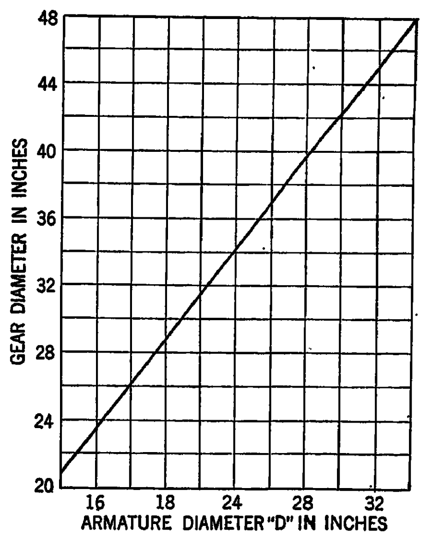

FIG. 11—AXLE-MOUNTED, FOUR-POLE MOTORS GEAR, DIAMETER

as for a similar motor with 750 volts on the commutator.

The length of coil extension L_e, for the same armature diameter and the width gear-face L_g for the same kw. output, will also be the same. The length of commutator L_c and output-constant C, will, however, be different.

The length of commutator will be less, due to the smaller amount of current, with the higher voltage.

The output constant for the smaller diameters will be less than for the 750-volt motor due, mainly, to the smaller slot-space factor, but for diameters over 26 in. there will be but little difference.

Taking all the factors into consideration, an expression similar to that given in equation (25) was derived. Curve B in Fig. 5 shows kw.-output plotted against

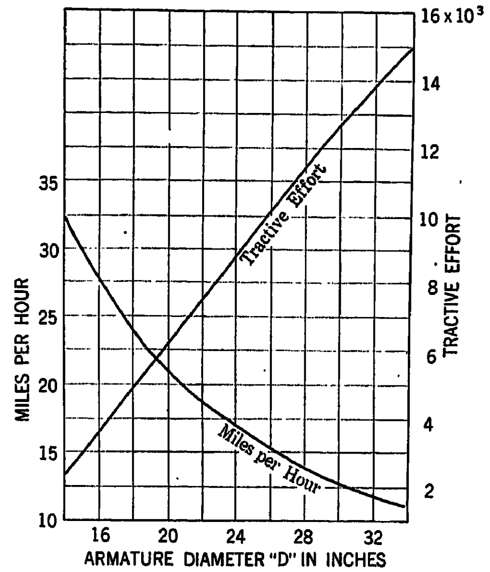

FIG. 12—AXLE-MOUNTED, FOUR-POLE MOTORS, MI. PER HR. AND TRACTIVE EFFECT

armature diameter for the four-pole, 1000-volt-per-commutator motor.

Curves for varying track-gage, or peripheral speed, are not shown, as the effect of these factors on the output is clearly displayed in the curves for the 750-volt motor.

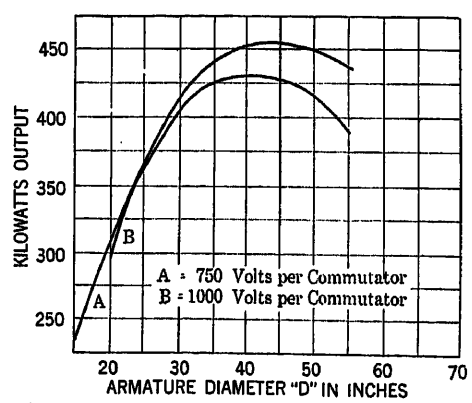

FIG. 13—AXLE-MOUNTED, 3000-VOLT, SIX-POLE MOTORS 3500 FT. PER MIN. PERIPHERAL SPEED, 56.5 IN. TRACK GAGE

FOUR-POLE AXLE-MOUNTED MOTOR, 1500 VOLTS PER COMMUTATOR

The proportion of space for the 1500-volt motor as included in L_k will be the same as for the 750-and 1000-volt-per-commutator machine.

The length of coil extension L_e, and gear face L_g will also be the same.

The output constant C, and length of commutator L_c will, however, be different than for either of the lower voltages.

Taking these factors into account, an expression was derived, as in the preceding cases. Curve C of Fig. 5, shows relation of kw.-output to armature diameter for a 1500-volt-per-commutator, four-pole motor.

Six-Pole Axle-Mounted, 750 and 1000 Volts-Per-Commutator Motor

The proportions of space for the six-pole 750-and 1000-volt axle-hung motors are the same as for the four-pole. The length of commutator L_c, and coil extension L_e, will, however, be different, due, in case of commutator length, to the larger number of brush-arms and, in the case of coil extension, to the shorter coil throw.

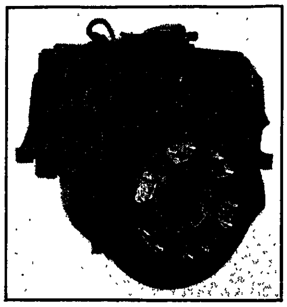

Fig. 14—Quill-Type Drive

Curve A of Fig. 13, shows the relation of kw.-output to armature diameter for a six-pole, axle-mounted, 750-volt-per-commutator motor, while curve B, in the same figure, shows a similar relation for the 1000-volt-per-commutator motor.

Fig. 15—Quill-Type of Drive and Twin Motors Mounted

Frame Mounting—Quill Drive

In the quill drive, the motor is mounted on the spring-born frame of the locomotive, and the main driving axle centered through a hollow quill. The driving gear is mounted on the quill, this quill being held in definite relation to the motor and locomotive frame. The actual drive takes place between the gear and drive-wheel by means of springs which permit the drive-wheel and axle to move in relation to the gear and motor.

In general, it is found desirable to have somewhat more clearance between the wheel-flange and end-housing of motor in quill-mounting, than in axle-mounting; otherwise the proportions of space are the same and, therefore, the curves of output will be approximately the same as those for axle-mounting.

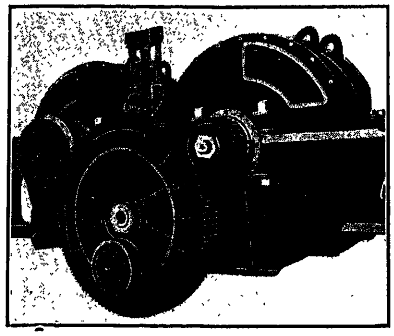

Fig. 16—Inside-Hung Frame

The quill drive does, however, permit the use of a twin motor construction and thus, unless limited by the drive, gives twice the power per axle as with an axle-hung motor.

Fig. 14 shows the quill type of drive while Fig. 15 shows a locomotive with quill drive and twin motors mounted in place.

Fig. 17—Inside-Hung Frame Motor, Mounted Complete

Frame-Mounting Side-Rod or Gear and Side-Rod Drive

In the case of frame-mounted motors, with side rod or gear and side-rod drive, the distance between the side frames of the locomotive L_t, available for the motor, is not a definite quantity, but for the case of inside-hung frames, perhaps 44 in. will be a fair average for the size of locomotives under consideration.

This type of motor mounting is shown in Fig. 16, while Fig. 17 shows the locomotive complete.

If the motor is made self-contained, so that it may be lifted out of the locomotive frame complete, there will be less room available for active material than if the armature bearings are mounted in the side-frame of the locomotive and end-housings omitted except for

comparatively thin protective covers. For the latter case, the constant L_k will contain the following:

1. Clearance between the frame and commutator V-ring	0.75 in.
2. Creepage on commutator V-ring	2.50 in.
3. Commutator groove and clearance between brushes	0.75 in.
4. Cell extension both ends	2.00 in.
5. Clearance between coil and frame at rear	1.25 in.
Total for L_k	7.25 in.

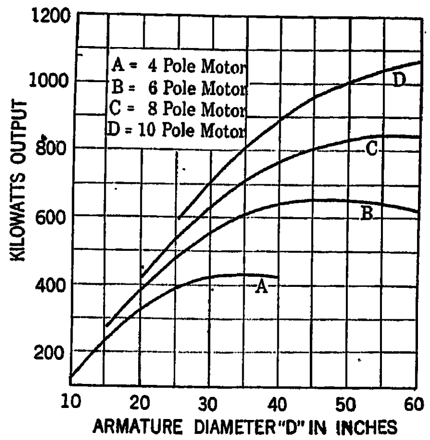

Fig. 18—Frame-Mounted, 3000-Volt Motors, 3500 Ft. per Min. Peripheral Speed, 750 Volts per Commutator

A = Four-Pole Motor
B = Six-Pole Motor
C = Eight-Pole Motor
D = Ten-Pole Motor

In this case, space need not be allowed for gears and the output equation becomes:

$$\text{kw.} = (L_t - L_c - L_e - L_k)\, D^2\, C\, S \qquad (28)$$

From which with the proper substitutions and a peripheral speed of C_s

$$\text{kw.} = \frac{3.82\, C_s\, D\, C\, (L_h - C_e\, D)}{1 + 3.82\, C_s\, C\, C_c\, D} \qquad (29)$$

Substituting the proper constants for a 750-volt, four-pole, frame-mounted motor, in equation No. **29**,

$$\text{kw.} = \frac{(37.6\, D - .46\, D^2) \log (.385\, D - 1.31)}{1 + .0231\, D \log (.385\, D - 1.31)} \qquad (30)$$

The graph of equation (**30**) is given as curve A in Fig. 18.

In a similar manner, expressions were derived for six, eight-and ten-pole, 750-volt motors, and the results shown in curves B, C and D of Fig. 18. Also, expressions for four-and six-pole motors, with 1000-volts per commutator, were derived and the results shown in curves A and B of Fig. 19.

Gearless Motors

The gearless motor may be divided into two classes:

1. Direct axle-mounting
2. Quill-mounting

Direct Axle-Mounting. In this case the armature is pressed directly on the driving axle, and therefore follows the motion of wheels and axle in both a vertical and lateral direction. This, for all practical purposes, necessitates a bi-polar construction with the pole faces eccentric to the armature, thus permitting the movement of the core vertically in relation to the poles.

With this type of motor design, it is desirable, from a mechanical standpoint, to have a comparatively large air-gap, also the pole constant C_p will be relatively small; the latter, taken by itself, would mean a low output constant, but owing to the comparatively low rotational speed and the bi-polar construction, the frequency will, in general, be quite low, and, therefore, the air-gap, teeth, and core-flux density may be high without undue iron loss or heating, thus giving a higher output constant than would otherwise be the case.

It is even more difficult to give an expression for the so-called output constants in terms of the armature diameter for the bi-polar type of construction than for the motor with a larger number of poles, but, by segregating the separate factors which go to make up the output constant, it is believed that no gross error has been introduced.

The same nomenclature will be used for division of space between wheel flanges as was used on the axle-mounted, geared motor, but in this case, the constant L_k will be made up of the following items:

1. Clearance between wheel and commutator V-ring	2.25 in.
2. Creepage on commutator V-ring	2.50 in.
3. Commutator groove and clearance between brushes	1.00 in.
4. Cell extension both ends	2.00 in.
5. Clearance between wheel and rear of armature	2.25 in.
Total L_k	10.00 in.

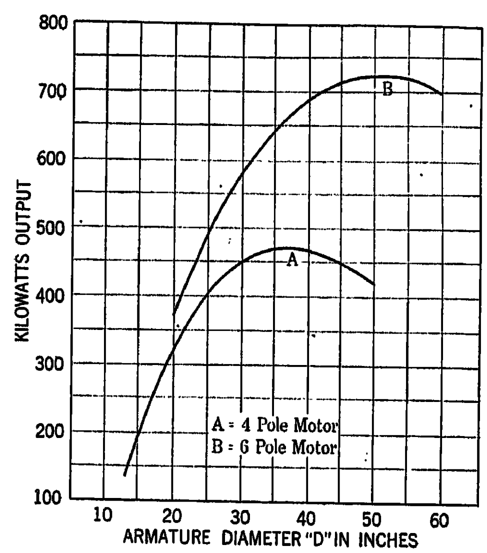

Fig. 19—Frame-Mounted, 3000-Volt Motors, 3500 Ft. per Min. Peripheral Speed, 1000 Volts per Commutator

The problem of output will be approached in a somewhat different manner for the bi-polar gearless than for the proceeding type.

It will be assumed that the clearance between armature surface and rail is constant at 7½ in., regardless of armature diameter, thus giving an armature diameter 15 in. less than the diameter of wheel.

At 25 mi. per hr. which is used as a basis of comparison, the peripheral speed of wheel is 2200 ft. per min. If

R = rev. per min. of wheel and armature at 25 mi. per hr.

D_w = Wheel diameter in inches

Then

$$R = \frac{2200 \times 12}{D_w \times \pi} = \frac{8400}{D_w} \qquad (31)$$

also

$$R = \frac{C_s \times 12}{(D_w - 15)\,\pi} = \frac{3.82\,C_s}{D_w - 15} \qquad (32)$$

where C_s = Peripheral speed of armature in ft. per min. equating (31) and (32) and solving for C_s

$$C_s = \frac{2200\,(D_w - 15)}{D_w} \qquad (33)$$

The construction of the bi-polar, gearless motor does not permit the use of commutating poles and the armature winding may, therefore, be chorded to the point where further chording would give a reduction in counter electromotive force, and increase the speed for a given flux per pole. This coupled with the wide interpolar space, gives a wide commutating zone and permits the use of a wider brush than might otherwise be be used. The chording also shortens the armature-winding end-extension.

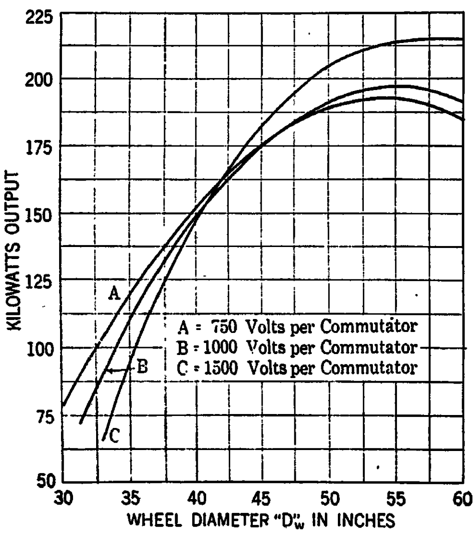

FIG. 20—GEARLESS 3000-VOLT BI-POLAR MOTORS, 25 MI. PER HR. 56.5 IN. TRACK GAGE

For the case of 1000-volts-per-commutator, brush width of 0.75 in., 60 amperes per sq. in. in brush, and 90 per cent efficiency at the one-hour rating.

the commutator face = 0.0247 kw.

neck = 0.0035 kw.

or neck + face $= L_c = 0.0282$ kw. (34)

Without giving details of derivation, the following expression for coil extension was used:

$$L_e = 0.6\,(D_w - 15) \qquad (35)$$

also the output constant within the range considered was given the following value

$$C = \log\,(1.45\,D - 13.5)\;3.43 \times 10^{-5} \qquad (36)$$

In order, therefore, to obtain an expression for kw.-output in terms of wheel-diameter for the bi-polar gearless motor equations (33) and (36) and the following values were substituted in equation (29):

$$D = D_w - 15$$
$$L_h = 43.25$$
$$C_e = 0.6$$
$$C_c = 0.0282$$

giving

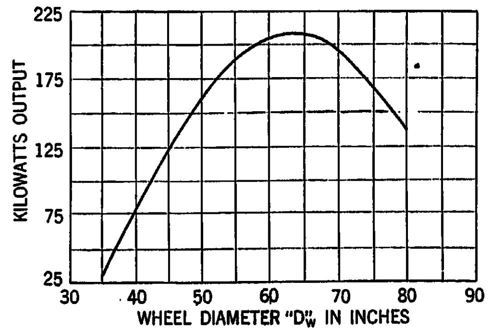

FIG. 21—GEARLESS 3000-VOLT, FOUR-POLE QUILL MOTOR 25 MI. PER HR., 1000 VOLTS PER COMMUTATOR 56.5 IN. TRACK GAGE

$$\text{kw.} = \frac{(20.3\,D_w^2 - .173\,D_w^3 - 490\,D_w + 3380)}{D_w + (0.00813\,D_w^2 - 0.244\,D_w + 1.84)}$$

$$\frac{\log\,(1.45\,D_w - 35.3)}{\log\,(1.45\,D_w - 35.3)} \qquad (37)$$

Curve B in Fig. 20 is the graph of equation (37).

If, in place of varying the wheel diameter, the peripheral speed or, in other words, the mi. per hr., is taken as the variable and the wheel-diameter held constant at 44 in. the following equation gives the approximate kw.-output in terms of peripheral speed of armature for a 1000-volt bi-polar, gearless motor:

$$\text{kw.} = \frac{0.145\,C_s}{1 + 0.000156\,C_s} \qquad (38)$$

The curve shown in Fig. 22 is the graph of equation (38) except that mi. per hr. is used in place of peripheral speed.

Expressions for kw.-output, in terms of wheel-diameter for 750 and 1500 volts per commutator, were derived and the results are shown in curve form as A and C in Fig. 20.

GEARLESS QUILL-MOUNTING

With this type of motor, the armature is mounted on a hollow quill which surrounds the driving axle with sufficient clearance between the inside quill wall and axle to allow of maximum movement of wheels and axle in a vertical or horizontal direction. The quill is supported through quill bearings and end-housings

by the motor frame, which, in turn, is supported on the spring-borne locomotive frame.

In the case of the gearless quill drive, the constant L_k will be divided as follows:

1.	Wheel flange to commutator V-ring	8.00 in.
2.	Creepage on commutator V-ring	2.50 in.
3.	Cell extension both ends	2.00 in.
4.	Rear end to wheel flange	8.00 in.
	Total L_k	20.50 in.

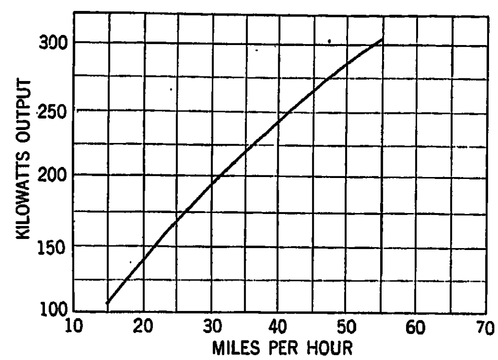

FIG. 22—GEARLESS 3000-VOLT BI-POLAR MOTOR, 44 IN. WHEEL DIAMETER, 56.5 IN. TRACK GAGE, 1000 VOLTS PER COMMUTATOR

As was done in the case of the bi-polar, gearless motor, the clearance between the armature surface and rail will be considered constant. This, of course, is not strictly true, as, on this type of motor, room must be allowed for field coil and frame between armature surface and rail, as well as for the proper clearance. However, within the range considered, the assumption will be approximately correct.

This distance between armature surface and rail will be assumed as 11 in., thus giving an armature diameter 22 in. less than the diameter of wheel.

From this point on, the same procedure was followed as for the bi-polar gearless, except for difference in number of poles, output constant, etc.

Fig. 21 shows kw.-output plotted against wheel diameter for a four-pole, 1000-volt-per-commutator gearless quill mounted motor.

1000-VOLT MOTORS

Some explanation may be in order as to why a unit of 1000 volts was chosen as an illustration of the use of lower voltage in place of—for example—600 or 750 volts.

In general, the designer of d-c.-traction motors is confronted with two difficulties,—not limits, but difficulties; that is, for 1500-volts-per-commutator motors, commutating difficulties are encountered, especially for two-circuit armature windings. On the other hand for 600-volts-per-commutator motors, the size of commutator becomes unduly large for a given number of poles. As a happy medium, therefore, a unit of 1000 volts was chosen.

It is realized, of course, that this is not a standard line voltage, but in making this choice, a higher line voltage was presupposed, either a-c. or d-c., with some method of conversion to a lower voltage for use on the traction motors.

For the purpose of this paper, the following classification has been chosen for the 1000-volt motors:

1. Axle-hung Gear-Drive
   - *a.* Four-poles
   - *b.* Six-poles
2. Frame-mounted, Quill and Gear Drive
   - *a.* Four-poles
   - *b.* Six-poles
3. Frame-mounted, Gear and Side-Rod Drive
   - *a.* Four-pole
   - *b.* Six-pole
   - *c.* Eight-pole
4. Gearless
   - *a.* Two-pole
   - *b.* Four-pole
   - *c.* Six-pole

The analysis of this class of motor was made in much the same way as for the 3000-volt motor; therefore, the giving of details would be a needless repetition.

Two factors, however, should be mentioned; viz, the better slot-space factor for the 1000-volt motor, due to the use of less insulation, this giving a higher output constant, and the smaller creepage surfaces on the commutator V-ring and shorter cell-extension outside of the core.

For the case of 1000-volt motors, therefore, the output-constant was expressed imperically as follows:

$$C = \log (0.32\, D + 0.2)\, 8.2 \times 10^{-6}$$

and L_k was made up of the same items as given for the

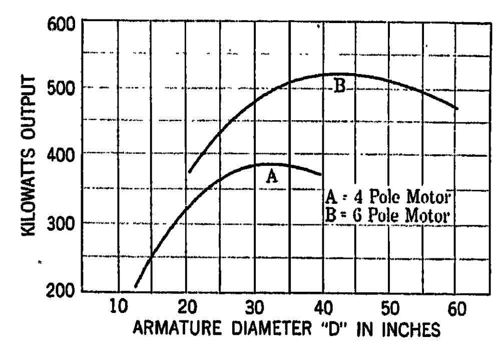

FIG. 23—AXLE-MOUNTED 1000-VOLT MOTORS, 3500 FT. PER MIN. PERIPHERAL SPEED, 56.5 IN. TRACK GAGE

3000-volt, axle-mounted motor, except that the creepage on the V-ring and the cell-extension for both ends were each given a value of one inch, giving for the total 12.75 in.

It will be noted that this value of L_k is 2.50 in. less for this voltage motor than for the 3000-volt, axle-mounted geared motor. This same reduction holds true also for the frame-mounted and gearless motors of this type.

Expressions were derived for 1 *a*, and 1 *b*, 3 *a* and 3 *b*, and 4 *a* of the classification table. Curves *a* and *b* of Fig. 23 give kw.-output in terms of armature

diameter for a 1000-volt, axle-mounted geared motor, four-pole and six-pole respectively.

Curves *a* and *b* of Fig. 24 give kw-output in terms of armature diameter for a 1000-volt frame-mounted motor, four-pole and six-pole, respectively.

Curve of Fig. 25 gives kw.-output in terms of wheel diameter for a 1000-volt, bi-polar, gearless motor.

Discussion of Curves and Conclusions

It will be noted that in the foregoing no mention has been made of commutation limits. This will actually prove the practical limiting factor in some cases, but

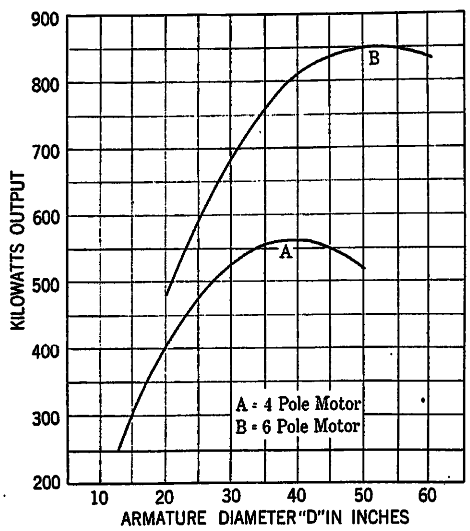

Fig. 24—Frame-Hung, 1000-Volt Motors, 3500 Ft. per Min. Peripheral Speed

in general it may be met by refinements in design. However, the flashing and commutation characteristics of a d-c. motor limit the number of poles which may be used for a given armature diameter, and it is largely for this reason that the classification given at the opening of this paper was employed.

The paper is not intended to include a discussion of types of locomotive-drive, but the application is so intimately allied with this much discussed problem that it must be touched on, at least incidentally.

Reverting now to Fig. 5 which shows output in kw. for four-pole 750-, 1000- and 1500-volt motors, plotted against armature diameter, it will be noted that for the smaller diameters, the lower voltage make the better showing. However, as the diameters increase the higher voltage approaches and finally crosses the lower voltage curve. All three voltages reach a maximum output at between 32 in. and 36-in. diameter with very little gain after 32-in. diameter.

It is evident, therefore, that there is a real limit to the amount of power which may be placed between the wheels with an axle-mounting, regardless of wheel size. Fortunately, this limit is sufficiently high to permit of a fairly heavy axle loading with speeds between 15 and 20 mi. per hr. This, coupled with the simplicity of drive and ruggedness of motor construction, place the combination well towards the front as a solution of the direct-current heavy traction problem.

The curve of Fig. 6 shows strikingly the handicap of a 42 in. track-gage, or, on the other hand, the advantage of a 60-in. gage over the standard.

With better methods of balancing, and a closer study of the stresses involved, advantage is being taken of higher peripheral speeds. The relative advantages to be gained by change in peripheral speed is shown in Fig. 7, where armature diameter is held constant and kw. plotted against peripheral speed.

The curves of Fig. 13 for six-pole, axle-mounted motors as compared with those of Fig. 5, show the advantages of a larger number of poles for a given armature diameter and also show that it should be possible to place more power between the wheels with the larger number of poles. The point of maximum output, however, is not reached in this case under 40-in. armature diameter.

The curves of Fig. 18 show the advantage of a larger number of poles in obtaining large output when faced by space limitations, and also show that the amount of power which the motor designer is able to produce is practically unlimited in the case of frame-mounted motors.

The output for the bi-polar, gearless motor is shown in Figs. 20 and 22, and is also limited. This limit may, however, be determined more by the dead-weight per axle than by maximum output limit. It will be noted from Fig. 22 that this type of motor finds, perhaps, its best application in high-speed service, for, if

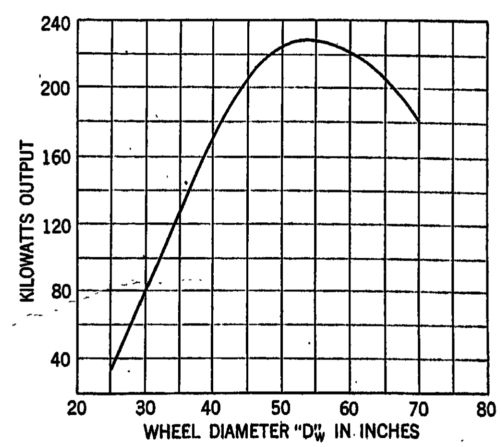

Fig. 25—Gearless 1000-Volt Bi-Polar Motor, 25 Mi. per Hr., 53.25 In. Track Gage

the curve of Fig. 22 is compared with that of Fig. 7, it will be found that the output of the bi-polar motor increases much faster with a given increase in peripheral speed than is the case with the four-pole axle-mounted motor.

The curves of Fig. 23 for the 1000-volt motor should be compared with similar curves of Figs. 5 and 13 for the 3000-volt motor. The gain in maximum output is quite pronounced, approximately 20 per cent for the four-pole and 15 per cent for the six-pole motor. The

same advantage is also shown when comparing curves of Fig. 24 with those of Fig. 19 for frame-mounted motors.

The curve of Fig. 25 for a 1000-volt, bi-polar gearless motor as compared with Curve *B* of Fig. 20 also shows the advantage of the lower voltage motor in so far as output is concerned.

It would seem, therefore, that in so far, at least, as the driving motors are concerned, a very decided advantage may be gained by the use of lower voltage,—say around 1000 volts. The method or methods of obtaining this voltage is beyond the scope of this paper, but we believe sufficient evidence has been presented to show that the direct current motor designer has something to offer in return for the lower applied voltage to the motor.

In conclusion, it may be said that d-c.-motors may be built for any type of locomotive drive. The qualifications of the more common types are summed up, as follows:

1. Axle-mounted d-c.-motors may be built which have sufficient power to permit fairly heavy axle loadings, as shown by the curves.

2. Quill drive d-c.-motors may be built, of which the power-per-axle will probably be limited by the method of transmitting power to the wheels rather than by the motors, themselves.

3. D-c.-motors for side-rod or gear and side-rod drive may be built with practically any desired power.

4. D-c.-gearless motors may be built which have sufficient power for comparatively light axle loadings, this light axle loading necessitating a larger number of axles for a given locomotive rating than would otherwise be used.

5. A lower voltage motor has a definite advantage in possibilities of greater output for a given armature diameter.

A Study of Direct-Current Corona in Various Gases

BY F. W. LEE*
Associate, A.I.E.E.

and

B. KURRELMEYER*
Non-member

Synopsis.—1. The critical corona intensities have been determined for helium, hydrogen, oxygen, nitrogen, air, and carbon dioxide for pressures ranging from 2 to 760 mm.

2. In each case the relation $\frac{E}{P} = A + \frac{B}{\sqrt{P}}$ *was found to hold approximately for pressures above 4 cm.*

3. The values found for air agree well with those found by Whitehead and Isshiki from their investigation of alternating-current corona.

4. No simple relation could be found giving the connection between $\frac{E}{P}$ *and* $\frac{1}{\sqrt{P}}$ *over the whole range of pressure.*

5. The influence of temperature on critical corona intensity was investigated for hydrogen, and found to consist merely of a change in δ, as was expected.

6. It is shown that the data obtained do not permit the explanation of corona as a process of ionization by collision, unless we make further assumptions. The nature of the assumptions necessary is not evident.

* * * * *

1. Introduction

The law of formation of corona on wires is an empirical relation which was first developed about 15 years ago by Whitehead. The electric intensity at which corona forms on a circular wire coaxial with a circular cylinder is given by the relation

$\frac{E}{\delta} = A + \frac{B}{\sqrt{\delta r}}$, where δ is called the density factor: $\delta = \frac{3.92\,P}{T}$ A and B are constants which depend on the kind of gas and on the polarity of the wire. P is the pressure of the gas in centimeters of mercury. T is the absolute temperature, and r is the radius of the wire, in centimeters.

The corona law was developed experimentally for alternating potentials by Whitehead, Peek and others. Whitehead,[1] was the first to determine both the exact influence of the radius of the wire and the constants. Peek,[2] considering the influence of temperature, first established the density factor δ. Farwell,[3] and later Whitehead and Brown[4] determined the constants A and B for continuous potentials by changing r. Whitehead and Isshiki[5] found that for alternating-current corona there was a break in the linear relation between E and $\frac{1}{\sqrt{\delta\, r}}$ at a definite value of $(\delta\, r)$. This value of $(\delta\, r)$ was found to be the same as the value at which the straight lines for positive and for negative corona crossed. Whitehead and Isshiki also investigated the influence of temperature for alternating-current corona, while Whitehead and Lee did the same thing for direct-current corona, Whitehead[1] had previously shown that the moisture content of the air had no effect on the critical intensity.

Townsend[7] derived the relation $\frac{E}{P} = A + \frac{B}{\sqrt{P\,r}}$ from the laws of sparking between parallel plates, introducing the assumption that ionization by collision takes place out to a certain distance from the surface of the wire, where the electric intensity is constant. Even if we admit this assumption, Townsend's analysis has no way of distinguishing between positive and negative corona, and it does not account for the departures found to exist for low values of $(\delta\, r)$.

Davis and Breese[8] investigated the continuous corona in hydrogen. They found that whereas in air, for the higher values of $(\delta\, r)$, negative corona occurs at higher values than positive corona, the reverse was true for hydrogen. The purpose of the present investigation was to determine the critical corona voltages for a number of different gases over a wide range of pressure, and to determine, if possible, what physical processes are involved in the formation of corona.

2. Description of Apparatus

The apparatus was similar to that used by Whitehead and Lee[6] and is shown in Fig. 1. In preliminary experiments it was found that there was a small fluctuation in the continuous potential at the corona tube, the amplitude of which varied with the frequency of the generator voltage. To eliminate this fluctuation, the capacity between the kenotron and the corona tube was increased to 0.1 microfarad, and an inductance of 143 henries was placed in the same circuit. Under these conditions the fluctuation was reduced to a negligible quantity in the range of frequencies used, (500 to 600 cycles). This is shown by the following table of observed corona voltages:

Frequency	Volts
60	133.0
133	135.0
600	135.6

*Of Johns Hopkins University, Baltimore, Md.

1. For references see Bibliography.

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 9-12, 1925.

The voltage fluctuation to be expected was calculated from the formula given by Hull[9] to be about 0.5 per cent, without the large inductance. Oscillograms taken with the inductance in series showed no noticeable fluctuation.

For convenience in manipulation the kenotron, together with the filament battery, condensers, choke coils, and the multiplier resistance for the corona-voltmeter, was separated from the remainder of the apparatus and placed on a well-insulated wooden platform, directly above the transformer and the corona tube.

The corona tube. The corona tube was the one used by Whitehead and Lee[6]. The main chamber was made from a piece of 6-in. steel piping, 19 in. long, carefully bored out in a lathe to receive the supports for the

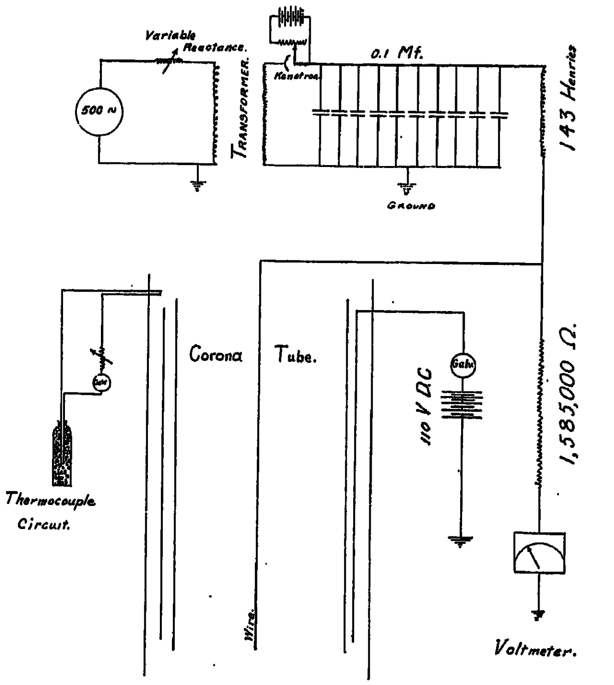

FIG. 1

concentric cylinders. The inner cylinder was of heavy brass, and had a number of small perforations. Its inside diameter was 3.75 in. = 9.52 cm. Two caps of bakelite in the form of crosses were machined to fit tightly around the ends of this cylinder, and the wire used in the corona measurements was stretched through small holes carefully centered in the caps, and was held taut by lock-nuts. In this way it was possible to remove the wire without removing the lower end of the tube.

3. Calibration of Instruments and Accuracy of Measurements

The voltmeters used to measure the corona voltage has been calibrated and found to be accurate within the error of observation. These limits were ± 3 volts for the Siemens-Halske voltmeter and ± 10 volts for the Weston (used only above 7000 volts). The limits within which the corona voltage could be determined varied from ± 5 to ± 30 volts at the two ends of the range. At pressure 1-5 mm. the initial deflection was very large, ranging from 10 cm. to complete off-scale. For pressures ranging from 20 cm. up to atmospheric pressure, and especially for positive corona, the initial deflection was only one mm. or less. Hence the accuracy of observing the critical voltage is less at the higher pressures; but the percentage accuracy is about the same, namely 0.5 per cent.

Since it was necessary to use pressures both above and below atmospheric pressure, the manometer was of the open-tube type; a wooden meter-bar mounted between the two manometer columns served as a scale. The barometric pressure was taken to the nearest hundredth of a centimeter. Since the scale of the barometer was accurate at 0 deg. cent., a correction had to be applied to the observed barometric readings to reduce them to scale readings at 0 deg. cent. A similar correction was applied to the wooden meter-bar. The final accuracy of the pressure readings is considered to be about ± 0.04 cm.

The galvanometer used to detect the beginning of corona was made by Leeds and Northrup, and had a resistance of 10 ohms. Its current constant was determined with a standard shunt and milliameter. The mean of several determinations gave one cm. scale deflection = 2.8×10^{-8} amperes. A deflection of two millimeters or more was considered an indication of corona.

4. Materials

a. Wires. Several different wires were made up from steel wire of diameter 0.0663 cm. The specimens chosen were free from kinks and surface irregularities, and were tested for variations in diameter with a micrometer caliper. They were then cut to the required length, 25 cm., and were mounted in the tube between brass rods of about two millimeters diameter. The surface was polished with fine emery cloth and soft leather. It was found that the surface conditions of the wire were affected by the corona, and so a steel wire with a chemically deposited surface of copper was tried and found unsatisfactory. The wire used in most of the experiments was a steel wire on which a thin layer of gold had been deposited electrolytically. This wire was polished with jewelers' rouge, and with soft leather. The surface so obtained was affected very little by chemical action in the corona. The data finally selected were taken partly with the gold wire, partly with the steel wire, and were always taken with a freshly polished wire.

b. Gases. In every case the only purification of the gaseous material which was attempted was the removal of water vapor. This was effected by passing the gases through a series of tubes containing calcium chloride and phosphorous pentoxide. In the earlier experiments sulphuric acid was used as a drying agent, but was found unsatisfactory.

Hydrogen and oxygen were made electrolytically in the generator shown in Fig. 2. Various electrodes, current strengths and electrolytes were used, but no corresponding variations in the corona characteristics were detected. Hence the influence of any impurities depending as to their amount on the conditions of generation was considered negligible.

Hydrogen, oxygen, nitrogen, CO_2 and helium, were obtained commercially. The hydrogen was made electrolytically, the oxygen and nitrogen by fractionation of liquid air.

The air used was laboratory air passed through the drying train, which also contained provisions for removing the coarser motes and dust particles.

The amounts of the impurities in the various gases were stated by the manufacturers to be as follows: hydrogen, nitrogen, oxygen, less than one per cent: CO_2, less than one-half per cent: helium, about five per cent nitrogen (estimated).

Pressure changes were always extended over a period of time ranging from two to five minutes, depending on the amount of gas to be admitted. The time interval between cutting off the gas supply and reading the critical voltage was also several minutes. Since the

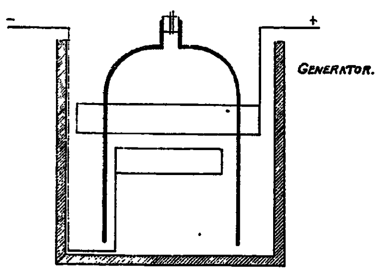

FIG. 2

volume of gas admitted was small and the heat capacity of the corona tube very large, no initial temperature fluctuation of as much as ½ degree cent. was ever observed; and with the time allowance given, temperature variations from point to point in the gas were certainly very much less than 0.5 deg. cent. In taking observations of the critical intensity, the heating effects due to corona were carefully avoided. The error introduced by temperature variations was always less than the other experimental errors.

5. RESULTS

a. Appearance of the Corona. With the wires used, all of which had a diameter of approximately 0.0665 cm., the appearance of light was simultaneous with the first galvanometer deflection due to ionization. This was true for all conditions of pressure and temperature within the range of these experiments, and for all the gases examined.

With the wire positively charged, the corona glow was uniform around and along the wire, and was confined to a region very close to its surface. The extent of this region did not vary with pressure or current density, except that above a certain voltage there was a small brilliant intermittent discharge across from some point near the middle of the wire, to the tube. The rest of the wire retained its uniform glow.

With the fire negatively charged, and a pressure of 2-5 mm., the first corona deflection was sometimes jerky, and the corresponding flow was a faint flicker which was not restricted to any point or points, but was uniform along the wire. A slight increase in voltage brought out the steady continuous glow of negative corona. This was much more diffuse than the positive glow. A further increase of 50 to 100 volts brought out the first faint beads. These were localized discharges on the wire, and were always fairly evenly spaced, especially at higher currents. They increased in number with pressure and current density, and also varied from one gas to another. At approximately equal pressures and current densities the beads were most numerous in the gas for which the corona voltage was lowest. It was frequently observed that when the current density was increased, each new bead appeared approximately midway between two old ones. If the corona was run for a few minutes with the beads in any one position, marks were found on the surface of the wire, which looked as if they might be the result of local heating. The negative beads have been investigated in great detail by Farwell,[3] Davis and Breese,[8] and Crooker.[11] Their results have been found to be confirmed, in general, for all the gases investigated.

The color of the corona discharge was the same for the continuous negative and positive glow; whereas the beads were much more brilliant, and sometimes different in color. The glow was generally a pale red or purple, the color depending on the gas used, but not on the pressure or current density. In helium the discharge was yellowish; and examination with a small grating showed the presence of a yellow line, probably 5875. In hydrogen the glow was generally reddish, while in air and nitrogen the nitrogen bands predominated.

In all cases the critical voltage as well as the appearance of the corona glow was found to be independent of the material of the wire.

b. Variation of corona current with E and P. The initial corona current was always much greater and much more sharply defined for low pressures than for high pressures, and was greater for negative than for positive corona. At low pressure, (1-3 mm.), the first corona deflection was always accompanied by a sharp drop in the voltage across the tube, due to the high rate of discharge of the condensers.

Fig. 3 shows the variation of current with increasing and decreasing voltage, for various pressures and gases. The curves have the same general character in all gases, the negative curve being much steeper than the positive curve. The positive curve for decreasing voltage follows closely that for increasing voltage; in negative corona this is not the case. The negative

increasing curve has a double break, while the decreasing curve has only one, which is very well defined. The double break in the increasing curve may be due to a change in the sign of the space charge near the wire.

The actual values of the total corona current can

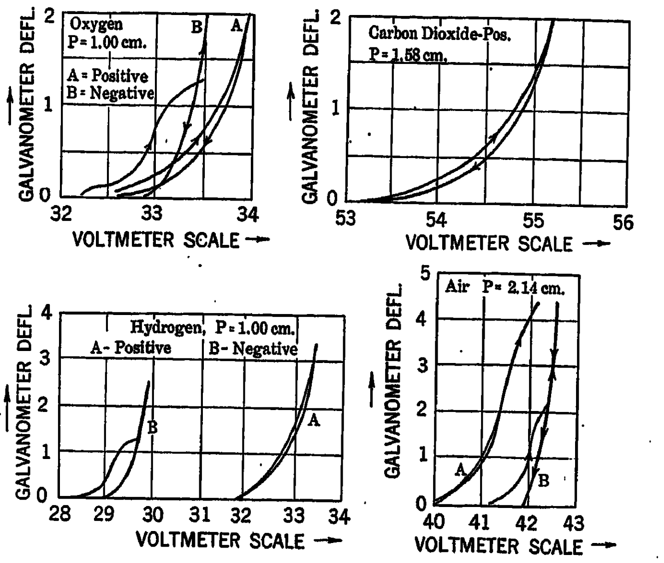

FIG. 3

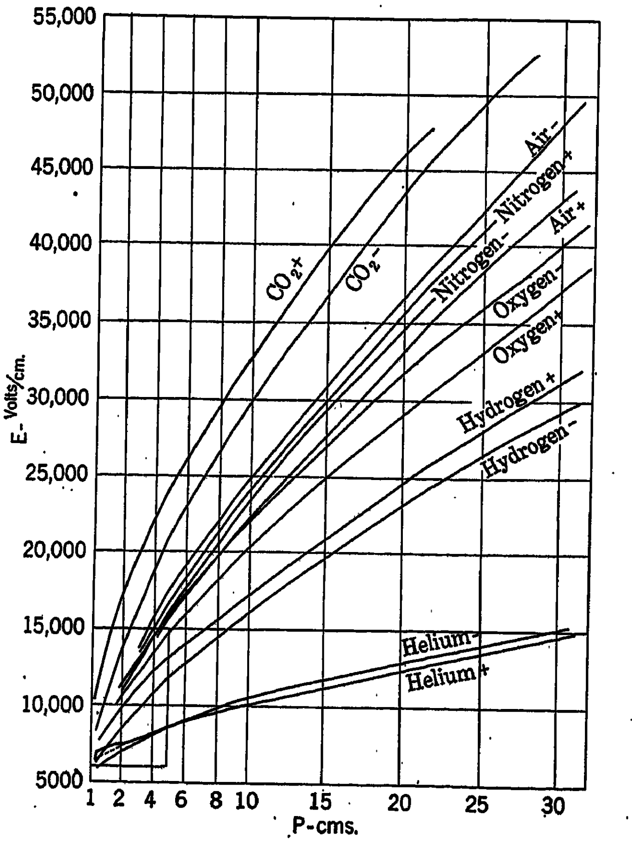

FIG. 4

only be estimated; they are of the order of 10^{-5} ampere per cm. scale deflection. The heating effect of the corona current was always negligible, because the current was never left on for a long time, No changes in pressure were to be expected from this cause. The volume of the corona tube was much too large to give any evidence of the other types of pressure change found by Kunz and his co-workers[12].

c. Variation of critical intensity with temperature. Some preliminary experiments were made with hydrogen at a temperature of 42 deg. cent. When the values of the critical voltage obtained in these experiments were reduced to room temperature (22.5 deg. cent). by applying the density factor $\frac{315}{295.5}$, they agreed well with the values found in experiments at 22.5 deg. cent.,

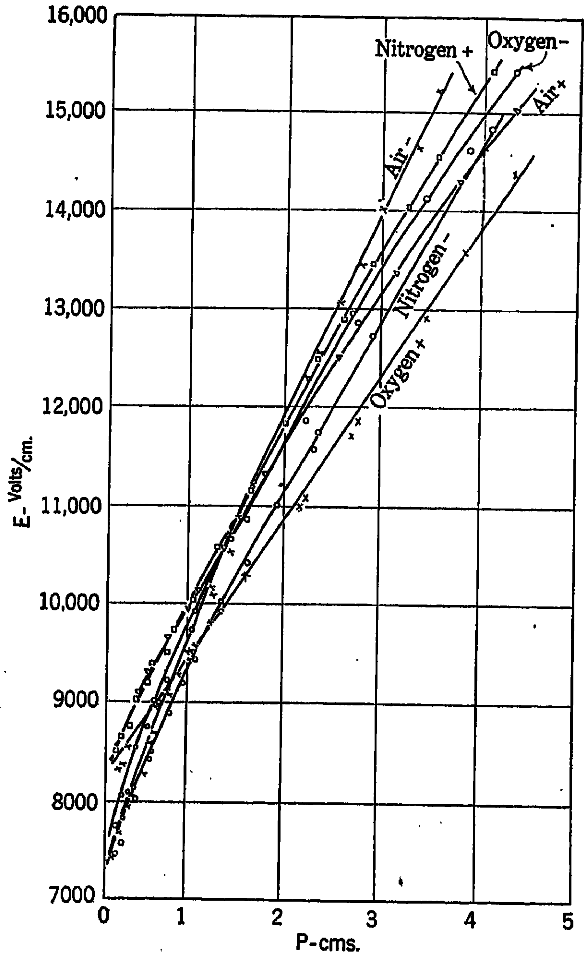

FIG. 5

except for a few points in negative corona at very low pressures. Since the same result was found by Lee for air, no further experiments with higher temperatures were made.

d. Variation of critical intensity with pressure. Figs. 4 and 5 show the variation of critical intensity with the pressure graphically. It will be seen at once that the general shape of each type of curve is the same for all gases and for both polarities.

The curves showing the relation of E to P, (Figs. 4 and 5), are not especially interesting theoretically, but they bring out several important facts. For all but the lowest pressures, $P < 1$ cm., the values of the

critical intensities are in the same order as the values of the mean free path of a gas molecule in the different gases. For all gases, when $P < 1$ cm., positive corona occurs at higher voltages than negative corona. At the higher pressures this is still true for hydrogen, nitrogen, and carbon dioxide; but in helium, air, and oxygen a crossing takes place at intermediate pressures,

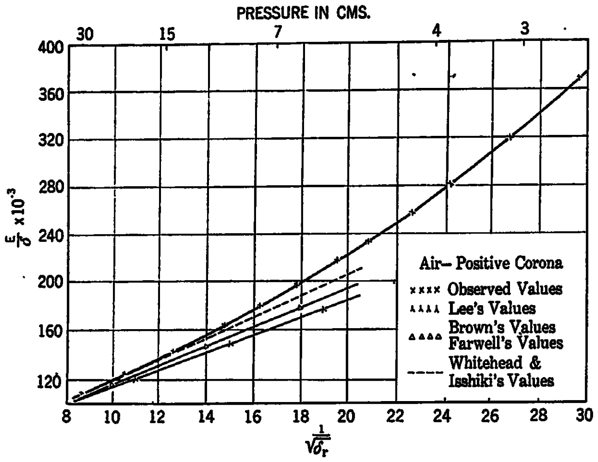

Fig. 6

so that the negative critical intensities become higher than the positive values. For $P > 10$ cms. the positive and negative curves for each gas are approximately parallel.

Fig. 5 shows, on a large scale, the E-P curves at low pressures in oxygen, nitrogen, and air. At the lowest pressures the air curves coincide with the nitrogen

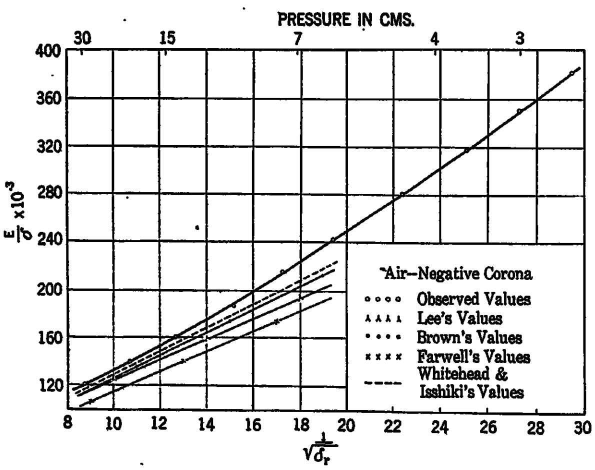

Fig. 7

curves. The positive curve for air remains intermediate between $N_2{}^+$ and $O_2{}^+$, which might be expected; whereas the negative air curve becomes higher than the negative curve for either oxygen or nitrogen; which is difficult to understand.

The curves which are most interesting historically and theoretically are those which express the relation of $\frac{E}{P}$ to $\frac{1}{\sqrt{P}}$. The law of corona formation which was established empirically by the work of Whitehead[1] and Peek[2] on air, states that this relation is a linear one:

$$E = A + \frac{B}{\sqrt{\delta\, r}}, \text{ where } \delta = \frac{3.92\ P\ \text{cm}}{T_{abs}}.$$

This question has been confirmed experimentally by Farwell[3], Whitehead and Brown,[2] and others for variations in r. A number of investigators has confirmed the law for variations in P, while Lee has recently confirmed it for variations in T. All this work was done on air. Davis and Breese[8] conclude that the law is approximately true for hydrogen, departures occurring for low values of P and r.

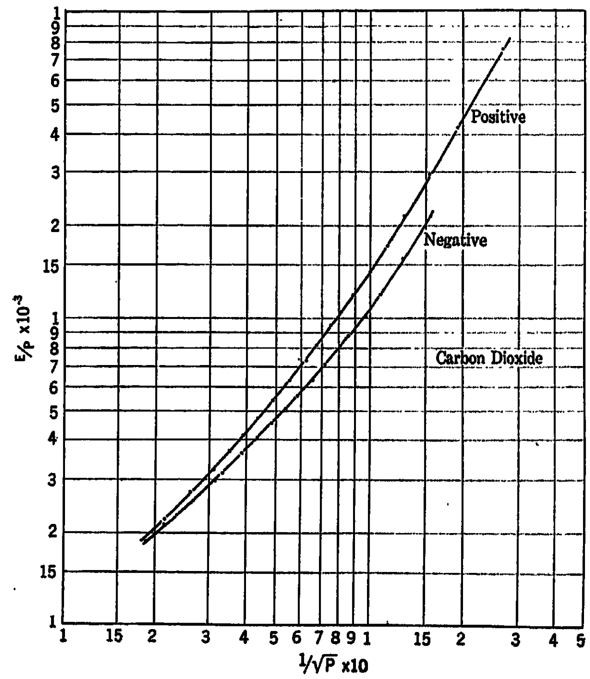

Fig. 8

Figs. 6 and 7 show how the values obtained in the present investigation compare with those obtained by Whitehead and Lee,[6] Whitehead and Brown,[4] Whitehead and Isshiki,[5] and Farwell.[3] The agreement with the values obtained by Whitehead and Isshiki is especially good, in view of the fact that 30 cm. was both the lower limit of their range of pressure and the upper limit of the range of this investigation.

Figs. 8-13 show the relation between $\frac{E}{P}$ and $\frac{1}{P}$, plotted on logarithmic coordinate paper. In this way any power function $\frac{E}{P} = a\left(\frac{1}{\sqrt{P}}\right)^n$ appears as a straight line whose slope is n. An inspection of the curves shows that they all have two regions of small

curvature, one at the lower pressures, where the slope is very near tan 60 deg., or $\sqrt{3}$, and one at the higher pressures, where the slope is near tan 45 deg., or 1. (However, for still higher and still lower pressures, the slope passes beyond these values in some cases.) This means that there is a considerable range of pres-

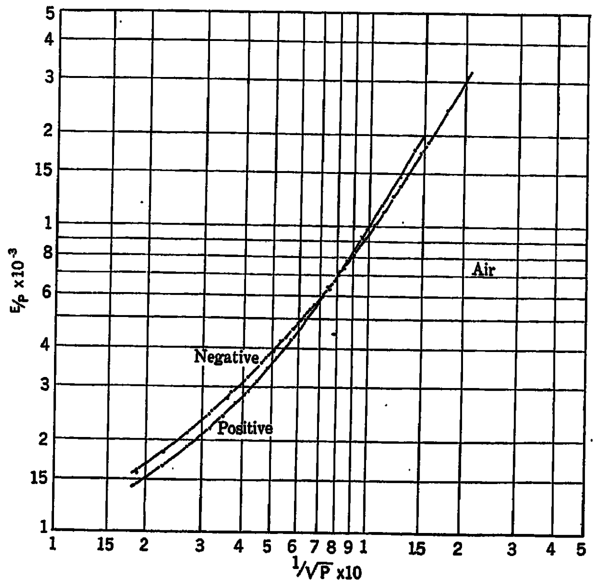

FIG. 9

sures where the relation between $\frac{E}{P}$ and $\frac{1}{\sqrt{P}}$ is very nearly linear; this happens to be the range covered by previous investigations.

All attempts to find a simple formula expressing

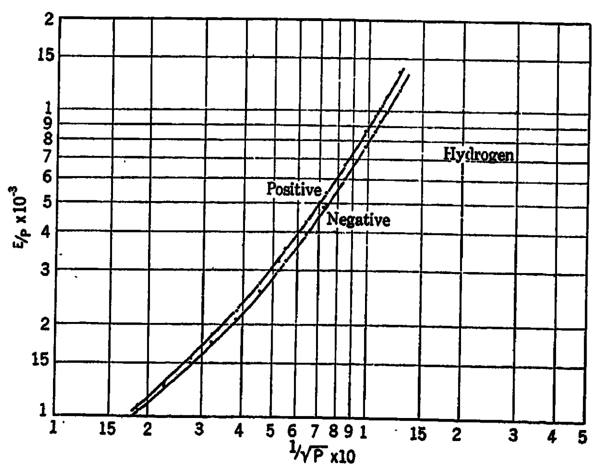

FIG. 10

the relation of $\frac{E}{P}$ to $\frac{1}{P}$ over the whole range of pressures have been unsuccessful. The most satisfactory formula seems to be $\epsilon \frac{A}{P}\frac{E}{} = \frac{B}{P}$, where A and B are constants. The agreement is not close enough, however, to warrant a calculation of the values of A and B for the different gases.

The relation $\frac{E}{P} = f\left(\frac{1}{P}\right)$ is of theoretical in-

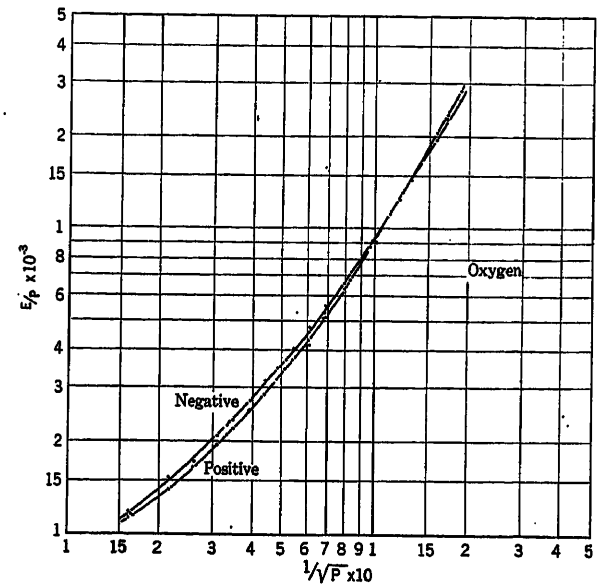

FIG. 11

terest because of the physical significance of $\frac{E}{P}$. This quantity is proportional to the energy which an ion would acquire in traversing its mean free path at

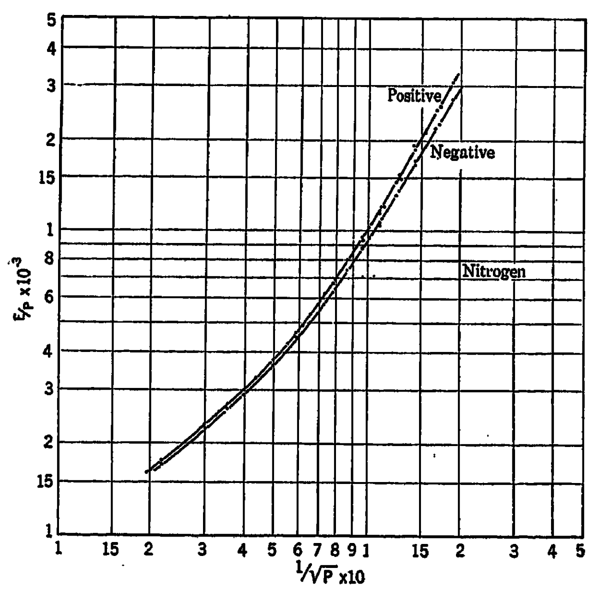

FIG. 12

pressure P in a field of intensity E. If it is assumed that corona is a process of ionization by collision, $\frac{E}{P}$ represents the energy required to ionize a gas molecule. This energy has been shown to be constant

at very low pressures; whereas within the range of this investigation $\frac{E}{P}$ is a function of the pressure. There are several possible explanations: 1. The corona process may not be one of ionization by collision. 2. The ionizing potential of a gas molecule may vary with the pressure. 3. The mean free path of the ionizing agent may not be a function of P only. 4. The E of the theoretical formula may not be equal to the actual electric intensity at the surface of the wire. 5. The ion in question may not acquire its maximum energy in the region of maximum intensity. These possible explanations will be considered in order:

1. The fact that the appearance of a glow in the gas is simultaneous with the first corona current, is strong evidence that corona is an ionization process.

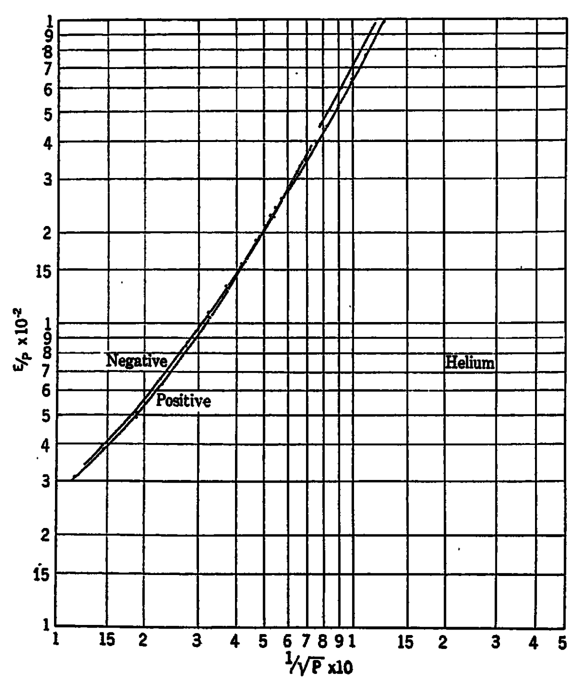

FIG. 13

2. At very low pressures the ionization energy of a gas molecule is known to be independent of the pressure. The present conceptions of atomic structure demand that this be true at all pressures.

3. For the case when the ionizing agent is an electron, the mean free path is almost certainly dependent on E as well as on P, so that this factor must be taken into consideration.

4. When there is an appreciable excess of ions of one sign over those of the opposite sign, the potential gradient at any point in space will differ from the theoretical value because of space charge effects. Before corona begins, the space charge is merely the residual ionization, and the effect is probably insignificant, so that it will not serve to explain the variation of $\frac{E}{P}$ with P. After the corona current is established, however, such an effect will certainly be present, and its amount will depend on the polarity of the wire. When this is negative, the predominating space charge may be negative at first; but eventually, on account of the great difference in the velocities of electrons and positive ions, there will be an accumulation of positive ions; which means that after a period of comparatively slow rise, the potential gradient at the wire will suddenly begin to increase very rapidly, with a corresponding increase in current, until the discharge becomes arc-like. With the positive wire the effect will be much smaller, and may amount to a decrease in potential gradient at the surface. This explains, at least qualitatively, the shape of the current curves.

5. K. T. Compton[13] has shown that electrons moving from a negative wire out to a positive cylinder acquire their maximum energy $\frac{E}{a}$ at a point $r = x$ in the space between the electrodes. x depends upon E, P and the dimensions of the wire and the cylinder. $a = k f^{1/2} p$, where k is a constant characteristic of the gas, f represents the average fraction of the average energy lost in any collision. E_x is the theoretical electric intensity at the surface of the cylinder $r = x$. The case when the wire is positive was not considered by Compton; but a simple calculation shows that the electrons attain their maximum energy at the surface of the wire. The maximum energy is still given by $\frac{E}{a}$ where $x = r_\omega$, the radius of the wire; so that the electrons acquire greater energy when the wire is positive; conversely positive ions attain their greatest maximum energy (at the surface of the wire) when the latter is negative. No matter which we assume to be the ionizing agent, it is necessary to assume a variation of f with electric intensity; in order to give the right effect, f must increase with decreasing E. This is to be expected from the definition of f. This probably involves a departure from theory in the values of the mean free path. Thus the effects considered in Sections 3 and 5 may be used qualitatively to explain the relation of $\frac{E}{P}$ to P.

The curves of $\frac{E}{P}$ against $\frac{1}{\sqrt{P}}$ for + and − corona approach each other very closely at the higher pressures, but diverge more and more when the pressure decreases. This is explained by the equations and curves of Comption (l .c. p. 342). The point x at which the ion when going out from the wire attains its maximum energy, approaches the surface of the wire

as the pressure increases; therefore $\frac{E_x}{a}$ approaches $\frac{E_\omega}{a}$; *i. e.*, the maximum energies of positive and negative corona become more nearly equal as the pressure increases. This is true no matter which type of ion we assume to be the effective ionizing agent.

The mechanism of the corona has been assumed to be a process of ionization by collision. From the general similarity of the positive and negative curves it may be assumed that the mechanism is the same, or at least very similar, for both polarities. Positive glow appears exclusively at the surface of the wire, while negative glow extends considerable distances out into the body of the gas. This points to ionization by electrons. Unfortunately, this assumption leads us to the conclusion (from section 5) that positive corona should appear at lower surface intensities; which in the majority of cases is not true. The maximum energies calculated from Compton's formulas are about 100 times the ionization potentials of the negative gases. Similar difficulties arise if we assume that positive ions are the ionizing agent. It is hard to see how this can be possible, because the energy of the electrons present must be greater than that of the positive ions. Neither assumption can be made to explain the crossing of the two curves in air, oxygen, and helium, without some auxiliary assumptions; and of what nature these assumptions would have to be in order to explain the observed effects, is an open question.

In this discussion, nothing has been said about the possible role of the photoelectric effect in the corona, because visible glow was always found to be simultaneous with the beginning of ionization. Whitehead[1] has shown that there is ultra-violet light present in the corona glow at all stages. It might be supposed that before ionization, ultra-violet light is emitted by excited atoms. This might cause photoelectric emission of electrons from the metal surfaces, thus causing the corona deflections.

There are two possible ways of determining whether photoelectric action is the cause of corona; (a) to study photographically the intensity variation of the ultra-violet light emitted in various stages of the corona. (This is not a conclusive test, because the time interval between the emission of the first traces of light and the beginning of "corona" might be very small.) (b) To bring the critical intensity up to a point just below the critical value, and illuminate the tube with a strong source of ultra-violet light.

The test (b) was tried in air at atmospheric pressure for both polarities. The source of ultra-violet light, an iron arc, was held a few inches from the open end of the tube. The voltage was raised successively to within 200, 50 and 20 volts of the critical voltage, (about 12,000 volts). In each case no effect was produced by starting the arc. As there should have been abundant photoelectric emission at the brass cylinder, this suggests that the emission of ultra-violet light is a consequence and not a cause of corona. Whitehead[1] using x-rays as the ionizing agent also found that artificial ionization produced no change in the critical intensity.

Nevertheless, a spectroscopic investigation of the different stages of the corona glow might prove valuable. This might be conducted in two different ways: (a) by determining whether the different spectral lines appear in any definite order as the voltage is raised up to and beyond the critical value; and (b) by investigating the Stark effect at different points in space in the corona tube. The effect of a longitudinal magnetic field upon the critical intensity is also under investigation. The effect to be expected is a change in the speeds of the ions due to the spiraling around the wire, as in the case of the "magnetron" described by Hull.[14]

Discussion

J. B. Whitehead: In the first studies of corona that were made in our laboratory, one of the questions that came up was whether or not the separate constituents of air played any part in the determination of the laws by which the corona was formed. And the original question which Dr. Lee started out to investigate was whether the oxygen of the air or the nitrogen of the air would show any remarkably different properties as regards breakdown.

For the engineer there are, then, two matters in this paper which I think are of immediate interest. The first is the answer to the question that I have already indicated, namely: that the properties of oxygen and nitrogen are not markedly different as regards the formation of corona. If they had been different, it would have been very easy to imagine conditions under which advantage might have been taken of any such differences.

The other matter has to do with the values of voltage at which corona forms around wires in the range in which we use high-voltage conductors; that is to say, pressures that are not greatly different from atmospheric pressure.

A matter of interest to me directly is the fact that Dr. Lee and Mr. Kurrelmeyer have linked up the behavior of the several gases investigated at low pressures with that at high pressures. Those who remember my corona-voltmeter paper will recall that there the pressure was carried down to about 30 cm. only. We stopped at 30 cm. I think largely because it became increasingly difficult to make the corona tube tight at lower pressures. Dr. Lee has picked up the air curve below 30 cm. and carried it on well down below 1 cm. He has found that his curves link up with those brought out by Mr. Isshiki and myself, but he shows also that the empirical law which we show for the corona-voltmeter does not hold in his low pressures, that is, in the range of very low pressures.

Turning to the physical discussions in the paper, Dr. Lee has indicated the main results of their investigation. I regard it as a very distinct contribution to the field of physical investigation in the matter of the ionization of gases. The authors have shown very clearly indeed the difficulties of coordinating their results with the only important theory we have, namely: the theory of ionization by collision. And I feel quite sure that this paper will suggest to a number of physicists who are interested in the phenomena of the ionization of gases, the importance of carrying further the study of these interesting questions.

F. W. Peek, Jr.: In establishing the visual corona relation for variation of radius of wire, temperature and pressure, my experiments were carried down to fairly low pressures. The relation holds very well down to 5 cm. This means, of course, that the transmission-line range is more than covered by the equation.

For a given conductor the visual corona gradient decreases with decreasing pressure until a minimum gradient is reached. The gradient then increases with decreasing pressure. At the very low pressures the molecular separation may be fairly large compared to the diameter of the outer tube. A different phenomena thus occurs and the above relation could not be expected to hold.

The interesting part of the paper is that a number of different gases have been investigated. So far the data are limited in that the authors have only used one size of conductor. I hope that the investigation will be carried over a greater pressure range and that different sizes of conductors will be investigated.

NOTE. See also discussion of this subject by Joseph Slepian, page 202.

F. W. Lee: I can say only this in regard to Dr. Slepian's discussion: that so far as using the value E over P as an indication of the energy given in the mean free path of a gas electron is concerned, that was given only with the idea that the values so used came within the range of magnitude that had been worked out at pressures very, very low, such as are used in vacuum tubes. In other words, the phenomenon that we are observing is that the observed results checked in the order of magnitude, although not within the absolute value. The agitation velocity under a charged field, where the transfer of energy goes, you might say, from the very great velocity of the electron and imparts the velocity to the molecules, will give other mean free paths and other distributions of velocity from those given with gas under normal conditions, which I used as the indication of the results in the beginning of the paper.

With regard to Mr. Peek's remarks, I will say that the work is being extended as fast as we can extend it, with the limiting conditions under which we are working and with the material available.

Dielectric Properties of Fibrous Insulation
As Affected by Repeated Voltage Application

BY F. M. CLARK[1]
Associate, A. I. E. E.

Synopsis.—*It is believed by many that the most plausible explanation of fibrous insulation failure is the pyro-electric theory. Under this theory as elaborated by Steinmetz, Wagner and others, insulation under stress is heated by the transformation of electric energy to thermal energy. Insulations are considered as of the nature of poor conductors and subject to the same characteristics. The transformation of electric to thermal emergy is therefore dependent upon the inherent electrical and thermal conducting properties of the material. This transformation proceeds at a rate proportional to the stress applied, until such a voltage value is reached where the heat is generated in the insulation at a rate faster than it is dissipated to the surrounding medium. Further increase in voltage leads to a rapidly mounting temperature with ultimate insulation failure. A strict interpretation of this theory would indicate that insulation failure is a matter of the insulation resistance—temperature relation. Therefore, as the heat stored in a dielectric during stress is allowed to dissipate, care being taken to prevent injury from the testing electrodes, etc., the orignial properties of the material should be restored. This has been found to be true only to a limited extent.*

The present paper deals largely with the effect of relatively high-voltage applications on sheet insulation tested between parallel plate electrodes. It is shown that the question of the mechanism of insulation failure can be separated into two parts. First, failure caused by short-time voltage applications as determined by rapidly applied tests, and secondly, failure of insulation under longer periods of stress as determined by the minute or endurance test methods.

Peek has found that voltages greatly in excess of the "rapidly applied" 60-cycle puncture voltage may be applied to the insulation without rupture, if the time of application be sufficiently short. All such over voltages injure the insulation, "probably by a mechanical tearing and the effect is cumulative." In these experiments of short duration, the problem of heat storage in the insulation is eliminated.

Raynor has found that the rapidly applied strength of insulation is greatly lowered by the previous application of a high voltage. This decrease in strength, however, is lost, given sufficient rest period between the initial and final voltage application. These results are substantiated in the work of the present paper. The length of rest period is shown to be proportional to the initial test voltage applied.

For tests of long duration, the work of this paper has been divided into two parts,—those voltages producing failure with an arbitarry time limit (15 minutes) and those voltages which are able to be applied for an indefinite time without a puncture. According to the pyro-electric theory, the first class deals with those voltages of such value as to produce a slowly mounting temperature rise in the insulation which ultimately reaches a value leading to rapidly decreasing insulation resistance and total loss of dielectric strength. The second class includes those voltages of such value that the rate of transformation of electric to thermal energy is equaled by the rate of dissipation of the heat so formed; thus preventing heat storage in the insulation. According to the thermal theory of breakdown, neither of these voltages should produce permanent injury to the dielectric,—the first, if removed before the stage indicating rapid loss of insulation resistance is reached, and the second, even if applied indefinitely. The present paper shows that the application of voltages of either of the above types leads to deterioration in dielectric strength of fibrous insulation, even aside from such effects that might be traced to corona or mechanical injury to the material. The effect for voltages of the first class is cumulative and expressed by the formula $R \times T = K$ *where* R = *number of repetitions of voltages,* T *the time of each voltage application, and* K *the time needed to puncture for the same voltage continuously applied. The application of this formula to various insulations, its limitations, etc., are discussed.*

The work detailed herein concerns the application of a-c. voltages at room temperature. The investigation is being extended to cover both low and high a-c. and d-c. voltages at and above room temperatures.

Object

It has generally been assumed that when a fibrous insulation is subjected to a potential stress, unless the critical point is reached and exceeded (that is, the point where the resistance suddenly decreases thus allowing the current to run away), the structure of the insulation although temporarily weakened dielectrically, is not permanently damaged and will recover if given a sufficient rest period. Some tests made in a preliminary way indicated that the above assumption was not correct. An extended study of the effect of repeated application of voltage on the dielectric strength of fibrous insulations has proven the validity of these preliminary experiments.

Up to the present time the tests have been confined to 60-cycle voltages and with the materials at room temperatures. Further work is being carried on in this field of research covering the effect of intermittently applied stress under various conditions using d-c. as well as a-c. voltages.

1. Physicist, General Electric Company, Pittsfield, Mass.

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 9-12, 1925 and at the Regional Meeting of Dist. No. 1, Swampscott, Mass., May 7-9, 1925.

Conclusions and Results

The work done under the above stated conditions shows that the breakdown point is generally decreased by a previously applied voltage, this effect being greater as the actual point of failure is approached during the previous test. The exception to the case occurs with rapidly applied tests after a rest period following a previous voltage application. In this instance the material breaks down at approximately the same value with or without the previous application of stress.

However, the intermittent application of a voltage of such a value as will cause breakdown within 15 minutes, if continuously applied, results in a progressive weakening in the strength of unvarnished oil treated fibrous material, the effect being roughly additive.

With the application of a very low voltage producing

no puncture for indefinite time, a deterioration in the strength of oil treated paper has been observed. This in part, however, is able to be traced to a change accompanying oil immersion over long periods.

For varnished insulation, the repeated application of voltage leads to increased long time strength, probably due to a further drying out process taking place under the influence of the applied stress.

With mica or with fibrous materials heated in oil between voltage applications, the effect of intermittently applied stress is diminished and an increase in dielectric life is observed.

For low-voltage application, no permanent change in percentage power factor determination for oil treated fibrous materials has been noted. With high voltages, the per cent power factor values are extremely erratic, but in general show an increase up to the point of failure.

Discussion

It has been shown in an unpublished paper[1] that the strength-thickness relation characteristic of fibrous insulation is greatly affected by voltage application even at low stresses. Thus for example, the relation expressed in the formula $K\,V = A\,T^{0.72}$ as determined for oil impregnated 0.0005-in. linen paper from 0.002-in. to 0.008-in. in thickness is changed to $K\,V = A\,T^{0.56}$ for a ten-day application of 3300 volts. At the end of 51 days the relation has become $K\,V = A\,T^{0.52}$ which is practically unchanged at the end of 77 days of voltage application.

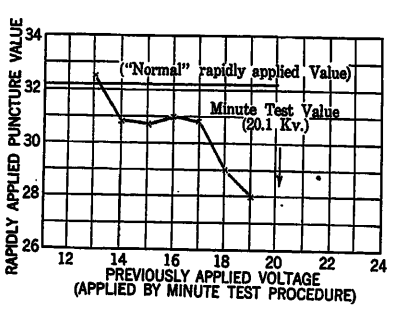

Fig. 1—Effects of Previously Applied Voltages on the Rapidly Applied Puncture Value of Three Layers Black Varnished Bond Paper (0.005 In.)

Test Medium—Transil Oil at Room Temperature
Electrodes—1½-in. Brass with Edges Rounded to 3/64-in. Radius
Test Voltage—60-cycle

Continued study has been made of the effect of voltage upon the breakdown values of a variety of fibrous insulating materials. Experimental data has shown that the important factors involved are the voltage itself, the rest period allowed between applications of stress, the duration of voltage application, and the treatment of the insulation during the rest interval between stress periods.

1. Dielectric strength-thickness relation in fibrous insulation by F. M. Clark and V. M. Montsinger.

The Voltage Factor with Reference to the Rapidly Applied Test Values

It has been found that the rapidly applied breakdown value for black varnished bond paper tested under oil at room temperature is affected by the previous application of electric stress, the effect being greater the nearer the applied voltage is brought to the actual breakdown strength of the insulation. This is illustrated in the following data, all values of which are the average of at least ten tests, the individual tests for the different points being run alternately on the same samples of insulation.

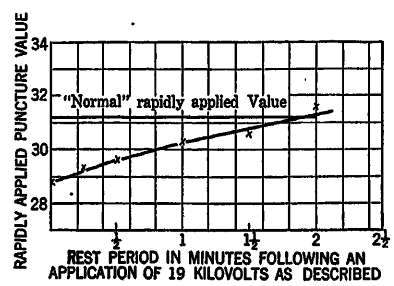

Fig. 2—Effect of a Previously Applied Voltage on the Rapidly Applied Puncture Value of Three Layers of Black Varnished Bond Paper (0.005 In.) as a Function of the Rest Period Involved

Test Voltage—60-cycle
Test Medium—Transil Oil at Room Temperature
Electrodes—1½-in. Brass with Edges Rounded to 3/64-in. Radius

Insulation—3 layers black varnished bond paper (0.005 in.)

Testing voltage—60 cycles.

Testing medium—transil oil at room temperature.

Electrodes—1½ in. brass, with edges rounded to 3/64 in. radius.

Voltage Applied	Breakdown
Rapidly applied (original)	32.2 kv.
Minute test (initial voltage 12 kv. with 1 kv. step-up each 30 seconds) (Original)	20.1 kv.
Rapidly applied preceded by voltage application according to the above minute test procedure up to and including 19 kv.	28 kv.
Rapidly applied preceded as above by the minute test voltage application up to and including 18 kv.	29 kv.
Rapidly applied preceded as above by the minute test voltage application up to and including 17 kv.	30.8 kv.
Rapidly applied preceded as above by the minute test voltage application up to and including 16 kv.	31.0 kv.
Rapidly applied preceded by voltage application by the minute test procedure up to and including 15 kv.	30.7 kv.
Rapidly applied preceded by voltage application by the minute test procedure up to and including 14 kv.	30.8 kv.
Rapidly applied preceded by voltage application by the minute test procedure up to and including 13 kv.	32.5 kv.

These results are illustrated in Fig. 1. Similar effects have been noted using 3-mil. oil-impregnated kraft paper.

The Effect of Rest Period Between Voltage Applications

The extent of the deterioration in the rapidly applied test strength of fibrous insulation is dependent upon the rest period allowed between applications of stress.

Insulation—3 layers black varnished bond paper (0.005 in.)

Test medium—transil oil at room temperature.

Electrodes—1½ in. brass electrodes, edges rounded to a radius of 3/32 in.

Averages based on ten tests. The individual tests for each point were run alternately upon the same samples of insulation.

CASE I (FIG. 2)

Original rapidly applied strength....................31.2 kv.
Minute test strength (Initial voltage 12 kv. followed by 1 kv. increments each 30 seconds)..(original)..20 kv.

Preliminary treatment—voltage applied according to the above minute test procedure up to and including 19 kv.

Rest Period	Final Rapidly Applied Strength
No rest	28.8 kv.
¼-min. rest	29.3 "
½-min. rest	29.6 "
1-min. rest	30.3 "
1½-min. rest	30.6 "
2-min. rest	31.6 "
3-min. rest	31.8 "

Similar results have been obtained using 0.003 in. oil impregnated kraft paper.

CASE II (FIG. 3)

Original rapidly applied strength....................30.7 kv.
Minute test strength (initial voltage 12 kv. followed by one kv. stepup each 30 seconds)....(original)......20 kv.

Preliminary treatment—voltage applied according to the above minute test procedure up to and including 17 kv.

Rest Period	Final Rapidly Applied Strength
No rest	29.5 kv.
¼-min.	29.8 "
½-min.	30.2 "
1-min.	30.5 "
1½-min.	30.6 "
2-min.	30.5 "
3-min.	30.8 "

Similar results have been obtained using 0.003 in. oil impregnated kraft paper.

Effect of Previously Applied Electric Stress Upon the Time-Voltage Relation

The effect of stress application upon the time-voltage relation in fibrous insulation is of interest since it not only involves tests of short duration but also long time tests. In this work the time factor involved has been limited to 15-minute intervals.

In investigating this phase of voltage effect, the stress applications fall into two classes,—first those voltages which will puncture the insulation within an arbitrary time (15 min.) and secondly, those voltages which will give no puncture independent of the time for which applied.

Case I: Those voltages producing a puncture within 15 minutes. The effect of voltages of this type has been investigated with the use of oil impregnated 0.003 in. kraft paper and 0.005 in. black varnished bond paper. The results are shown in Figs. 4 and 5. In these figures the points shown are the average values of at least ten tests. The individual tests upon which the averages of the curves are based have been obtained alternately.

The following facts in Fig. 4 are to be noted:

First, the rapidly applied test value of oil treated kraft paper is greatly affected by the previous voltage application, which effect is partly eliminated with the the intervention of a rest period between the preliminary voltage application and the final test value;

Secondly, the application of stress leads to a permanent injury as determined by the long time test value. That is, the curves with and without a rest period following the initial stress application become identical when the time to puncture factor equals one minute or more.

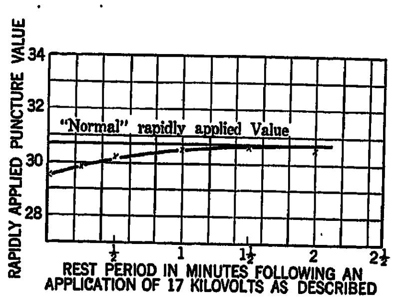

Fig. 3—Effect of a Previously Applied Voltage on the Rapidly Applied Puncture Value of Three Layers of Black Varnished Bond Paper (0.005 In.) as a Function of the Rest Period Involved

Test Voltage—60-cycle
Test Medium—Transil Oil at Room Temperature
Electrodes—1¼-in. Brass with Edges Rounded to 3/64-in. Radius

In Fig. 5 for the varnished paper, although similar effects are noted for short time tests, as observed in Fig. 4 for kraft paper, nevertheless considerable difference is observed in voltage strength for tests occupying more than one minute, where an apparent increase in dielectric strength is obtained following the intervention of a rest period between the initial and final voltage applications. In view of the fact that it is impossible to thoroughly dry varnished materials without injury before test, the increase in strength always noted with low voltage applications has been attributed to a further drying out process.

Case II: Those voltages which do not puncture at indefinite time. The effects of very low stress application involving as it does a period of weeks and months has necessitated the use of a slightly different test method. In this procedure aluminum foil electrodes (1½ in. by 2½ in.) were prepared between which was clamped the insulation under test. The dielectric used was linen paper, 0.0005 in. per layer and made up to a thickness of 0.004 in. The individual units so prepared were carefully dried under vacuum at 115 deg. cent. and impregnated. Part were then tested for the

time voltage relation. The remainder were then submitted to 3300 volts in oil at room temperature. No attempt was made to protect the oil in which the units

were placed from the effects of the room conditions, aside from the fact that the tests were made in a large "voltage box," covered but not air-tight. The results are shown in Fig. 6. Here again it will be noted that

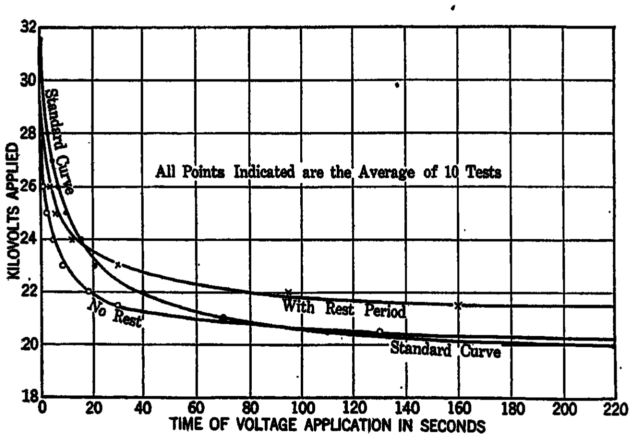

FIG. 5—EFFECT OF A PREVIOUSLY APPLIED VOLTAGE ON THE TIME-VOLTAGE RELATION

permanent deterioration has occurred in the insulation except in the case of rapidly applied test values.

The effect of long time voltage application at low stress has been investigated by means of the effect noted upon the one minute test values of 0.0005 in. linen paper in thicknesses from 0.002 in. to 0.008 in. In this connection, units similar to those described above were carefully dried under vacuum and oil impregnated. Part were tested by minute test procedure and the remainder placed under 3300 volts in oil at room temperature for varying periods, after which the minute test values were again determined. The results are shown in Fig. 7. It should be remembered that in this case the units tested being of varying thicknesses, the actual electric stress (volts per mil) was not constant. It is to be noted, however, that the minute test value for the 4-mil thickness is affected in almost equal amount in Fig. 6 and Fig. 7, in both of which cases the voltage has been applied for equal intervals, 77 days.

During the course of these experiments, no attempt

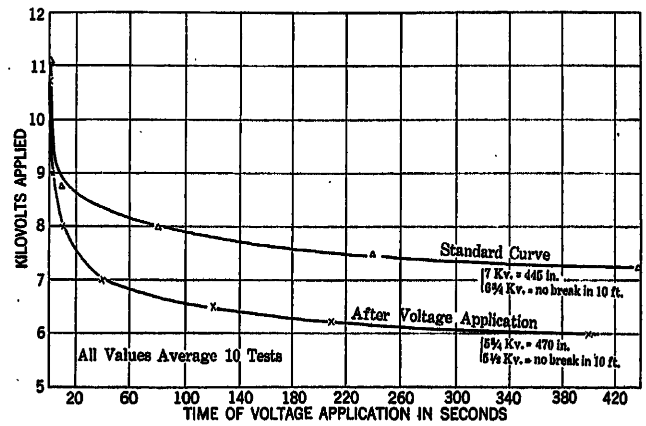

FIG. 6—EFFECT OF A PREVIOUSLY APPLIED VOLTAGE ON THE TIME-VOLTAGE RELATION

has been made to protect the insulation from the effects traceable to atmospheric conditions, the samples being merely immersed under oil whose surface was in contact with the air, of the "voltage box." Fig. 7 also shows the effects which are traceable to factors aside from the applied voltage.

It will be noted in Fig. 4 that the total time to produce a puncture with oil impregnated kraft paper at 22 kv. was originally 188 seconds. In the case when 22 kv. was applied for 2.5 minutes followed by a rest period of 5 minutes, the insulation punctured on the second application of voltage in 42 seconds, the total time for which the 22 kv. was applied before and after the rest period being 192 seconds. Thus the breaking-up of the voltage application into two steps separated by a rest period produced no material increase in the original voltage life of the insulation. A permanent injury of an additional type was apparently produced by each application of voltage.

Repeated Applications of Voltage Stress

In investigating the effects of repeated applications of electric stress, the voltages used were in general limited to those producing a puncture within a time interval of 15 minutes. In order to express the results of the various individual experiments in an easily comparable manner, the following scheme was used. A definite voltage was selected which would produce a puncture continuously applied within the time interval desired. Using this voltage, the average time to puncture on at least 10 tests was determined. This time was accepted as the 100 per cent time factor, *i. e.*, the total time needed to produce a puncture for only one application of the voltage used. With this factor as a basis, the constant voltage accepted was applied for various intervals such as 90 per cent, 80 per cent, 70 per cent, etc., of the 100 per cent time value. With a period of rest allowed between voltage applications, the number of permissible repetitions of stress for each time interval was determined.

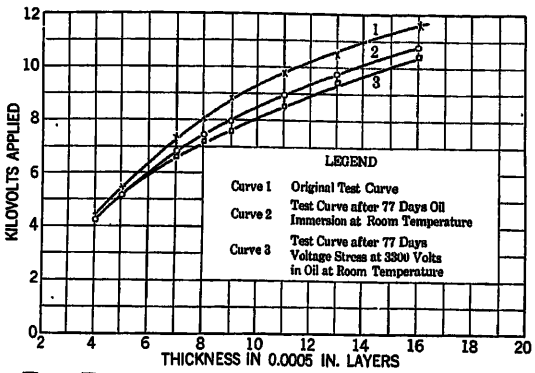

Fig. 7—The Effect of Low-Voltage Stresses upon the Minute-Test

Puncture Value of Fibrous Insulation
Insulation Used—Linen Paper, 0.0005 in. per Layer (2 in. by 3 in.)
Electrodes—1 mil Aluminum (1½ in. by 2½ in.) held in Place by Means of Glass Plates and Spring Clamps
Test Medium—Transil Oil at Room Temperature
Test Voltage—60-cycle
All Values Average of 8 Tests

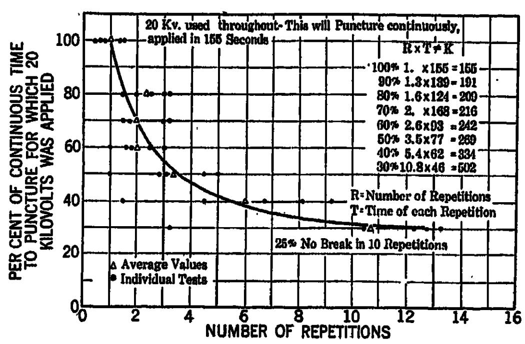

Fig. 8—Effect of Repeated High-Voltage Application upon Varnished Cambric

Insulation—Two Layers of 0.012 in. Black Varnished Cambric
Test Medium—Transil Oil at Room Temperature
Test Voltage—20-kv. 60-cycle
Electrodes—1½-in Brass with Edges Rounded to 3/64-in. Radius
Rest Period—Five min. between Tests

Case I: Figs. 8, 9, 10, 11, 12 and 13 illustrate the typical results produced by repeated voltage applications upon black varnished cambric (0.012 in.), black varnished paper (0.005 in.), kraft paper (0.003 in.), cable paper (0.005 in.), and pressboard (1/32 in. and 3/32 in.) tested under oil at room temperature. In these tests the total number of voltage applications was

Test Voltage—16-kv. 60-cycle
Electrodes—1½-in. Brass with Edges Rounded to 3/64-in. Radius
Rest Period—Five min. between Tests

limited to from 10 to 15. During the rest period, the insulation was allowed to remain in place between the electrodes immersed in cold transil oil. The varnished cambric and varnished paper were dried in air at 100 deg. cent. for four hours, after which they were immersed in transil oil for 24 hours before test. The unvarnished insulation was subjected to a vacuum drying process and oil impregnation at 110 deg. cent.

Test Medium—Transil Oil at Room Temperature
Test Voltage—23-kv. 60-cycle
Electrodes—1½-in. Brass Electrodes Edges Rounded to 3/64-in. Radius
Rest Period—Five min. between Tests

It will be noted in Figs. 8 and 9 that with the varnished materials, the actual voltage life continually increases as the time of each application is diminished. This bears out the results of Fig. 5 showing the effect of previously applied stresses upon the time-voltage relation of black varnished paper. In cases where the breakdown value of varnished insulations, dried as

described, is not closely approached either with respect to the voltage or time factors, an apparent increase in voltage life results. In the case of fibrous, unvarnished but vacuum dried and oil impregnated materials, the effect of each application of voltage seems to be additional and permanent. This effect is expressed in the formula $R \times T = K$ where R is the number of

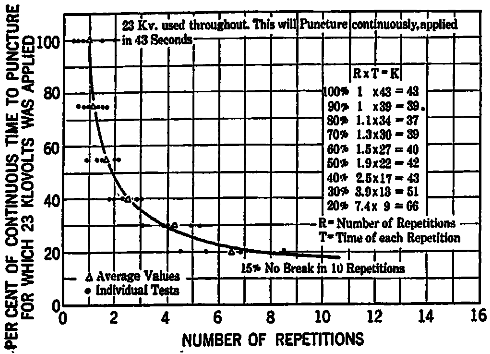

FIG. 11—EFFECT OF REPEATED APPLICATIONS OF 23 KV. ON CABLE PAPER

Insulation—Six Layers of 0.0045-in. Oil-Treated Cable Paper
Test Medium—Transil Oil at Room Temperature
Test Voltage—23-kv. 60-cycle
Electrodes—1½-in. Brass with 3/64-in. Edge Radius
Rest Period—Five min. between Tests

repetitions possible for the time T of each application. The value of K is the time to puncture for the voltage used when continuously applied. The application of this formula is given in each of the figures showing the effect of repeated high-voltage stresses. Increased dielectric life does not result until the time factor of each voltage application has been reduced to less than

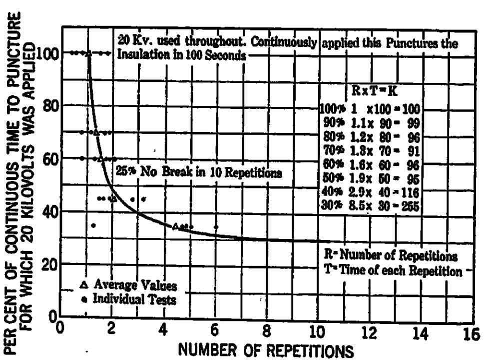

FIG. 12—EFFECT OF REPEATED HIGH-VOLTAGE APPLICATIONS ON PRESSBOARD

Insulation—One Layer, 1/32 in. grade AA Oil Treated Pressboard

Test Voltage—20-kv. 60-cycle
Electrodes—1½-in. Brass with 3/64-in. Edge Radius
Rest Period—15 min. between Tests

40 per cent of the continuously applied time to puncture value for the same voltage. This effect is shown in the case of kraft paper, cable paper and pressboard of Figs. 10, 11, 12 and 13.

Case II: In a previous article[2] it has been shown that the dielectric strength-thickness relation for fibrous insulation approaches the first power with the use of impregnated wooden electrodes. Fig. 14 shows the effect of intermittently applied voltage on 0.003 in., oil impregnated kraft paper, tested under transil oil at room temperature with 3-inch round edge impregnated wooden terminals. The effect of voltage application with these electrodes is roughly additional and in no wise different from the results illustrated in the previous figures using metallic electrodes.

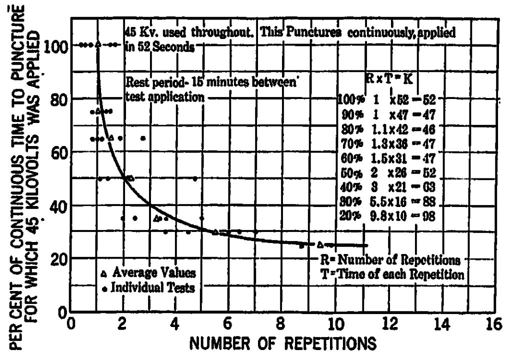

FIG. 13—EFFECT OF REPEATED APPLICATIONS OF HIGH VOLTAGE ON PRESSBOARD

Insulation—One Layer 3/32-in. Grade A Oil-Treated Pressboard
Test Medium—Transil Oil at Room Temperature
Test Voltage—45-kv. 60-cycle
Electrodes—1½-in. Brass with 3/64-in. Edge Radius
Rest Period—15 min. between Tests

Case III: In Figs. 8 to 13 inclusive 1½ in. brass electrodes with edges rounded to a radius of 3/64 of an inch have been used. It has already been shown[2] that in cases where such electrodes are replaced with terminals identical, with the exception that an albarene stone collar has closely fitted around the electrode edge

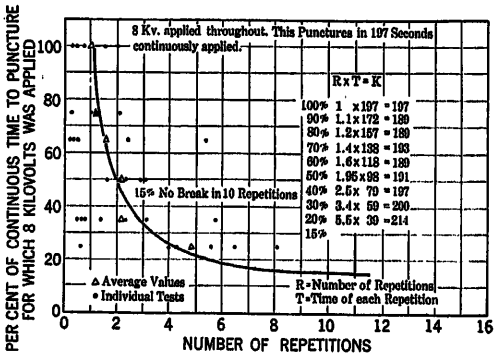

FIG. 14—EFFECT OF REPEATED APPLICATIONS OF VOLTAGE ON KRAFT PAPER

Electrodes—Three-inch, Round Edge, Impregnated Wooden Electrodes
Rest Period—20 min. between Tests

forming a smooth surface with the testing face, the dielectric strength-thickness relation is changed from $Kv = A\,T^{0.70}$ to $K\,v = A\,T^{0.86}$. The effect of such "protected" electrodes on fibrous insulation under repeated applications of stress is shown in Fig. 15 for ⅛ in. pressboard in oil at room temperature. The

2. F. M. Clark and V. M. Montsinger—Ibid

results show a deteriorating effect additional in nature accompanying each application of voltage comparable to that illustrated in the previous figures for "unprotected" electrodes.

Case IV: In the results shown in Cases I, II and III the insulation between test applications has been allowed to rest untouched in oil at room temperature.

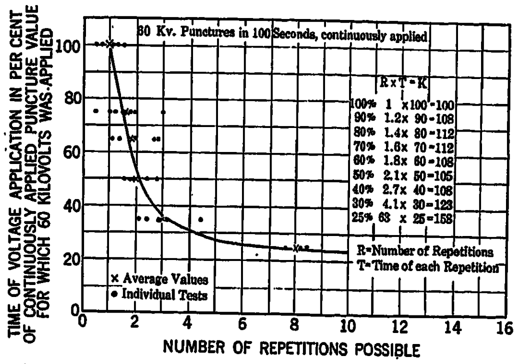

FIG. 15—EFFECT OF REPEATED HIGH-VOLTAGE APPLICATION ON PRESSBOARD

Insulation—One Layer 1/8-in. Oil-Treated Pressboard
Test Medium—Transil Oil at Room Temperature
Test Voltage—60-kv. 60-cycle, Sine Wave
Rest Period between Voltage Applications—10 min.
Electrodes—1½-in. Brass with Albarene Stone Edge Protection

Fig. 16 shows the relationship obtained, using the same procedure as in the previous cases, except that during the rest period the insulation has been heated in oil for a predetermined period. In running these tests, account had to be taken of the aging effect which would result from the intermittent hot oil immersions.

The change in dielectric strength following hot oil

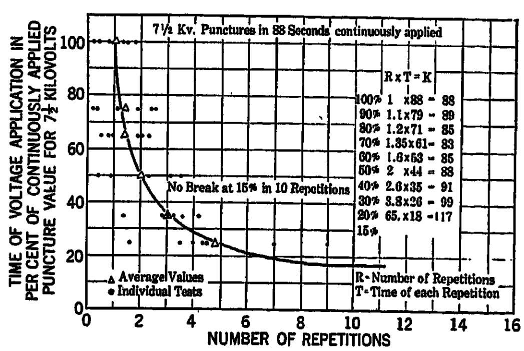

FIG. 16—EFFECT OF REPEATED HIGH-VOLTAGE APPLICATION ON LINEN PAPER

Insulation—8-Layers of 0.0005-in. Linen Oil-Impregnated Paper
Test Medium—Transil Oil at Room Temperature
Test Voltage—7½-kv. 60-cycle
Rest Period between Voltage Applications—One Hour
Electrodes—1½-in. by 2½-in. Aluminum Foil, held in Place between Glass Plates by Means of Spring Clamps

immersion has been found to be rapid in the first stages. In order to avoid such changes during test, the insulation after drying was therefore placed in 80 deg. cent. oil for one week before submitting to voltage stress. Furthermore, the tests, involving long rest periods between voltage applications, eliminated the possibility of using large 1½ in. brass electrodes as done in the previous cases. The following method was therefore adopted. Aluminum foil was cut 1½ in. by 2½ in. for use as electrodes. The insulation tested (0.0005 in. linen paper) was cut 2 in. by 3 in. and held in place between the aluminum terminals by means of glass plates and spring clamps. The miniature condensers so pre-

Test Voltage—5½-kv. 60-cycle
Electrodes—1½ in. by 2½-in. Aluminum Foil, held in Place between Glass Plates by Spring Clamps
Rest Period—One hour between Voltage Tests

minutes. The condensers were then quickly transferred to a cold oil tank and brought to room temperature before further voltage was applied. The period between tests was approximately one hour in all cases. Typical results are given in Fig. 16. As will be noted, the application of voltage in steps by this procedure leads to increased voltage life of the insulation as the

time of each voltage application is diminished. This is shown in the values of $R \times T$ given in Fig. 16. These results are directly comparable to those of Fig. 17. In the latter, using the same type of insulation and testing methods, except that the insulation was not heated between voltage periods, the effect of each stress application was found to be additional.

As contrasted to the results obtained with oil treated fibrous insulation, miniature condensers, similar to those used in Case IV above, were made up using mica as insulation. The typical results are shown in Fig. 18. As will be noted, with voltage application in steps, an apparent increase in dielectric life is obtained with or

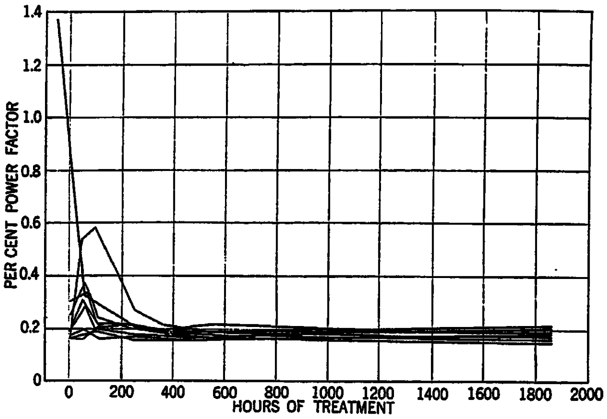

FIG. 19—EFFECT OF LOW-VOLTAGE APPLICATION ON POWER FACTOR

Insulation—8-Layers of 0.0005-in. Linen Oil-Treated Paper

Test Medium—Transil Oil at Room Temperature

Test Voltage—3300-volts 60-cycle

Electrodes—1½-in. by 2½-in. aluminum Foil, held in Place by Spring Clamps between Glass Plates

without heating in oil between tests, *i. e.*, the product of $R \times T$ in Fig. 16 is not constant, but increases as the time of each voltage application is diminished.

EFFECT OF VOLTAGE APPLICATION UPON POWER FACTOR VALUES

The effect of voltage application upon per cent power factor values was investigated using both low and high stresses. In all cases the investigation was carried out by means of miniature condensers as described above, using 1½ in. by 2½ in. aluminum foil electrodes and 0.0005 in. linen paper made up to a thickness of 0.004 in., vacuum dried and oil impregnated at 115 deg. cent.

Case I: Applied voltages producing no puncture for indefinite time.

The results shown in Fig. 19 indicate power factor determinations at 1000 cycles (bridge method) made between voltage applications of 3300 volts on linen paper insulation prepared as described above. The voltage gradient, 825 volts per mil, produced no puncture of the insulation within the limit of the experiment, 77 days. Aside from the power factor variations during the initial stages of the experiment, no change was noticed.

Case II: Applied voltages of relatively high stresses producing puncture when continuously applied within a period of 15 minutes.

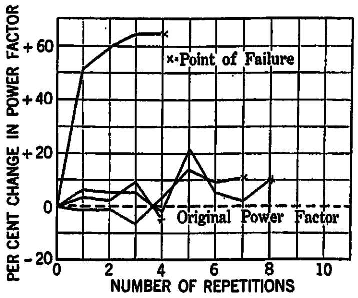

FIG. 20—EFFECT OF HIGH-VOLTAGE APPLICATIONS ON POWER FACTOR

Insulation—8-Layers of 0.0005-in. Oil-Treated Linen Paper (2 in. by 3 in.)

Test Medium—Transil Oil at Room Temperature

Test Voltage—8-kv. 60-cycle, held for 20 sec. which was 40 deg. of the Time to Puncture when continuously Applied

Electrodes—1½-in. by 2½-in. Aluminum Foil, held in Place between Glass Plates by Spring Clamps

The effect of relatively high stresses intermittently applied upon the per cent power factor at 1000 cycles (bridge method) leads to extremely erratic results. In general, the effect shown in Fig. 20 is obtained.

Discussion

J. B. Whitehead: I think the striking result of this paper is the indication that sometimes insulation that has been strained will recover and sometimes it will not. It is easy, from our present knowledge of the properties of insulation, to see how both of those things may occur. Composite insulation is distinguished principally by the property of dielectric absorption, sometimes called viscosity, sometimes spoken of as the property of having residual charge.

If you take a dielectric showing residual charge or absorption and carry it up in temperature, you will find that the absorption will merge into a pure conductivity at high temperatures. If the dielectric is sufficiently homogeneous and uniform and controlled, it may be brought down again from those regions of high temperature, and show all of its original properties. In other words, absorption generally merges into conductivity at high temperatures. It is easy to see, then, how a non-homogeneous dielectric may have this property in excess or preponderance over other properties, and so recover.

The case of non-recovery it seems to me is also equally easy to understand. We very rarely have homogeneous composite dielectrics. Particularly in the case of fibrous dielectrics, we have a variety of other phenomena entering. We have the question of moisture. We also have undoubtedly the phenomena of electrolytic conduction. We have fibers present. We have every possible suggestion of localized structural paths. It is quite easy to see that if we apply voltage to such a structure for a limited time, it is possible that electrolytic conduction, to fix our attention on only one of them, may take place along certain

limited paths to their ultimate destruction. This electrolytic conduction can be a cause of local heating; it can be a cause of the disintegration of the structure of the material itself, without resulting in breakdown.

The conditions of experiment in Mr. Clark's observations were not sufficiently controlled, I think, really to offer us any definite information on the subject of Dr. Wagner's hypothesis. I think we have assumed a wider field for the application of this hypothesis than is warranted. I believe that if we talked to Dr. Wagner himself he would immediately limit his proposal to the range in which the absorptive properties of dielectrics are merging into those of conduction.

H. W. Fisher: Mr. Clark is to be congratulated on his ability to prepare a number of samples in the tests of which he gets such remarkably consistent results. I know from experience that this is quite a difficult undertaking.

I was interested in the fact that some of the samples showed that the material was injured electrically by the application of very high voltages. I have often had reason for believing that the regular run of cables may be permanently injured if too high test voltages are applied. Cables, no matter how well saturated, are changed in their structure, due to the winding and rewinding in the lead covering and installation processes, whereas, the samples prepared by Mr. Clark, were not subjected to mechanical stress, after being prepared for test.

A number of years ago, we had a customer who never specified any high-voltage tests on cables purchased from us. We always made a routine factory test on these cables of at least double working voltage. For years and years no burn-outs were ever reported on cables furnished this customer and our vice-president, Mr. W. A. Conner (who was well known by many of the older members of the A. I. E. E.) often used to remark that the operators who did not specify very high voltage tests seemed to have the least operating troubles so far as the cables were concerned.

I shall cite the case of an experimental cable made about 15 years ago which, when repeatedly tested, did not show this deteriorating effect by the application of high voltages. In the construction of the cable, an extremely viscous and elastic compound was used. The cable withstood voltage tests which were very remarkable at that time and which, in fact, were higher than any required at the present time. Still more remarkable was the fact that although the cable was broken down, a great many times, the fault removed and new tests made, the breakdown tests were within 1000 or 2000 volts of each other every time, the tests being in the neighborhood of 50,000 volts.

Good as this cable appears to be, it would not have withstood the N. E. L. A. bending tests at minus 10 deg. cent. The compound used was a vegetable material, no mineral compound entering into its composition. This does not necessarily mean that cables made with vegetable-base compound do not deteriorate so much from high-voltage tests, as those made with mineral-base compound.

M. F. Skinker: In the synopsis of his paper, Mr. Clark mentions the pyroelectric theory of breakdown as developed by Steinmetz, Wagner, and others. The possibilities offered by thermal theories have been admirably discussed by Dr. E. Dreyfus in Bulletins No. 7 and No. 12 of the *Schweitz Elektrotechnischer Verein*, 1924. His paper deserves to be carefully studied by all who are interested in problems of this nature, particularly from a designer's standpoint. Mr. Clark states that the transformation to thermal energy proceeds "at a rate proportional to the stress applied." Obviously, it should be "at a rate proportional to the *square* of the stress applied."

In order that the original properties of the dielectric after stress might be restored, it must be assumed that no electrical strain or chemical action has taken place until the stress actually reaches the point of failure. Since none of our dielectrics are perfectly homogeneous, we would expect partial deterioration of stresses even far below the average breakdown value, the partial deterioration being nothing but the premature breakdown of weak spots or filaments. It is on the presence of such weak filaments that Wagner builds his thermal breakdown theory, and it has very justly been criticized on account of the arbitrary assumption that must be made relative to their size and physical constants.

"Rapidly applied 60-cycle voltage" is not a definite reproducible quantity unless the exact phase of the voltage is known at the time of its application. There may well be transients and reflections in the dielectric under certain conditions. Therefore, when studying the laws governing breakdown under prolonged stress, the voltage should never be applied abruptly but always should be allowed to start from zero. The time to reach full value need be only a fraction of a second, provided it is large compared to the time taken for an electromagnetic wave to cross the dielectric.

Further, before taking fifteen minutes as an arbitrary time limit, it would be well to investigate thoroughly the effect of long-time application of lower voltages. If we are making tests

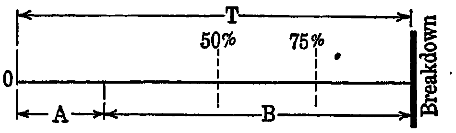

FIG. 1

in the light of the pyroelectric theory, we must take into account all the thermal properties of the system we are studying. When we get a failure due to a continuously applied voltage of several minutes duration, it may be satisfactory to neglect the specific heat of the insulation and that of the electrodes, but certainly when we are considering intermittent application of voltage we must take this into account.

It is possible to make a very simple picture of the reason for the apparent discrepancy in the law $R \times T = K$. When we apply a voltage that will cause a breakdown in an interval, some time will be spent in heating up the system before the critical point is reached. In Fig. 1 let the total interval be T, B the time to reach the danger zone of breakdown and A the rest of the interval.

Now each time we apply the same voltage for a shorter interval (that is, various percentages of the time T as indicated in Mr. Clark's paper) we see the quantity B enters in and should be corrected for. By making simple calculations, considering each of the indicated points on the graph, a mean value of B can be found. For instance, in Fig. 15, B came out 10.2 per cent of the continuous time to puncture; in Fig. 17, 15 per cent; in Fig. 9, 33 per cent, etc.

Now obviously, if we only apply the stress for these percentages of the time, we should not expect to get a breakdown of the insulation. This is faithfully indicated in the curves by the fact that they apparently have asymptotes at these values. If the equation were $R \times T = K$ the horizontal axis should be the asymptote.

The thermal conditions do not permit definite calculations but I cannot see anything in the data that definitely disproves the pyroelectric theory, but they seem to substantiate it.

G. E. Luke: These tests show without doubt that fibrous insulation has the characteristic which may be called "dielectric fatigue." The author stated that this fatigue or deterioration is permanent under the conditions given except for the case when a rapidly applied test is made after a rest period following a pre-

vious voltage application. In this instance the material breaks down at approximately the same value with or without the previous application of stress.

The above author's conclusion will evidently hold true only under the particular conditions tested, since Rayner[2] found that a prevoltage application followed by a rest will materially change the rapidly applied breakdown. Thus Rayner found that a certain oiled cloth will break down in 81 min. on the application of 5500 volts on a green sample, and 6500 volts will break down in about 29 min. on a similar sample. Now when the material is given a prevoltage test of 5500 volts for 40.5 min. (one-half the breakdown time) and allowed to recover over night, its breakdown time on the application of 6500 volts is only 0.8 sec. instead of 29 min. as found on the green material.

The intermittent application of voltage as shown on Figs. 9 to 18 show that the insulation has deteriorated and would not recover since many of the tests were made with 60 min. between tests. The author says, "with mica or with fibrous materials

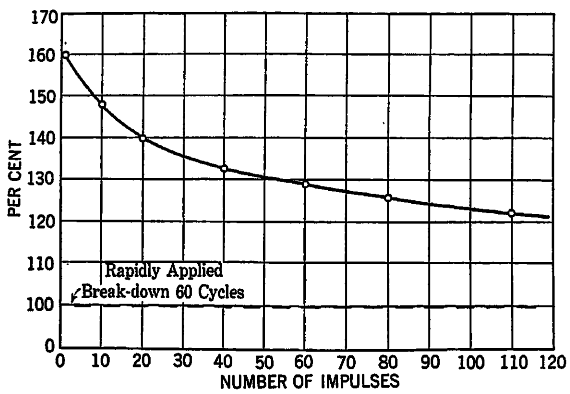

Fig. 2

heated in oil between voltage applications the effect of intermittently applied stress is diminished and an increase in dielectric life is observed." Complete data for such a conclusion could not be found in the paper since the only tests given for mica were on Fig. 18 taken at room temperature. Also due to the erratic variations in the test points it is believed that no definite conclusions can be drawn from the slight differences of curves on Figs. 16 and 17.

In this paper the repeated voltage applications were made with 60-cycle voltage over periods of time of about a minute in order of magnitude, while the time of voltage strain in service due to lightning surges would be measured in microseconds. It will probably be of interest to show the effects of repeated voltage impulses of such short-time waves. Fig. 2 shown here gives the average results of a great number of tests made in the Westinghouse Research Laboratory. The material tested was 0.015-inch sheet fullerboard under oil. The rapidly applied breakdown strength (5 to 10 sec.) with 60-cycle voltage is called 100 per cent. The curve gives the dielectric strength compared to the 60-cycle strength for various number of impulses. The impulse was obtained by charging a condenser until the voltage discharged through a spark-gap. The voltage impulse given to the insulation could be controlled by the constants of the circuit. The total time of the damped single wave of impulse for the tests shown was 4.0×10^{-6} sec. so that on breakdown with one impulse the time of the voltage application was about 2.0×10^{-6} sec. The time interval between impulses was about 5 sec., hence the energy was too small to give any noticeable heating. With 500 to 1000 impulses the voltage breakdown strength was about the same as the 60-cycle breakdown (rapidly applied). The fact that this strength with an impulse of 2×10^{-6} sec. is only 60 per cent higher than the 60-cycle, 5 to 10 seconds, breakdown seems remarkable. Such facts are also confirmed by Peek[3] of the General Electric Company.

This discussion leads up to the questions, what causes the "dielectric fatigue" such as described in Clark's paper, and in general, what causes insulation failure? It is known that under certain conditions insulation may fail due to accumulative heating of small fibers in accordance with the Wagner's pyroelectric theory. This may account for the recovery in insulation strength with a 2-minute rest as shown in Fig. 2 of the paper. In this case the localized heating was non-sufficient to change the material. The results shown with the repeated voltage applications in the author's Figs. 8 to 18 show a deterioration in the insulation, since the time interval between tests was generally sufficient to remove such localized heating, it is evident that some of the insulation fibers were permanently injured by each voltage application. However, on the basis of this pyroelectric theory one would naturally expect mica to stand up much better than fibrous insulation, but the curve on mica, Fig. 18, does not differ much from similar curves on fibrous materials. The data given on Fig. 2 with 4-microsecond impulses can hardly be explained on the basis of the pyroelectric theory since the time of application is so infinitesimal compared to the time used in the other tests. It appears that the fibrous insulation might have a critical voltage similar to the breakdown voltage of air. Such a breakdown might be explained on the basis of corona or excessive internal ionization. Whether dielectrics have free ions and can form corona due to critical voltage stresses is problematical and little information is available. The difficulties of researches along this line are due to the heterogeneous composition of the common dielectrics.

Corona may form in built-up insulation due to occluded air pockets, the results of which may form a chemical action on the insulation. Such action would cause permanent deterioration. This also does not explain the tests shown, since many of the samples were vacuum-dried and impregnated in oil. Also mica, which deteriorated about as fast as the fibrous materials, is especially resistant to this chemical action.

Anderson[4] has shown that if a powerful condenser is discharged through a small wire the wire can be completely exploded into a gaseous residue. The time of the discharge being only a few microseconds, the heating effect is too small even to scorch the cotton covering on the wire. The breakdown of a dielectric sheet with such a voltage impulse seems to be of the same nature, as a small thread through the material may be completely removed without showing signs of burning. The explanation of such a phenomenon does not seem possible on the basis of electrostatic repulsion nor on the basis of electromagnetic forces due to the displacement current; it is a complete disassociation of the molecular structure.

Joseph Slepian: The three papers on *Study of Direct-Current Corona in Various Gases, Effect of Repeated Voltage Application on Fibrous Insulation and Corona in Oil* illustrate two kinds of cumulative effects in insulation, a space-cumulative effect, and a time-cumulative effect. The space-cumulative effect arises from the fact that contiguous layers of insulation mutually influence one another so that the conductivity of one layer is communicated to the next layer, with a resultant cumulative mutual weakening of these layers under stress.

For example, 1 cm. of air will break down at 30,000 volts per cm. gradient, but 0.001 cm. of air withstands 300,000 volts per cm. gradient. Thus, if a thousand layers of air, each 0.001 cm.

2. "High Voltage Tests and Energy Losses in Insulating Materials," by E. H. Rayner, National Physical Lab. 1913.

3. The Effect of Transient Voltages on Dielectrics," by F. W. Peek, Jr. Journal A. I. E. E., 1915.

4. "Spectrum of Electrically Exploded Wires," by J. A. Anderson. *Astrophysics*, January, 1920.

thick, are placed next to one another, they will exert a mutual cumulative effect upon one another in such a manner that each layer is respectively weakened by effects coming from other layers, so that the breakdown gradient is reduced from 300,000 volts per cm. to 30,000 volts per cm.

Similar results are obtained with liquid dielectrics, or solid dielectrics. In Peek's "High Voltage Engineering," I find in one table that 1 cm. of a certain grade of oil would break down at 166,000 volts per cm., whereas ⅛ cm. of that same oil was able to withstand 364,000 volts per cm., a gradient more than twice as great. Evidently by taking eight of these ⅛-cm. layers and building up a whole centimeter, the mutual cumulative effect of these layers upon each other was such as to reduce the strength of each individual layer.

In solid insulation, the breakdown voltage is not proportional to the thickness of the insulation, but to some fractional power of the thickness, which again demonstrates a space-cumulative effect.

The mechanism of this cumulative effect is probably to be found in the nature of conduction in dielectrics. The conductivity is undoubtedly due to charged particles capable of motion in the material, and the effect of high voltage somehow is to increase the number of these charged particles. With insulation of any appreciable thickness, the conductivity produced by the high-voltage gradient at any one portion of the insulation may be communicated by direct motion of these particles to other portions, and vice versa, so that there results a cumulative effect of one layer upon the other, the increase in conductivity of one portion stimulating the increase of conductivity in other portions.

In the paper by Crago and Hodnette, this mutual influence of portions of dielectrics upon each other is very clearly shown. Only the oil next to the wire was very highly stressed, but Crago and Hodnette observe and actually measure the decrease in dielectric strength and increase in conductivity produced at points rather remote in the oil. That this effect exists is not new, but I don't remember seeing any definite quantitative information with respect to this for commercial transformer oil under ordinary operating conditions, so that the results they give are of very considerable interest and in some respects of considerable value.

The other type of effect with which Mr. Clark is principally concerned is the time-cumulative effect. We consider now contiguous elements of time. An element of time in which the insulation is highly stressed will influence the conductivity or dielectric strength of the insulation in the following period of time, usually causing the conductivity to increase and dielectric strength to decrease; a period of low stress may also influence the period immediately following, usually by causing the conductivity to decrease and the dielectric strength to increase.

This time-cumulative effect is not limited to solid insulation. In the case of gaseous insulation, it is a phenomenon long known, but described ordinarily as spark-lag. High voltage may be applied to a spark-gap for a very brief time, with only a very small current flow. If the voltage is kept on, this current flow increases at a very rapid but nevertheless finite rate, until full breakdown takes place. Complete breakdown of a sphere-gap requires a few hundreths of a microsecond. The successive moments of stress all contribute to the breakdown.

That a period of low stress tends to improve the dielectric properties of air is well known to the operating man. When an insulator flashes over, and the circuit breaker trips out, he closes it in again with the reasonable expectation that the rest given to the broken-down air will have permitted it completely to recover its dielectric properties.

In oil we also have this effect and Crago and Hodnette give quantitative measurements on the time involved. In their curves they show the time it takes for abnormal conductivity to disappear during a period of low stress.

Of course, as one would expect, in the case of the gaseous insulation, the time-cumulative effect is exceedingly rapid, in the case of liquids much less rapid, and in the case of solids still less rapid.

The mechanism of this time-cumulative effect is fairly well understood for gases. A high enough gradient in air will cause the production of charged particles which can serve as carriers of current, but the rate at which new charged particles are produced is also proportional to the number of charged particles present. Thus the number of new charged particles produced in any time interval depends on the number of particles left by the preceding time interval. The theory of ionization by collision gives a very vivid picture of this process.

In liquids and solids in all probability, similar phenomena take place, but in these cases another effect may contribute to the time-cumulative effect, namely, the heating of the insulation with resulting increase in conductivity. This aspect has been particularly stressed by K. W. Wagner in his pyroelectric theory of insulation breakdown. There is no doubt that in very many cases breakdown is caused by cumulative heating, but some of the data presented here today, and data given by others, notably Rogowski in the *Archiv der Elektrotechik* show that the pyroelectric theory does not adequately explain dielectric breakdown. If the breakdown voltage for various insulating materials is calculated according to Wagner's theory, using the electrical conductivity and thermal constants of the material as ordinarily measured, values are obtained very much larger than those obtained by experiment.

With all these effects in mind, there is a point that I would like to bring out very emphatically, and that is that we have no right to speak of a breakdown gradient characterizing a dielectric material.

The idea of a definite breakdown gradient probably rose out of the analogy with failure under mechanical stress. Any particular point of a body will yield mechanically if and only if the mechanical stress at that point reaches a certain definite value characteristic of the material, and independent of the stresses which may exist elsewhere. How natural to suppose that under electric stress also, the failure of any point in a body is determined entirely by the electric stress at that point. But it isn't true! There is no definite breakdown gradient. Because of the cumulative space effect, and the cumulative time effect, the gradient which may exist in any dielectric system when breakdown occurs will have no simple relation to the nature of that dielectric. This idea of there being a definite breakdown gradient characterizing materials is one that has colored our engineering thought on insulation for a long time: I believe it has done a great deal of harm and it is time that it should be discarded.

Only a few years ago I remember there was a very considerable discussion as to whether the breakdown in cables could be determined by the maximum stress in the cable or the minimum stress. In the light of the phenomenon that has been described in these papers such discussions seem to be meaningless. Even for a perfectly definite reproducible material, the gradient at breakdown will not be the same for this material with different thicknesses and with different arrangements of conductors. There is no reason why it should be, according to the theory of breakdown in dielectrics and in the light of these effects that have been described.

Lee and Kurrelmeyer, in their paper, take some time to discuss the adequacy of the theory of ionization by collision in explaining their results, but I do not believe that this theory was quite fairly treated in their discussion and some of the conclusions which they say will follow from the theory of ionization by collision do not seem to me to be entirely warranted.

One of the conclusions which they draw from this theory is that E divided by P should be a constant for any particular

gas. E is the gradient at the wire surface when corona begins and P, the pressure of the gas used. They state that E/P is proportional to E times the mean free path, and therefore is proportional to the energy acquired by an ion moving through the mean free path, and that this energy should determine whether ionization by collision takes place or not.

If this were true, then the idea that there is a characteristic breakdown gradient would be justified, because then the breakdown would be determined entirely by whether or not a certain definite stress had been reached. Now I have been trying to bring out the point that breakdown is not determined only by some definite stress being reached.

The reason why this conclusion of Lee and Kurrelmeyer is not warranted is that the mean free path is not a real physical quantity. The mean free path in a gas is only a statistical quantity, an average quantity. If a large number of actual free paths are considered, it will be found that there are many very short ones, and a few very long ones. The average of them all is the mean free path, but there are always a few with much greater lengths. Ionization by collision will take place even at very low gradients due to these few very long free paths. Thus ionization by collision does not set in at a definite gradient, but it occurs weakly for small gradients and then more and more strongly as the gradients increase.

What is it that sets in at some definite voltage on the system? What sets in is an instability due to the mutual action of various portions of the ionized gas upon each other. Given a gas between definite electrodes ionization by collision will occur at all voltages; there is, however, a certain voltage where the ionization produced in one portion of the gas so multiplies the ionization in the next portion, that working back on the first portion, there is produced a cumulative instability and a breakdown.

The proper relation which should be expected, and which I venture to predict will be fairly accurately confirmed, is not that E/P shall be a constant, but another relation given by Paschen's law. Paschen's law connects the breakdown voltage for plane electrodes, the electrode separation and the pressure. Paschen's law has been generalized by Townsend to cover the case of any shape of electrode, and Townsend's generalization may be put in this way: if P is varied, and if at the same time the dimensions of the electrodes are varied so as to keep the ratio of the mean free path to the dimensions of the electrodes constant, then E/P will be constant. Hence in this case E/P will be a constant if the dimensions (here the radius of the wire) multiplied by the pressure is kept constant. It is only if the wire radius is varied in this manner that E/P will be constant, according to the theory of ionization by collision.

It is rather interesting to note that the formula of Peek is consistent with this condition.

D. Bratt: I believe that it is justifiable in this connection to emphasize some general consequences of the purely thermal idea of breakdown that seem to be less realized than warranted by their importance, and which have a direct bearing on the subject of Mr. Clark's paper.

First, it should be noted that breakdown is caused by excessive current, and that voltage as such has nothing whatsoever to do with the so-called "pyroelectric theory." We must therefore carefully distinguish between instantaneous breakdown and thermal breakdown, the former being caused probably by some sort of molecular yielding due to purely Newtonian forces. It does not appear that Mr. Clark makes this distinction in his voltage applications.

The development of heat in a plate, subjected to voltage, not only leads to higher temperatures in the interior, but also to a re-distribution of voltage gradient, even though there be no internal free charges by assumption.

The relation between current density and temperature should therefore be determined, and the subsequent numerical evaluation of the obtained formulas should be based on tests of dielectric losses as a function of current density and temperature.

The maximum stable current density can then be determined. We will get an expression of the following form:

$$\Delta_{max} = \frac{1.84}{d} \sqrt{\frac{\lambda}{\rho_0\, k}}$$

where d = thickness of the plate
λ = thermal conductivity
ρ_0 = initial value of dielectric loss per cm³
k = the logarithmic increment of temperature
and the dielectric loss has been assumed to obey the law

$$\rho = \rho_0 \Delta^2 \epsilon^{k\Theta} \frac{\text{watts}}{\text{cm}^3}$$

The corresponding temperature rise inside the plate

$$\theta_{max} = \frac{1.10}{k}$$

From these equations we obtain the maximum strength

$$E_{max} = \frac{1.84}{f} \sqrt{\frac{\lambda}{\rho_0\, k\, \mu^2}}$$

Where f = frequency, u = the average dielectric constant estimated from the known temperature distribution inside the plate and previous d-c. tests of dielectric constant as a function of temperature.

We have assumed here the simplest possible case, when the surface temperature of the plate is taken as reference level. This temperature is generally not known; therefore, the heat dissipation from the electrodes must be taken into account.

It should be carefully noted that E_{max} is independent at the plate thickness d, assuming as we have done, a homogeneous dielectric.

The strength of the insulation is, therefore, determined by neither $\rho_0\, \lambda\, \mu$ or k alone, but on the factor $q = \dfrac{A}{\rho_0\, k \cdot \mu^2}$.

During a prolonged stress, the strength of most materials has been found to decrease. Thus, were it possible to keep our plate under maximum voltage, we would have to decrease this voltage gradually in order to prevent breakdown.

It is a very reasonable assumption that the cause for this decrease in strength, aside from the natural aging of the insulation, is nothing but the applied voltage itself, or still better, the energy developed. Any structural change in a material requires energy.

For some time, T_0 onward, the change in q becomes very gradual, and we could write, tentatively

$$q = q_0 - a \int_{T_0}^{T} E_{max}^2\, d\, t$$

differentiating

$$\frac{d\, q}{d\, T} = -\, a\, E_{max}^2$$

and according to the expressions found for E_{max}

$$\frac{d\, q}{d\, T} = -\, A\, q$$

(where A is a constant)

Integrating, then, gives $q = q_0\, \epsilon^{-A\,(T - T_0)}$

E_{max} will, therefore, according to the hypothesis made, asymptotically approach zero, and this result indicates in my opinion very definitely the danger of prolonged stresses near the breakdown point.

Everything leads us to believe that this change in strength is an irreversible process. Therefore, if the material has been once so stressed, and the voltage then removed, nothing should lead us to expect a return to the initial state. This does not,

of course, apply to moderate stresses, which have been found to improve the strength in many cases, usually due to some drying-out process.

When studying the effect of prolonged or intermittent stresses on a solid dielectric, we believe it would be profitable to work along some hypothesis similar to the above. If correctly understood, the pyroelectric theory might yield results of great suggestiveness, and in this case, as always, a theoretical analysis prior to any experimental work offers the best possible guarantee against excessive laboratory expenses and results that have no general applicability.

Incidentally, I might add that for a crucial test on the pyroelectric theory as such, direct current ought to be used instead of alternating current. This would eliminate internal charges and some other unknown factors. If this theory failed for direct current, it would certainly not be expected to be valid for alternating current.

A. C. Crago: The most variable quantity which I have run into in engineering work has been the time of breakdown of dielectrics. So far as I know, it is the most variable quantity which we try to assign a definite value. We see in Mr. Clark's paper that the time of breakdown is a decidedly variable quantity.

I shall confine my discussion to the group of curves numbered 8 to 18 in Mr. Clark's paper. I shall review briefly the conclusions or the results which Mr. Clark has obtained from these eleven curves as I understand them.

First, that with oil-impregnated or oil-immersed fibrous materials, the cumulative effect of an intermittently applied voltage is directly additive; second, that with varnished materials, the cumulative effect is not additive; third, that the cumulative effect is not directly additive in any case for shorter times of application than 30 to 15 per cent of the 100 per cent time.

Using these results as evidence, Mr. Clark's general conclusion is, I believe, that there is some permanent deteriorating effect on the insulation in all cases due to this voltage application which is not removed by the rest period between tests.

After a rather detailed study of the data presented in Figs. 8 to 18, I believe that although the above conclusion may be correct, it is not warranted on the basis of the data presented, because of the wide variation in the time required for breakdown with a voltage continuously applied.

The following table presents the range of values obtained in determining the "100 per cent" points of the group of curves:

Fig. No.	Lowest	Highest	Ratio
8	0.40	1.60	4–1
9	0.40	1.7	4.2–1
10	0.50	1.55	3.1–1
10	0.35	2.0	5.7–1
11	0.35	1.8	5.1–1
13	0.35	1.75	5.0–1
14	0.25	2.0	8–1
15	0.5	1.5	3–1
16	0.2	1.85	9.2–1
17	0.2	1.9	9.5–1
18	0.2	2.5	12.5–1
Average Range 6.3 to 1			

Obviously, if we use the average of five or six values which vary over such a wide range, the mean value is subject to a rather large variation. A calculation with an average variation of 50 per cent from the mean, (which is found in some cases) shows that the probable error of this average is over 20 per cent.

However, although the reasoning given above will account for errors in the values of results, it presents no evidence to show that the relation $R\ T = K$ is not necessarily due to a permanent weakening which lasts over the rest period.

I shall now present evidence for this. First, let me say that not all observers have found the effect Mr. Clark gives. E. H. Rayner gives the following table for two thicknesses of Number 12 cloth immersed in oil, which it seems is comparable with the data of Clark:

Recovery in varying periods of rest after application of 9000 volts for 1 minute (breakdown at 9000 volts—1½ to 2 minutes)

Period to rest	Time to break at 11,000 volts
0	2.6 seconds
1 min.	9.5 seconds
2 min.	11.9 seconds
fresh material	12.0 seconds

It will be seen that after a rest period of two minutes, the insulation stood the test voltage for practically as long as unstressed material. I cannot tell you how these results were obtained or the laboratory conditions under which they were obtained, but give them to you as a result which was published by E. H. Rayner under the title of "High Voltage Tests and Energy Losses in Insulating Materials" in the *Proceedings* of the I. E. E. of 1912, Volume 49, page 214.

Instead of assuming that there is a permanent effect on the insulations used in Mr. Clark's tests due to high voltage stress, let us assume that when voltage is removed, the area under test returns, not to its original condition or to a poorer condition, but to the condition of a random point. That is, let us assume that it has the same chance to break down in 10 sec. or 20 or 30, sec., as though we had chosen a fresh point on the insulation. What will be the result?

Let us analyze one of Mr. Clark's curves on this basis, taking as an example Fig. 8.

Referring to this curve, we find, that there is one breakdown obtained at about 40 per cent of the time referred to as the mean value or the 100 per cent time, and that five tests have been used to obtain this average. This means that if we choose new points on the dielectric and apply voltage, approximately one time in five breakdown will occur in 40 per cent of the 100 per cent time. Of course, that cannot be a very definite quantity, because only five points are given here.

Also, if we apply the voltage for 40 per cent of the 100 per cent time, remove it, move the electrodes, and apply it again for the 40 per cent time, a breakdown will occur one time in five.

Let us see now what happens when we apply voltage for periods of 40 per cent of the 100 per cent time and do not move the electrodes. Referring again to Fig. 8, we come down to the 40 per cent time and across till we strike the curve, and we find that that corresponds to a number of applications of 5½, which I would consider an excellent check. That is, this insulation, whatever the cause of the variation, has acted in such a way that the curve could be explained on the basis which I have stated and will state again: that an insulation stressed under the conditions given does not return to its original condition, nor to a poorer condition, but to the condition of a random point.

I have analyzed the eleven curves given, attempting to explain their shape on this basis, and I find that nine of the eleven give a reasonably close check and that two of these nine are more than explained by this assumption.

After reading Mr. Clark's paper I made some tests with oil, using a standard Westinghouse test cup, which consists of two square-edged cylindrical electrodes 1 in. in diameter, spaced 0.1 in. apart. The oil was stirred after each application of voltage. The procedure described by Mr. Clark was used. Under these conditions, no permanent deterioration resulted, the oil on each application of voltage being fresh oil.

I have prepared three illustrations showing the results. Fig. 3 shows the effect of applying 30 kilovolts to oil under the conditions given. I have shown the individual points obtained in getting an average 100 per cent point. The variation is very wide; from 8 per cent to 250 per cent of the average.

The time was reduced to 70 per cent of the average time and new points were determined, getting a new distribution of break-

down time. That is, we applied the voltage for 70 per cent of this 71 seconds, or attempted to apply it for that long, and then cut off the voltage, stirred the oil, applying the voltage again, obtaining an average point which lies out at the value of 2. The time of application was then reduced to a little less than 40 per cent of the average time, obtaining another average point.

The testing voltage was reduced to 27 kv. (see Fig. 4). It was found that the average time for breakdown was 326 seconds.

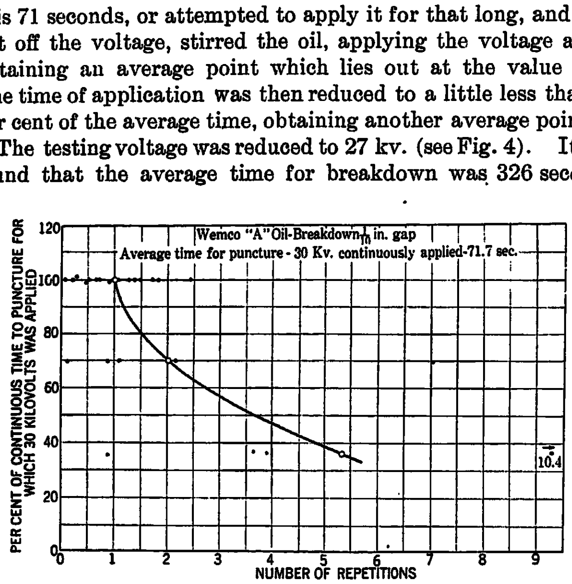

FIG. 3

Following a similar plan, we get a somewhat steeper curve than the one given for 30 kv. You understand, this is the same material, and that no permanent deterioration could occur, and yet we get a curve of this new shape. If we had had all these points lying right on the average point, instead of spread over a wide range as they are, then as soon as we had reduced the time to 70 per cent of the average time, we would have obtained no breakdowns. I realize that the number of points given here is not enough for complete proof, but it checks very well with the theory given.

I have taken the two curves shown before, and plotted them together in Fig. 5, showing the differences obtained, and also plotting a third curve which has the equation $R\ T$ = a constant. The object of this curve is to show that we can obtain almost any law by the conditions of test used; that is, even with the same

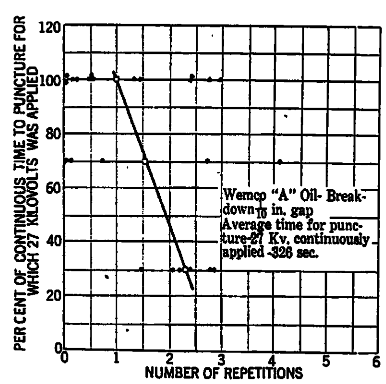

FIG. 4

dielectric, we can get $R\ T$ with a decreasing value, or with an increasing value.

Let me repeat then, in a few words, the ideas I have tried bring out in this discussion of the paper.

First, Mr. Clark's paper explains the shape of the curves in Fig. 8 to 18 by the presence of a permanent deterioration in the dielectric. I have presented evidence attempting to show that it is not necessary to assume permanent deterioriation to explain the shape of the curves, the evidence being, first, an actual experiment by Mr. Rayner in which no permanent deterioration occurred with similar dielectrics; second, an analysis of Mr. Clark's curves on another assumption; third, similar experimental curves where no permanent deterioriation did occur.

It seems probable to the speaker that in actual tests the curve shape is the result of a combination of two factors, variation and deterioration. Only more consistent results for identical tests can determine this point.

The most likely criticism of this discussion is that we are not dealing with the same thing in solid as in liquid dielectrics; that when we put a pair of electrodes down at a certain point on the solid dielectric, that point has certain properties which we will determine. Different points in the dielectric, it may be said, will vary widely, but a given point has rather definite properties, depending on the location of the electrodes.

Of course this is a rather good point, but we can see that because these variations are so very wide there must be something other than just a difference in the quality of the material to explain these wide variations. Perhaps a very slight variation in test voltage may cause it. Perhaps the distribution of charges in the dielectric may cause the variation. Perhaps where we have it immersed in oil, actual movement of the oil due to osmosis in the fibers of the insulation may cause it. Perhaps a slight shift or change in pressure or distribution of pressure of the electrode occurs. I do not offer a complete physical explanation based on

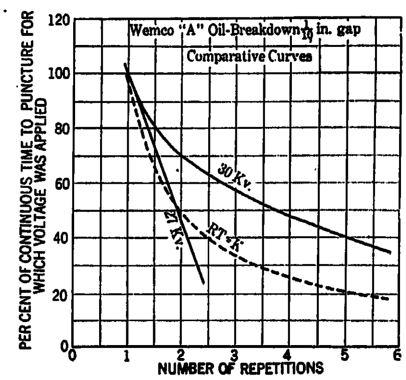

FIG. 5

this other assumption, but I do feel that we are in danger in interpreting results based on averages determined from a few points which vary as widely as those shown in Mr. Clark's tests.

Herman Halperin: It appears to me that the results of the tests in Mr. Clark's paper need not alarm the makers and users of high-tension, impregnated-paper insulated cables.

Figs. 2 and 3 of the paper show that a preliminary application of voltage, equal to about 60 per cent of the normal rapidly applied breakdown voltage, results in deterioration of only about 5 per cent and that after a rest period of three minutes the original dielectric strength is entirely recovered.

For the 12-kv., three-conductor cables purchased by the Commonwealth Edison Company in 1924, the normal rapidly applied breakdown voltage on the new cable at the factory would be about 100-kv. to 150-kv. The full-reel, high-voltage tests which were applied to this same cable was 32½ kv. for five minutes and this voltage corresponds to only about 25 per cent of the normal rapidly applied breakdown voltage of the cable. The acceptance test on the cable after installation and the subsequent proof tests are made at voltages considerably lower than those of the full-reel, high-voltage tests at the factory. The transient voltages, as found at several substations by means of needle gaps, are seldom as high as 32½ kv., when operating the cable. Therefore, the ratio of the extra high voltages that as applied to cables to their normal rapidly applied breakdown voltage is considerably below the ratio of 60 per cent which Mr. Clark used as his previous application of voltage, as pointed out in the previous paragraph.

In Fig. 4 the effect of applying for 2½ minutes a voltage of

about 65 per cent of the normal rapidly applied breakdown strength, is shown to cause a decrease of about 20 per cent in the instantaneous breakdown value of the insulation and the decrease in the voltage time curve at three minutes is only 12 per cent. So one wonders whether or not the effect of this previous application of a high voltage would be further decreased if the voltage-time curve were extended to a matter of hours, months, or years. As I have previously pointed out, in testing high-voltage cables, instead of using 60 per cent or 65 per cent of their normal rapidly applied breakdown voltage, the tests are at about 25 to 30 per cent, so the effect of those tests are further minimized to a very small amount, as may be deduced from Mr. Clark's work.

In Fig. 7, the difference between Curves 2 and 3 show the effect of the long-time application of voltage at a somewhat lower stress. The difference between the two curves is only 3 per cent or 4 per cent; hence it appears that nothing conclusive can be drawn

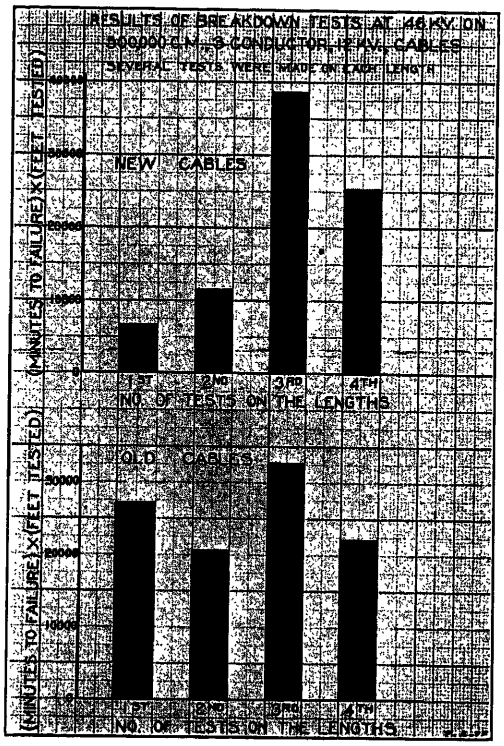

Fig. 6

as to the effect of this application of 3300 volts for seven days, for any one familiar with breakdown tests knows that test results, which show only a slight difference in dielectric strength, do not definitely prove any point, because the individual test results are liable to vary about 10 or 25 per cent. In connection with this curve, it is gratifying to learn that Mr. Clark expects to continue this work of the effect of long-time applications at lower voltages. The stresses which he is using for long-time application correspond to about the stresses used in full-reel high-voltage tests at the factory, after correcting for the thickness and form of the insulation.

Last year the Commonwealth Edison Company tested several 200-ft. lengths of three-conductor, 12-kv. cable. Some of these lengths were new cable as received from the factory and others were used cable which was removed from the system due to failures. The tests were made at 46 kv. three-phase with neutral grounded, and were continued until breakdown occurred. When a given length failed, the portion near one end was removed in case that portion was short; that is, if we had a 200-ft. length and the failure occurred at the 175-ft. mark, the 25 ft. were removed, a pothead was attached at that end and the test was repeated. If the failure occurred near the center of the length, a short section of cable including the failure was cut out and a joint made. Then the length was again ready for test. This was repeated on the various lengths, with from three to six tests on each length.

In the accompanying Fig. 6, the results of the tests on new cables are shown in the upper portion and those on old cables in the lower portion. In order to take into account the fact that the length of a given section of cable decreased due to cutting off portions, we plotted the product of the minutes to failure and the feet tested, against the number of the test on the length. For instance, on the second test, we took the results of all of the second tests on the various lengths, multiplied the minutes to failure of each section by the length of that section in feet, averaged all of these products, and obtained an ordinant of about 11,000. In general, the increase in the life of the new cable was very marked, while on the old cable the product of the minutes to failure times feet tested remained practically constant. If the item of feet tested had not been considered, then the increase of minutes to failure would have been greater for both old and new cables than shown in the chart.

Similar tests at higher voltages have been made on three-conductor, 33-kv. cable and the results are similar to those shown in the figure. That is, on the 33-kv. cable the average time that the section withstood the second and third tests was greater than the time which it withstood the first and second test, respectively.

These tests, which were made at nearly four times the operating voltage, indicate that one application of voltage of five to fifteen minutes at three or four times the operating voltage should produce practically no deterioration of the cable and should not affect its life in service.

E. S. Lee: In connection with Dr. Slepian's remarks regarding the effect of small laminations of the material as opposed to a greater thickness of the material, I want to bring to you something that we have noted, to see whether other folks have noted it because I think it is of great interest.

In Fig. 7 herewith results of dielectric strength tests on some black varnished cloth with both direct and alternating current are shown. It is interesting to see that while the relation between breakdown voltage and thickness for both alternating

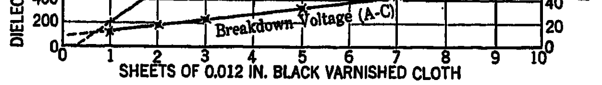

Fig. 7

current and direct current is approximately linear, the relation between dielectric strength and thickness for alternating current and direct current are quite different. This follows because the breakdown voltage-thickness curve with direct-current (extrapolated) cuts the x-axis, while the breakdown voltage-thickness curve with alternating current (extrapolated) cuts the y-axis.

The point I want to bring to you is this: While the a-c. curve says we have a given voltage with no thickness, and the d-c. curve says we have a certain thickness with no voltage, the point I want to make is that they probably both go through zero. Whatever is happening there, then, appears to

be happening within the thickness of one sheet of material. This bears out what Dr. Steinmetz has said: that we will have to study very small distances between electrodes in our study of insulation.

Just one other point: I did just as Mr. Halperin did in taking Mr. Clark's results and referring them to rated cable voltage and test voltage, and I came to the same conclusion that he did: that we were not in that range. But I noticed that when voltages occur on the system within 200 or 300 per cent of normal rated voltage, they come within the range of Mr. Clark's results. So it may be that in cable operation the results shown by Mr. Clark do enter.

R. W. Atkinson: As in the case of the discussion of Mr. Clark's paper authors of papers presented before the Institute are often criticized by physicists and engineers because not enough data are given, and authors are criticized by the Institute management because the papers are too long. These viewpoints are not always mutually exclusive, but very often they are, and an author always has quite a problem to meet both viewpoints, which are both very well taken. But usually a compromise must be arrived at, and usually both sides have some remaining good grounds for criticism.

I am very glad that Dr. Whitehead and Dr. Slepian have emphasized the fact that the pyroelectric theory of breakdown brought out by Dr. Wagner and Dr. Steinmetz is limited in application. Unquestionably this theory can explain breakdown in many cases and unquestionably in many cases breakdown is of that character, but I am convinced that in many cases it is not.

There is one conclusion in Mr. Clark's paper that is very directly applicable to cable insulation in general. I do not know that it makes very much difference whether the explanation of the conclusion is deterioration, or whether the explanation is the random effect suggested by Mr. Crago, but this conclusion is that the total breakdown time for a given voltage is often or usually somewhere nearly independent of whether one test is made on a cable or several. If insulation will break down at a given voltage on an average in one hour, it does not make a great deal of difference whether it is ten 6-min. tests or one 1-hr. test.

That is given with qualifications in Mr. Clark's paper, and I think the qualifications apply. But in general it has seemed in tests on samples of cable insulation and in reel lengths that that general conclusion applies.

F. W. Peek, Jr.: It is a well established fact that when voltages above a certain value are applied to insulation, damage is done. If a succession of over-voltages is applied, the effect is accumulative. This is perhaps more simply shown by the following experiment with impulses of short duration than by Mr. Clark's data. A voltage is readily found at which a single impulse will cause failure. If this voltage is lowered somewhat it may require ten impulses to cause failure; at a still lower voltage one hundred, etc. Finally a voltage is reached where there is no failure on any number of applications. The cumulative effect of the successive impulses of over-voltage is not a pyro effect; it is not due to an accumulation of the heat from each application because it does not depend upon the time between applications. It is caused by a disruption or tearing apart of the material without burning. Of course, this disruptive effect is quite different with different types of insulations. With certain electrically brittle insulations the effect is marked. With insulation built up of laminations filled with oil the effect is probably a minimum because damage is repaired by the flow of the oil. I think that Mr. Fisher's discussion illustrates this.

In addition to the above disruptive effect, there is without doubt a pyro effect. The pyro and conduction effect becomes predominant in certain insulations for moderate "over-voltages" and comparatively long times of application. The theory, now generally known as the Wagner theory, fails, I believe, in that it does not consider all of the variables. The mistake must not be made in neglecting either the disruptive or the pyro and conducting effects. Whether one or the other is the predominant cause of failure depends upon the conditions.

D. W. Roper: In the test described by Mr. Halperin the lead sheath of the cable was very thoroughly grounded so the operators could go along and feel the sheath with their hands and determine the location of the hot spots which developed through local heating. These hot spots were marked, for the purpose of orienting the subsequent failures. The failure occurred in the maximum hot spot in about 40 per cent of the cases. In 25 per cent additional, the failure occurred not in the maximum hot spot, but in some other spot where the heating was appreciable. About 35 per cent of the failures occurred where the temperature was normal, that is, where there was no hot spot. So that the number of cases in which there was no pyroelectric effect was about equal to the number of cases in which the heating was apparently due to the pyroelectric effect described by K. W. Wagner.

C. E. Skinner: I have been very much interested in Mr. Clark's conclusions, particularly in view of my paper entitled, "Energy Loss of Commercial Insulating Materials when Subjected to High Potential Stress," published in the 1902 TRANSACTIONS of the Institute, page 1047. I would especially refer to the numbered paragraphs, 1 to 8, inclusive, pages 1050 and 1051. My tests were made with the view of determining the effect of continued stress of various intensities and frequencies, but many of the conclusions from these tests anticipate those given in Mr. Clark's paper. For example, this statement appears, "The final breakdown in fibrous materials usually results from the burning of the material and not from mechanical rupture." My paper discusses the general question under the headings, "Variation of Temperature due to Variation of Stress," "Variation of Loss due to Variation of Temperature," "Variation of Loss due to Variation of Voltage," and "Variation of Loss due to Variation of Frequency." Mr. Clark has given the results of experiments made from a somewhat different viewpoint and it is naturally gratifying to find that where parallel conclusions are reached, they are substantially the same as those arrived at by the very crude instruments and methods available to us twenty-two years ago.

V. M. Montsinger (by letter): Mr. Lee has mentioned one very interesting point and that is the variation of dielectric strength with thickness. I cannot quite agree with Mr. Lee in that if the first layer is neglected, the points fall on a straight line on coordinate paper, or in other words that the dielectric strength is proportional to the thickness.

An examination of a large number of tests made on various kinds of fibrous insulation shows that in almost every case the points fall on a straight line on log-log paper. This means that the strength vs. thickness can be expressed by the expression:

$K.\ V. = A\ T^n$, where A is a constant T the thickness and n a numerical value depending mostly on the treatment of the material.

If the material is untreated the value of n is close to unity. If the material is well oil-soaked or varnished, the value is around $^2/_3$ or perhaps $3/4$. However, if the layers are very thin in the order of a few mils it is often found that the strength of the first layer is higher than the line indicates it should be. The effect is perhaps the same as what we find for air and oil, namely for very small distances the volts per mil goes way up and departs entirely from the law that holds for the larger thicknesses.

As stated in Mr. Clark's paper, there is scheduled for publication in the near future, an article by Mr. Clark and myself on the subject of dielectric strength vs. thickness and in which the subject is discussed more thoroughly than is possible here.

In reference to Mr. Bratt's formula, which states that the maximum strength is inversely proportional to the frequency of the applied voltage, I would like to point out that while strength

decreases with an increase in frequency, it is not in any way inversely proportional as indicated by the formula.

The results of a large number of tests covering a range of frequency from 25 to 420 cycles show that the factor F should have an exponent M whose value is approximately 0.137 for solid insulations. The difference in strength depending on whether the value of the exponent is 1 or 0.137, is of such a large magnitude that it cannot be neglected. For example, if the strength was inversely proportional to the frequency, the dielectric strength at 420 cycles would be $^1/_7$ or approximately 14 per cent of the strength at 60 cycles. As a matter of fact for solid insulation the 420-cycle strength is approximately 75 per cent of the 60-cycle strength.

Full details covering this subject are given in my paper on "Effects of Time and Frequency on Insulation Tests of Transformers" appearing in the 1924 TRANSACTIONS A. I. E. E. p. 337.

F. M. Clark: I would like to put one thing over and that is that I do not believe that I am attacking the pyroelectric theory of insulation failure. For that reason, I have been glad to hear Dr. Whitehead and others rise to the defense of the pyro theory in statements with which I can heartily agree.

Any discussion of the heat theory of insulation failure, generally involves, sooner or later, a discussion of "weak threads," conducting particles and the like, and such a talk usually ends in a thorough condemnation of the paper manufacturer. I can not agree that the paper or cloth, or whatever may be the solid concerned, is the sole seat of the weak spots involved. There are all sorts of ways in which a weak spot may be formed not even remotely involving the characteristics of the solid itself. From work which I have done, enumerated in this paper and otherwise, it seems as if a weak spot might actually be formed as a result of the voltage application. For example, we know that some molecules are unsymmetrical and polar. They thus possess the property of attracting other molecules. The water molecule has such a property and if present in oil it would become attached with its positive pole or its negative pole as the case may be toward the second molecule involved. This in effect would lead to a molecular polarization in the liquid dielectric possessing all of the characteristics necessary for a weak-spot formation. A thorough study of Fig. 17 will reveal the possibilities of this idea, in connection with the apparently cumulative effect of voltage upon insulating materials.

If we assume this explanation, it will explain a large number of the questions raised in the discussion, I cannot take up all of these but there are several to which I desire to reply.

Mr. Fisher and others have pointed out that apparently with viscuous materials such as impregnating agents the effect of voltage application on cables is negligible. In view of the fact that the cable cited by Mr. Fisher was apparently very well treated and voids eliminated no objection can be raised on that score. But does Mr. Fisher not consider the fact that it is somewhat remarkable that every time his cable broke down and he repaired it, the next break was at about the same voltage? If we assume that each time a break appeared, we are removing a weak spot, the next breakdown ought to be higher. In other words, by removing the weak spots of the cable, the actual breakdown ought to rise gradually with each succeeding test. The fact that it does not, might be explained from the standpoint of a cumulative voltage effect.

I can only remind Mr. Skinker that it is realized that further study must be given to the effect of voltage application involving longer times that an arbitrary limit of 15 min. As stated already, however, this phase of the research is at present being investigated and will be reported upon at the appropriate time. Furthermore, as far as can be detected with the oscillograph, the effects of surges cannot be used to explain the voltage effects set forth. The possibility of surges has been considered and eliminated. Mr. Luke has referred to the researches of Rayner on oiled cloth in which a long-time voltage application produced an effect which did not disappear during a rest period. Although no oiled cloth has been investigated in these researches, there is no apparent reason why its behavior should not correspond with that cited for oiled paper. Certainly its behavior must not be confused with that given for varnished cloth which Mr. Luke has apparently done. If we accept the case of oiled cloth as paralleling that for oiled paper then there should be no recovery from the voltage effect. This is clearly illustrated in Fig. 4 of the paper.

Mr. Luke furthermore points out the mechanical effect of impulses. These results are in agreement with work of similar nature with which I am familiar. Apparently Mr. Luke has misunderstood the statement on the second page with reference to the behavior of fibrous oil-treated material heated between voltage applications and to mica. (Figs. 17 and 18). All actual voltage application has been carried out at room temperature. When the insulation has been heated between voltage stress, it has been cooled to room temperature before the next application of voltage. We have never been able to obtain evidence of an additive voltage effect under such conditions. The effect is cumulative and somewhat erratic as shown in the figures mentioned but in no sense strictly additive. Mica has always been found rather erractic in tests of this sort but the results are in general of the same character.

Mr. Bratt has brought out the necessity of carefully distinguishing between an instantaneous breakdown and a thermal breakdown. This necessity has been recognized throughout and it is for that reason that the paper has been carefully separated into three parts. The very short-time test results are shown in Figs. 1, 2 and 3. Figs. 8 et seq. deal with breakdown involving thermal considerations. These two groups are connected by Figs. 4, 5, 6 and 7 showing the time-voltage relation involving a breakdown from those of "instantaneous" character to those involving thermal considerations.

Mr. Crago has cited the work of Rayner in which a stress application of 11,000 volts produced a break in 12 sec. which was unaffected by a previous voltage application followed by sufficient rest period, the time of rest demanded being about 2 min. A break involving only 12 sec. is of the same category as those designated in this paper as rapidly applied tests, involving roughly 10 sec. For breaks of this character, it is shown that a decided recovery of the insulation occurs during a rest period after a voltage application. Furthermore, as given in Figs. 2 and 3 the rest period demanded is approximately 2 min. although influenced somewhat by the value of the initial voltage stress.

Mr. Crago has claimed that the insulation after being stressed, returns not to the original value nor to a poorer condition but to a random point, which if I understand him correctly may be even better than the original. I can merely say that we have never observed that the strength of insulation when once subjected to high-voltage stress has returned to a value better or even as good as the original when such strength is estimated by tests involving thermal considerations, except in cases where the material has specifically been given a poor drying and oil-treating process. Here, the results have obviously involved factors such as a further drying-out process, and the like, whose effect has overshadowed the effect of the applied voltage.

Mr. Crago has objected to the conclusions of this paper on the ground that the results are based on tests involving wide variations which he calculated as amounting in some cases to as much as 50 per cent from the mean. He cites researches to support his contention using oil as the insulation investigated and draws conclusions based on the data illustrated in his Figs. 4 and 5. And yet the results upon which his conclusions are based show such wide variations that it is surprising that they should be submitted as scientific data. Thus he stated that the average relation of maximum to minimum of the 100 per cent points in the data which I have submitted is as 6.3 to 1. The relation existing for the corresponding values of his research are as 33 to

1 for Fig. 4 and as 118 to 1 for Fig. 5, an average ratio of maximum to minimum of 75.5 to 1. Stated otherwise, from Mr. Crago's calculations of the variations in the data which I have submitted the deviations for the fibrous materials investigated ranges from as low as 20 per cent of the mean to values as high 185 per cent of the mean. In Mr. Crago's work he states that the variations of his Fig. 4 range from 8 per cent to 250 per cent of the mean value. For his Fig. 5, a study will show that the values range from about 2 per cent up to approximately 297 per cent of the mean value. Obviously, the factors involved in Mr. Crago's work have not been sufficiently controlled and his results are condemned by his own contentions.

But suppose we consider Mr. Crago's results further. Why should his data suffer such a wide variation? Mr. Crago bases his experiments upon a time-voltage relation in oil. A study of pure liquid dielectrics and clean, dry oil in particular will reveal the fact that although the time lag is more pronounced than in air and other gaseous dielectrics, yet in no way is it comparable to that which has been found by Mr. Crago. It is only in the case of wet oil or oil containing contaminating dust or fibers that such a marked time-voltage relation can exist. Thus obviously what Mr. Crago is measuring is not the dielectric strength of the oil and therefore not the effect of voltage upon oil but rather the time factor needed to line up these contaminating materials in the 0.1-in. test gap. Thus the time factor involved will entirely depend upon the chance arrangement of these materials at the time of the voltage application together with the resistance which they offer to being sucked into the dielectric field. This explanation gives a reason why Mr. Crago should get two entirely differently shaped curves when he uses 30 kv. as compared to 27 kv. in his experiments. The 30 kv. will rupture, he finds, in 71.7 seconds as opposed to 326 seconds when 27 kv. is used. The lower voltage should obviously take longer to line up the fibres, dust particles, etc., in the test gap. This, however, is not the whole story. In his Fig. 4 the minimum time to puncture is 8 per cent of the 100 per cent time value or 5 sec. In Fig. 5 the minimum time to puncture is 2 per cent of the 100 per cent time value or about 6.5 seconds. Unless the experiment was very carefully controlled, this means that the oil broke down almost immediately when the full voltage was impressed across the gap. Such a breakdown could be explained by the chance "bridge" arrangement of a contamination in the gap at the moment of voltage application. One would not expect under these conditions that the number of repetitions of stress times the time of each repetition to break down would be constant. Rather would one expect that with high voltage and therefore a very short time of repeated voltage application, the product of the factors mentioned might possibly be greater than the original continuously applied (100 per cent) value, since in this case the breakdown would almost entirely depend upon the chance arrangement of a conducting bridge across the test gap at the time the voltage was impressed. With lower voltages and longer time for the repeated voltage application, obviously the second factor, the sucking of the contaminating material into the field would play a much larger part. The product of $R \times T$ might even be smaller than the original 100 per cent time value. This is because of the fact that although the importance of the "sucking actions" of the field has not been diminished to any great extent, nevertheless the possibility of the chance formation of a bridge has been materially increased by breaking the voltage application up into steps and the stirring up of the oil between each stress application. I can thoroughly agree with Mr. Crago that under the conditions of his experiments, he could obtain almost any law by the conditions of the test used.

The case of a 33-kv. cable has been cited by Mr. Halperin in which the average time a section withstood the second and third test was greater than the time it withstood the first. It must be remembered that in cable work failure may be due to a cause entirely foreign to the phenomenon investigated in this paper. For example, cable engineers recognize that a fundamental problem, in the manufacture of their product is the preparation and impregnation of the insulation in order to secure thorough drying and the absence of voids. When a cable fails prematurely it is generally assumed poor, not because of the cumulative effect of voltage, but because of poor treatment, drying and other mechanical factors in its manufacture. Thus in the case of Mr. Halperin's 33-kv. cable, is it not possible that the first failure, the second failure, etc., can be traced directly to some such cause? The removal of each successive section ought therefore to lead to higher and higher breakdown stress until only that insulation is left which contains a minimum of mechanically weak spots and thus allows the manifestation of the deteriorating effects due to the applied voltage. In the experiments of this paper, the use of a small vacuum-dried and well impregnated test specimen together with parallel-plane electrodes has prevented all such treating phenomena from being of major value and has thus allowed the effect of each voltage application an important place in the ultimate breakdown.

Corona in Oil

BY A. C. CRAGO*
Non-member

and

J. K. HODNETTE*
Non-member

Synopsis.—Experiments were made to determine certain effects of high local voltage stresses in transformer oil. The resistivity of the oil was measured by a special method immediately following a period of voltage stress. The results were:

1. A greatly reduced resistivity when the stressing voltage was greater than that producing visible corona.

2. A gradual increase in resistivity following removal of stress.

The "rapidly applied" breakdown voltage was found for samples of oil which had been previously subjected to high voltage stresses. The dielectric strength varied in a manner similar to the resistivity, but showed an actual improvement in dielectric strength when the oil was given a rest period of 15 minutes.

Definite conclusions are given at the end of the paper.

* * * * *

THE recent increasing investigation of the mechanism of conduction and breakdown in dielectrics makes any additional data bearing on this subject worth while[1]. This paper discusses certain effects on electrical, physical and chemical properties of transformer oil when subjected to high local voltage stresses, dealing chiefly with certain temporary changes in conductivity and dielectric strength resulting from this treatment.

In the latter part of 1923, Professor H. B. Smith of Worcester Polytechnic Institute raised the question of the possibility of the temporary lowering of dielectric strength of oil due to high local voltage stresses, such as might occur at sharp corners in a transformer, although visible corona might not be present. Investigations were undertaken to determine this effect at potentials both below and above corona voltage.

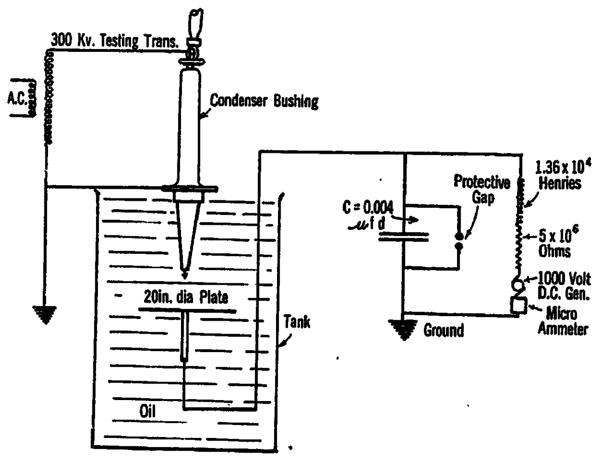

FIG. 1—APPARATUS FOR PRODUCING CORONA AND MEASURING SERIES CONDUCTIVITY

RESISTANCE MEASUREMENTS

A needle gap was used as a source of the high-voltage gradients. This gap consisted of a sharpened 0.05 in. brass rod spaced 12 in. from a ground plate. It gave visible corona at 55 kv., r. m. s.

It was decided to try the resistivity of the oil as an indicator of its quality. It seemed probable that any reduction in the dielectric strength of oil would be accompanied by a reduced resistivity. Various methods of measurement were tried in an effort to find one suitable. A microammeter with a sensitivity of 10^{-7} amperes per scale division was placed in the circuit in series with the high voltage line (see Fig. 1) and properly protected, the 60-cycle alternating current passing through a condenser to ground and the direct-current passing through a high inductance and the meter. A direct-current bias of 1000 volts was used, and the direct-current across the needle gap measured. The sensitivity of the meter was not enough for quantitative results, but deflections were found and increased with the voltage. No effect was noted at potentials lower than that producing visible corona.

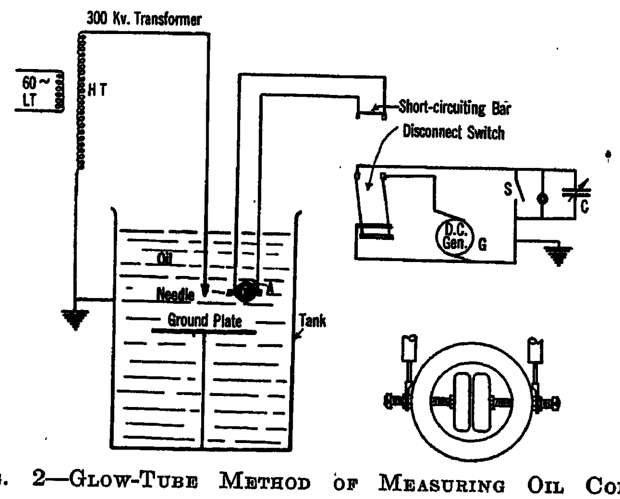

FIG. 2—GLOW-TUBE METHOD OF MEASURING OIL CONDUCTIVITY

Fig. 2A is a detailed sketch of the electrodes used in measuring conductivity

Attempts to measure conductivity between a pair of electrodes (Fig. 2) were more successful. These electrodes were brass disks with rounded corners. They were 1½ in. in diameter, and ⅜ in. thick, spaced 0.10 in. apart. The supporting ring was made of hard rubber, as were the tubes carrying the conductors to the electrodes. The assembled gap was suspended in the oil near the needle with the faces of the electrodes

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 9-12, 1925.

in the same vertical plane with it, and at approximately the same level as its point.

The conductivity of the oil was found by measuring the current flowing when 1000 volts d-c. was applied across the gap. This current was too small to be measured by available galvanometers. A novel type of meter was suggested by Doctor J. Slepian. This proved to be satisfactory for the service required. The circuit for it is shown in Fig. 2. It consists of a condenser C in series with a 1000 volt generator G and the measuring gap. This condenser is shunted by a neon glow tube and a switch S.

When switch D is closed and the generator is running, a small current passes across the gap, through the shunting switch and to ground. To measure this current, the switch S is opened, and the time required for the condenser to charge up to the glow voltage of the tube is measured with a stop-watch. The tube glows momentarily. The elapsed time is recorded. This operation is repeated as often as desired.

The approximate conductivity is found as follows: The generator was excited to give 1165 volts at the terminals. The glow voltage of the tube is 325 volts. The exact equation for the resistance, assuming it constant is:

$$r = \frac{t}{c} \cdot \frac{1}{\log_e \left(\dfrac{E_g}{E_g - E_t}\right)}$$

where

E_g is the generator voltage

E_t is the glow voltage of the tube

r is the resistance of the oil across the gap

C is the capacity of condenser C in farads

t is elapsed time in seconds.

As a first approximation, when E_t is small compared to E_g, the current equation is,

$$\text{Average current} = \frac{\text{final condenser volts} \times \text{capacity}}{\text{time}}$$

$$i = E_t \frac{C}{t} \text{ and}$$

$$r = \frac{\text{average gap voltage}}{\text{average current}}$$

$$r = \frac{E_g - 1/2 E_t}{i} = \frac{E_g - 1/2 E_t}{E_t} \cdot \frac{t}{C}$$

but $E_g - 1/2 E_t = 1165 - 162.5 = 1002.5$ volts. Using 1000 volts the resistance is,

$$\frac{1000}{325} \cdot \frac{t}{C}$$

This differs from the exact equation results by 1.1 per cent. For a capacity of 0.000115 microfarads and a time of one second, the resistance would be approximately 2.67×10^{10} ohms. Converting this to resistivity with the assumption that Ohm's law holds, the resistivity per inch cube with the above conditions would be,

$$\frac{(1.5)^2}{4 \times 0.1} \pi \times 2.67 \times 10^{10} = 4.73 \times 10^{11} \text{ ohms.}$$

This is resistance measured in one second. Sixty seconds seemed to be about the limit of time for good results. This corresponds to a resistivity of 2.8×10^{13} ohms per inch cube. This method was simple and dependable, and gave the required degree of accuracy.

In operation, the disconnect switch (Fig. 2) was opened. The desired stressing voltage was impressed on the needle-gap for a period of time. Immediately after removing this voltage, switch D was closed, and measurements of resistivity taken as indicated above.

Dielectric Tests

The actual dielectric strength of oil subjected to high local stresses was tested with a Westinghouse standard test-cup (sharp-cornered disk electrodes, one inch in diameter, spaced 0.10 inches apart.)

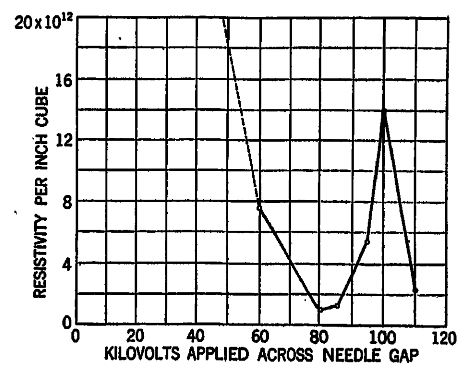

Fig. 3—Variation of Resistivity with Stressing Voltage

Resistivity measured with 1000 volts across 1/10 inch gap

A sample of oil was drawn from the vicinity of the needle immediately after the stressing voltage was removed, and tested for breakdown, an average of five or more breakdowns being used.

Experimental Results

A series of tests was made on Wemco A transformer oil. This oil had been used for miscellaneous testing purposes previous to these tests, but still had a dielectric strength of about 33-kv -r. m. s., which is an indication of good oil.

Fig. 3 shows the variation of resistivity with the stressing voltage, the voltage being applied for 15 min. Note the dip at 80 kv. and the lack of effects below 55 kv., the corona potential.

Fig. 4 indicates the way in which the resistance varies with time after the stressing voltage is removed. The shapes of these curves vary considerably with individual tests. However, they all show: 1. That the low resistance is only temporary: 2. that a resistance meas-

ured about a minute after stressing voltage is removed, is about as accurate as a resistance measured during stressing, since in general, the time-resistance curve approaches the zero-time axis nearly at right angles to it.

Fig. 5 shows the extent of the affected region around the needle. The curve shows that the effect of corona is very decided to a distance of one foot under the conditions of test. Since the effects observed last over

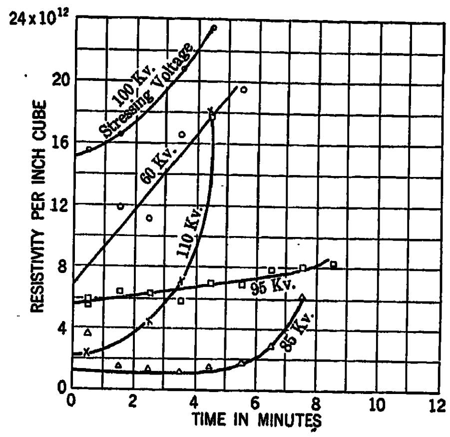

FIG. 4—VARIATION OF RESISTIVITY WITH TIME AFTER STRESSING VOLTAGE IS DISCONNECTED

a period of minutes, it would be very unlikely for them to be highly localized, as there would be a spreading due to diffusion.

Fig. 6 indicates the effect of time of application of the high gradient on the dielectric strength of the oil, showing that most of the lowering of the dielectric strength occurs very quickly.

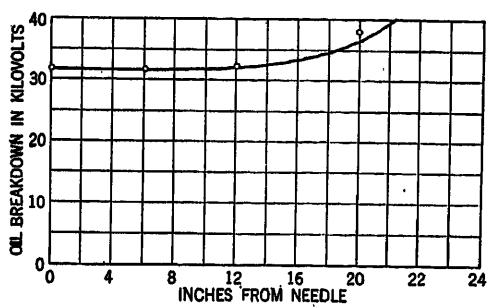

FIG. 5—EXTENT OF THE AFFECTED REGION IN THE TANK

The variation of dielectric strength with stressing voltage is shown in Fig. 7. The effects are not noticeable at voltages which do not produce visible corona, but become pronounced at higher voltages. The hump in the curve at 100 kv. is discussed later.

The following table brings out very emphatically the temporary nature of the corona effects. For each of the three tests, the strength of a sample was measured in the test cup. Then a stressing voltage was applied to the needle gap for the indicated time. Two samples were then taken from the region near the needle. One was given a dielectric test immediately. The other was tested after 15 min. In each test, the lowering of the dielectric strength disappears entirely, and an actual improvement occurs.

Initial breakdown	Stressing kv. r. m. s.	Time applied	Resulting breakdown	Breakdown after 15 min.
32.8	120	15 min.	29.4	39.6
29.6	100	15 min.	26.4	30.8
29.6	100	1 hr.	25.0	30.2

Attempts to find permanent effects on the oil due to the stressing voltage were unsuccessful. The conductivity of samples taken before and after stressing, was measured accurately several days afterwards.

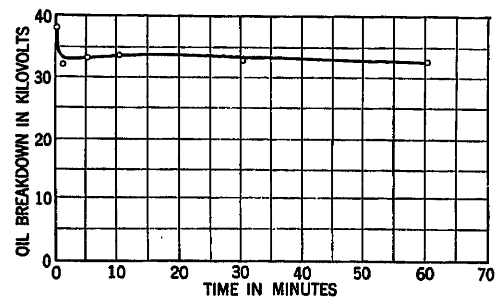

FIG. 6—THE EFFECT OF DURATION OF STRESS ON THE DIELECTRIC STRENGTH OF TRANSFORMER OIL

100 kv. applied on needle

The percentage of unsaturates was also determined. The only variations in these quantities were such as could be accounted for by ordinary experimental error. The water content seemed to gradually decrease as the tests progressed, but varied with the number of tests rather than as any function of the stressing voltage.

ACCURACY OF RESULTS

It is not the desire of the writers to give an impression of great accuracy in the quantitative results obtained. As in most tests with dielectrics, the variations were wide. To a certain extent, tests used in producing the

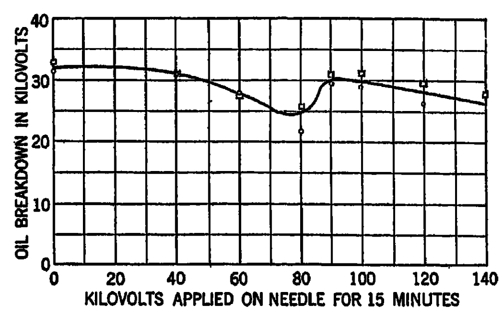

FIG. 7—THE EFFECT OF HIGH LOCAL VOLTAGE STRESSES ON THE DIELECTRIC STRENGTH OF TRANSFORMER OIL

curves are selected tests. However, the tendencies and shapes of the curves are definite and are found in practically all of the tests made. It is this rather than the quantitative results which should be emphasized.

DISCUSSION

Certain parallels may be drawn between the effects of corona in oil and the phenomena of ionization in air.

The conductivity in both cases must result from the presence of charges capable of moving. The normal conductivity in air is due to a very few ionized particles which are always present. The normal conductivity of oil might be due either to the transfer of electrons from one metal electrode to the other across conducting particles, or to the presence of positively and negatively charged ions in the oil or of the oil, migrating due to the electric field. As the voltage stress becomes very great, molecules may be torn apart into plus and minus ions. Due to the relatively high viscosity, and the high molecular weights, the diffusion rate, and consequently the rate of recombination of the charged particles and their rate of migration in an electric field, is very slow. This would account for the persistance over a period of minutes of the effects noted.

As to the effects on the dielectric strength: In air, the dielectric strength is hardly affected unless the ionization is intense enough to produce space charge and disturb the voltage gradient. In oil, the ionization necessary to produce a space charge will be much less since the mobility of the ions is so low. No attempt has been made up to the present to determine mathematically the possibility of space charge with the degree of ionization found in the experimental results. It should be possible to do this, and it will be attempted.

The "hump" mentioned in the curves of kv. vs. resistivity and kv. vs. dielectric strength (Fig 3 and Fig 7) was unexpected. When the first curve of the dielectric strength was determined, a smooth curve was drawn with a downward curvature, assuming the 100-kv. value as high and the 80-kv. value as low. However, when the run was repeated several days later, a curve identical to the previous one was obtained. The same hump was later found to exist in the resistance values.

One plausible explanation of this hump, and one which is presented because no better one appears, follows.

Tests made with oil of low water content did not show the decided dip at 80-kv. It is possible that the size of water particles are such that they migrate rather rapidly at the 80-kv. value, so that they exist in the concentrated electric field in rather large numbers, thus affecting the breakdown. At the 100-kv. point, the migration may be so rapid near the needle that the water content is reduced. Unfortunately, the water content was not determined for the tests referred to, and the oil was later destroyed.

Conclusions

The above tests allow certain definite conclusions to be drawn:

1. That, with the type of needle gap used, no appreciable effect on the electrical characteristics of the oil occurs below the point where visible corona starts.

2. That above this potential, a phenomenon similar in some respects to ionization in air, occurs with oil.

3. That with the sample of oil used, the resistivity and breakdown do not continually decrease as the stressing voltage is increased.

4. That the effects noted are produced in a very few minutes and are temporary in nature.

5. That, since the effects described in this paper all occur only at voltage stresses which produce visible corona, they do not exist in properly designed commercial apparatus.

Discussion

J. B. Whitehead: It has been known for a long time that liquid dielectrics of even the best type are subject to a moderate electrolytic dissociation, which means that the ultimate parts of the dielectric are at all times, some of them, in a state of separation as regards their component charges—not many, but some of them.

The laws of conduction in liquid dielectrics (and all liquids have some conduction) are in every way consistent with the theory of dissociation that has been built up for gases. It is possible to ionize liquid dielectrics. It is possible to subject them to a regular ionizing agency, and it is possible to measure the rate of recombination of the ions so formed. We have plenty of evidence to prove that liquid dielectrics may be ionized.

So I think it was a great pity that Messrs. Crago and Hodnette should have gone to such great trouble to show that under certain circumstances oil may have an appreciable conductivity. The fact has long been known.

Also, I would like to ask them whether they considered the use of the corona-tube as a method for investigating conductivity. It appears to me that if they had used a small tube and a small wire, the tube being filled with many holes, and immediately outside of it an insulated electrode, that they would have had not nearly the trouble in finding a method for measuring the current caused by the conductivity of oil.

M. F. Skinker: While Mr. Crago and Mr. Hodnette were interested primarily in securing an answer to an engineering problem, it is to be regretted that they did not add a few refinements which would have insured freedom from errror.

Let us see what is required for an accurate scientific investigation and try to outline what should have been done in these experiments.

It is necessary that all conceivable variable factors be kept constant except those which you are attempting to correlate by the investigation. It sometimes happens that a factor cannot be kept constant and a correction must be made in the final result. This, however, should only be done as a last resort.

In the experiments on corona in oil, we have to consider the electrical measuring devices, the oil, the electrodes, and the oil in contact with the electrodes. Fortunately, nearly every one takes care to see that the electrical measurements have a high degree of accuracy.

With regard to the oil, the authors only imply that it was clean and dry by saying the dielectric strength indicated good oil. Why did they not attempt to purify the oil first? I might suggest that if some fine pieces of metallic sodium, or a little aluminum chloride were mixed in the oil and then filtered, this would have removed *all* the water and almost all other impurities.

By an appropriate cover for the testing vessel impurities could have been kept out during the experiment.

Care must be used with parallel plate electrodes which are close together for the electric stress may well be high enough to alter the spacing by several per cent.

It should also be well known that catalytic action of the brass or common metals in the oil can materially affect the results of any experiment. The simplest and most effective way of preventing this would have been to gold-plate all metallic surfaces in contact with the oil, as done by Lee and Kurrelmeyer in their experiments on gases.

With these simple precautions the authors could have collected data that was really worthy of definite conclusions.

The test of accurate data is in the following question: "Can this experiment be reproduced in another laboratory and exactly the same results obtained?"

The test of properly recorded work is in the question: "Have all the conditions under which this experiment was performed been recorded, so that others may draw their own conclusions from the data?"

If these two questions cannot be answered in the affirmative, the experiment is hardly worth publishing.

I make this plea for more scientific work because I believe it is only in this way that we may eventually solve the insulation problems.

J. A. Duncan: There are two significant statements in the paper by Messrs. Crago and Hodnette, namely: "This oil had been used for miscellaneous testing purposes previous to these tests, but still had a dielectric strength of about 33-kv. r. m. s., which is an indication of good oil," and, "Unfortunately, the water content was not determined for the tests referred to, and the oil was later destroyed."

F. W. Peek showed in 1915 that a sample of dry transil oil had a dielectric strength of 62.3 kv., and that the addition of moisture to the extent of one part in twenty thousand caused a 50 per cent decrease in dielectric strength, while twenty times this amount of moisture only reduced the dielectric strength sixty per cent. This certainly shows that it is the first trace of moisture which causes the greatest decrease in strength and indicates the importance of the removal of this trace from oil which is to be used for any scientific purpose. Of course, I do not know how "Wemco" oil compares with ordinary transil oil, but whatever the relation may be, it is safe to say that comparison would probably be more favorable to a recently and carefully dried sample of Wemco than to one with a long and unknown past.

I should like to suggest with Drager in the very paper cited by the authors that it may be the presence of moisture which provides the conducting particles mentioned by the authors in the first paragraph on the fourth page of the paper. On the other hand, attention was called to the fact that "as the voltage stress becomes very great, molecules may be torn apart into plus and minus ions." Evidently they mean to consider the possibility of ions being formed by the actual disruption of the hydrocarbon chains into parts, each containing one or more carbon atoms, this in addition to those formed by the simple removal of an electron from the molecule. Long carbon chains such as we have to deal with here are so easily broken up by the action of heat that it does seem reasonable to suppose that they might also be broken up by the action of the electric field. If such ionization does take place, and Dr. Whitehead has just told us that some ionization is known to occur, it could be identified by its effects on certain properties of the oil such as the temperatures at which various components of the oil would distill off from the remainder. When these long molecular chains do break it is not generally at the center. We have the possibility of ions containing anywhere from one carbon atom to one less than the normal number in the original oil molecule. The products of recombination will then vary anywhere from neutral molecules of two carbon atoms, which would be ethane gas, to one of two less than twice the normal number of carbon atoms. There, abnormally long molecules might again ionize and some of the ions recombine to form still longer and therefore heavier molecules. Such breaking up of the molecules and recombination into molecules both lighter and heavier than normal is known to take place in oils when heated to sufficiently high temperatures. In fact, this action is the very basis of one of our well-known commercial processes for the manufacture of gasoline from crude oils.

I am sorry that the experiment on corona in oils was not continued far enough and long enough to give these recombinations a chance to occur in detectable amounts. The products are easily detected when present. The abnormally heavy ones will settle to the bottom of the oil as a sludge. The abnormally light components will distill off even at near room temperatures and are detectable by various means. There is one method of detecting the formation of the gases which although known long before my time was discovered independently by me in a very striking manner. It was by the simple process of bringing a lighted gas jet a little too near the mouth of a flask half filled with transil oil which had just been heated to slightly above the cracking point. In this case I am forced to join in the conclusion that unfortunately that sample of oil is no longer available for further tests.

One of the conclusions is "That the effects noted are produced in a very few minutes and are temporary in nature," and a curve, Fig. 7, is drawn which shows that the dielectric strength passes through a cycle. In this connection it seems well to emphasize the fact, and this applies not only to the experiment under discussion but to all others as well, that because one property of a substance passes through a cycle all other properties pass through a cycle and return to their original value. One could name an endless number of cases in which this is not so, and Dr. Hans Staeger mentions one which is particularly applicable here.[1] Under the influence of metals as catalyst, the acidity of an oil, for example, may pass through repeated cycles, while the sludge formation and contamination of the oil proceeds cumulatively with the total time.

In that connection, I only want to refer to the conclusions which we have considered most important, and see whether they have not been drawn from the data presented. Probably the most important is a negative conclusion: "That since the effects described in this paper all occur only at voltage stresses which produce visible corona, they do not exist in properly designed commercial apparatus."

This was the main object of the tests and was, I believe, proved rather definitely.

The other conclusions you have already heard and they are in the paper. We feel that they are not extremely definite conclusions, but have been definitely based on the work, the results of which have been given.

I might say in connection with this catalytic action of brass electrodes that Mr. J. E. Shrader of the Westinghouse Company several years ago made a large number of tests on conductivity of oil using gold, copper, silver and brass electrodes, with results so nearly identical that differences were within the limits of experimental error.

I wish to say in conclusion that I do feel that the paper presents data which should be useful as a guide for future work, that we get these effects at rather large distances from the electrodes, and that they do not occur below corona voltages.

A. C. Crago: I realize that those discussing our paper, "Corona in Oil," have been at a disadvantage because the paper was printed within the last week. I believe that the scope of the tests has been somewhat misunderstood. For that reason I wish to give in more detail the reasons the tests were made and the

1. *Schweitz Elektrotechniser Verein Bulletin*, March 1924.

conditions under which they were conducted, reading two paragraphs from the paper.

The tests as they were originally planned were intended to discover whether there were deteriorating effects in oil below a voltage which would give visible corona with certain type of electrodes in the oil. We, therefore, first made an attempt to find these effects. This was naturally an engineering problem, which we expected to solve in a short time. Since we did not find any effects below corona voltage, we continued the work further with higher voltages. The conditions were not greatly changed in extending the work.

Quoting the paper: "In the latter part of 1923, Professor H. B. Smith of Worcester Polytechnic Institute raised the question of the possibility of the temporary lowering of dielectric strength of oil due to high local voltage stresses, such as might occur at sharp corners in a transformer, although visible corona might not be present. Investigations were undertaken to determine this effect at potentials both below and above corona voltage." And:

"It is not the desire of the writers to give an impression of great accuracy in the quantitative results obtained. As in most cases with dielectrics, the variations were wide. To a certain extent, tests used in producing the curves are selected tests. However, the tendencies and shapes of the curves are definite and are found in practically all of the tests made. It is this rather than the quantitative results which should be emphasized."

Let us take the discussions in the order in which they were presented. Professor Whitehead has expressed regret that we have gone to the trouble to show that there is electrical conductivity in oil, and points out that this conductivity is influenced by radioactive or other radiating sources. If the sole purpose of the paper had been to demonstrate the existence of these two well-known phenomena, we agree that the paper would be without value. I believe that Professor Whitehead has misunderstood the purpose of the paper, which was not to show that there is a conductivity, but more to show the effects of a particular source of ionization, which may be found in practise. The use of the "corona tube" was not considered.

Mr. Skinker asks us two questions, which I will quote: "Can this experiment be reproduced in another laboratory and *exactly* the same results produced?" Certainly and emphatically no. The word "exactly" cannot be used properly with respect to experimental results.

"Have *all* the conditions under which this experiment was performed been recorded, so that others may draw their own conclusions from the data?" *All* conditions have, of course, not been recorded. This is a physical impossibility. Whether conditions *necessary for the conclusions drawn* have been given must be judged by those who read the paper; not by the authors.

I might say in connection with the catalytic action of brass electrodes, mentioned by Mr. Skinker, that Mr. J. E. Shrader of the Westinghouse Research Laboratory points out in an unpublished paper that the conductivity of oil using gold, silver, brass, copper and nickel electrodes show no greater differences than the experimental errors.

Mr. Duncan states that "dry transil oil had a dielectric strength of 62.3 kv." omitting to state; 1. whether the value is r. m. s. or peak; 2. the shape and spacing of electrodes. This figure thus cannot be compared with that of 33 kv. r. m. s. given for Wemco "*A*" tested in the present Westinghouse standard-test cup. Most of Mr. Duncan's discussion, although raising interesting possibilities and explanations of certain phenomena, is outside the scope of the paper and does not affect the conclusions drawn.

Mechanical Stresses in Busbar Supports During Short Circuits

BY O. R. SCHURIG*
Member, A. I. E. E.
and
M. F. SAYRE†
Non-member

Synopsis.—*With the increased magnitudes of short-circuit current obtained in modern busbar circuits, it becomes a matter of great importance to determine the mechanical stresses imposed on busbar supports during short circuits. The stresses are due to the electromagnetic force produced by the current flowing in adjacent conductors in the bus structure. When usefully applied, the electromagnetic force propels electric motors, or sends the pointer of a voltmeter along the scale; but the same electromagnetic force when destructively applied may bring about rupture of bus supports, distortion of conductors or even shut-down of stations. In the days when currents were low, or when large spacings between conductors were maintained, a support sufficiently strong to carry the weight of the conductors often was sufficient to withstand the stresses, due to the electromagnetic forces, but with large short-circuit currents and with reduced spacing between conductors, a more accurate knowledge of the stresses due to the electromagnetic forces is absolutely essential to the designer.*

The electromagnetic force has been the subject of investigations in the past not only for the case of busbars but also for transformers, current-limiting reactors, and disconnecting switches. In the case of busbars, as well as in some of the other cases mentioned, the stresses resulting from the action of the forces applied are very materially affected by the mechanical vibrations produced. The vibrations of the busbar for example have been carefully analyzed by Biermanns‡ who showed that a busbar rigidly supported could be considered as a single-element vibratory system similar to a system comprising a mass suspended from an elastic spring. In the customary busbar structures, however, the supports also are appreciably resilient, so that the busbar-insulator structure must be regarded as a system having two vibratory elements joined together, i. e., a composite structure resembling, for instance, the system comprising a turbine rotor keyed to a flexible shaft, the shaft bearings being attached to an elastic base.

Hence, the determination of short-circuit stresses in busbar supports involves a study of the transient vibrations occurring in the busbar structure which is essentially a damped mechanical system composed of two vibratory elements and having two interrelated natural frequencies, the system being impelled during short circuits by a decreasing electromagnetic force having a unidirectional component and two harmonic components, one at current frequency and another at twice the current frequency. The electromagnetic force upon the busbar itself is given by a well-known formula involving only the current magnitude, the conductor spacing, and the length of busbar span. This force, however, acts upon the busbar rather than on the insulator, and the insulator is stressed only indirectly, after a time lag, as a result of the bending of the busbar. Therefore, the likelihood of failure of the support hinges not only on the initial electromagnetic force but also on the rate of decrement of that force and upon the vibratory characteristics of the busbar-insulator system.

This paper gives an analytical method of maximum stress calculation based on all of the factors mentioned, for the basic case of a bus structure having long, straight, uniform, parallel busbars with equidistant, rigidly mounted supports of uniform characteristics. The method of calculation is a general one applicable to all cases of elastic busbars intermittently supported, irrespective of whether the conductors are placed face-on or edge-on with respect to the supports and irrespective of whether the supports themselves are stressed in bending tension or compression.

The actual bus structure is, of course, often quite complex involving, for instance, the effects of tap connections, bends unequal spans, non-uniform current division. Special consideration may have to be given to these factors in many cases. Moreover, in structures with long spans where the forces so act as to cause relatively large busbar deflections, the tension set up along the busbar may cause large secondary bending stresses in the supports, which stresses act in a direction at right angles to the stresses covered by the formulas developed in the paper. For this type of structure, the secondary stresses have often proved to be the controlling factors in design.

The method of calculation presented here differs from those employed in the past, since the calculations used heretofore have only partially taken into account, or totally neglected, the oscillatory characteristics of busbars and of supports.

Since the natural frequencies of busbar structures range from, say, 10 to 300 cycles per second, mechanical resonance is within common possibility in buses of 25-cycle circuits as well as in buses of 60-cycle circuits. While not all cases of resonance give rise to stresses greatly in excess of those at non-resonance, resonance in some cases multiplies the stresses five or even ten times. It will often be possible by proper methods of design so to change the natural frequencies as to avoid the cases of resonance giving extra heavy stresses.

The analytical equations developed for stress calculation are inherently complex, but their results may be expressed with sufficient accuracy in the form of curves, each group of curves covering a wide range of cases. A representative curve is given in this paper in Fig. 1. The development and use of any practical set of working curves depends in a large measure upon a detailed knowledge of the mechanical characteristics of the structural elements involved.

The following paper contains a discussion of the factors affecting support stresses and an outline of the practical procedure for maximum support stress calculations, including illustrative examples. The appendix contains the development of the equations used in the calculations.

The equations have been confirmed by tests on miniature and on full scale structures. Typical test results are presented.

INTRODUCTION

THE design of busbar layouts calls for the determination of the stresses occurring in the bus supports during short circuits, because the stresses in question may become sufficiently large to weaken, or even rupture, the supports. Moreover, an understanding of the factors affecting the stresses will often permit the designer to modify the layout so as to reduce the stresses, and thus save material or prevent failure. Hence investigations have been directed to-

† Assistant Professor of Applied Mechanics, Union College, Schenectady, N. Y.

‡Bibliography No. 6.

wards the calculation of support stresses due to electromagnetic forces caused by short-circuit currents in busbar structures.

The investigations involved are:

Tests to determine the mechanical characteristice of busbar structures; measurements of the support stresses due to short-circuit currents in assembled bus structures; an analysis of the electromagnetic forces during short circuits; an analysis of the vibrations of bus structures; establishing a practical formula for approximate calculations of maximum stresses.

The progress made in the investigation is, in a large measure, due to D. Basch, for his helpful counsel and practical suggestions; C. W. Frick, for effectively conducting tests and making calculations; and L. F. Woodruff for his valuable cooperation in the experimental and theoretical studies in the early part of the work.

Definitions

The electromagnetic force, as considered within the scope of this paper, is the mechanical push or pull which is caused by the short-circuit current and its magnetic field, and which is exerted on the busbars; *i. e.*, it is the force tending to displace the busbars from their normal position.

The support stress is the mechanical reaction of the support, the reaction being due to the elastic restoring forces set up in the support when deflected; *i. e.*, the tendency of the support to push back towards its position of zero deflection in so far as the tendency is caused entirely by the resilience stored in the support. Hence the stress in a support is a direct measure of its approach to failure. For an elastic support, deflected within its elastic limit, the stress is proportional to the deflection regardless of whether the support is at rest or in motion.

Vibrations of Bus Structure Must Be Considered

While it has been fairly well known how to predict the *electromagnetic forces* acting on busbars during short circuits, the problem of determining the *stresses imposed on the bus supports*, as a result of the electromagnetic forces, has not been fully understood, as indicated by the fact that calculations have frequently been made on the assumption that the maximum stress imposed on a bus support is equal to the maximum electromagnetic force calculated for one span of the busbar. Actually, the support stress is ordinarily not of the same magnitude as the electromagnetic force per busbar span, on account of the vibratory characteristics of the busbars and of the supports. The peak stress on the supports may be far above or well below the maximum value of the electromagnetic force per span, depending on the natural frequencies of the busbar structure. Hence, stress calculations employing simply the peak value of electromagnetic force, or any other value of electromagnetic force, without proper allowance for the motional characteristics of the bus structure can ordinarily be expected to give but a rough approximation to the correct values. Since the methods of stress calculation employed in the past have only partially taken into account, or totally ignored, the oscillatory character of busbars and of supports, a method of calculation which includes the effects of the mechanical oscillations in the structure has been developed.

Object

It is the object of this paper to present

1. A brief review of the factors affecting support stresses.
2. An outline of the basis for stress calculations.
3. A practical procedure for approximate support stress calculations.

Review of Principal Factors Affecting Support Stresses

In order to arrive at a basis for stress calculations, the factors affecting the stresses must be considered. The principal ones are: The electromagnetic force, the current decrement, the mechanical characteristics of busbar structures, their motional resistance, and mechanical resonance.

The Short-Circuit Current and the Electromagnetic Force

The electromagnetic force acting on a pair of parallel, straight, current-carrying conductors (in the absence of magnetic bodies), is proportional to the product of the currents. If, for example, the currents are symmetrical sine currents of constant effective values, the force will consist of a harmonic (alternating), component at double the current frequency superposed on a constant, (or direct) force component, the amplitude of the harmonic component being equal to the magnitude of the direct component.

The maximum forces will result from short-circuit currents whose waves are displaced from the zero value of current. For example, in the case of a *two-wire short circuit* giving an initial sine-wave current fully displaced, *i. e.*, having the largest value of direct component of current, the electromagnetic force is composed of three parts: A harmonic component at current frequency, a harmonic component at twice the current frequency, and a direct component (of constant value if the decrement is neglected). The relative amplitudes of the two harmonic force components are, as is well known,* 1.33 for the first harmonic component and 0.33 for the second harmonic component, if the direct component is equal to 1.0. The proportions given are not maintained throughout the short-circuit transient, because the current decrement does not affect all the force components equally, as is indicated by the fact that the first-harmonic force component vanishes completely, while the second-harmonic amplitude and

*Bibliography No. 19.

the direct component are reduced to finite sustained values of equal magnitudes. Since the maximum stresses are reached during, say, the first fifth of a second of the short circuit, the first harmonic component of electromagnetic force will always be a vital factor in stress calculations for displaced short-circuit currents.

The foregoing considerations indicate, at once, the importance of the direct component of the short-circuit current on the stresses. If we compare the electromagnetic forces and their components at the beginning of the short circuit (two-wire short circuits) in the two cases, *a*, for an undisplaced (symmetrical) sine-wave current, and *b*, for a fully displaced sine-wave current having the same peak value of alternating component as that in case *a*, we find, in accordance with Table I, neglecting the current decrements, that

1. The fully displaced current has an average value (or direct component) of electromagnetic force three times as great as that of the symmetrical current.
2. The peak value of the electromagnetic force for the totally displaced current is four times as large as that of the symmetrical current.
3. The symmetrical current has no first-harmonic component of electromagnetic force, while the totally displaced current has a first-harmonic component of electromagnetic force four times as large as the second-harmonic force component of either case.

In the case of *three-phase short-circuits,* the currents are not in phase, nor are the amounts of displacement the same for the three currents. Moreover, each conductor is acted upon at any instant by two electromagnetic forces, one from each of the other two conductors. Examination of typical three-phase short-circuit currents has indicated that the total electromagnetic force acting on any of the three conductors has direct, first-harmonic, and second-harmonic components similar in character to, but differing in relative magnitudes from, those of the two-wire short circuit. As a rule, however, the electromagnetic forces for two-wire short circuits in a given bus system are greater than those for three-phase short circuits, so that the stresses calculated for two-wire short circuits are generally the ones on which to base the design. In some cases of second-harmonic resonance (or near-resonance) consideration should be given to the three-phase short-circuit stresses.

TABLE I

Comparison of Electromagnetic-Force Components for Fully Displaced and for Symmetrical Short-Circuit Currents, for Two-Wire Short Circuit

The a-c. component of the fully displaced short-circuit current has the same amplitude as the symmetrical current. Wave-shape sinusoidal in both cases. Current decrement neglected.

Current	Components of electromagnetic force			Maximum Electromagnetic Force
	Direct component*	1st Harmonic	2nd Harmonic	
Symmetrical sine current..................	0.333	0	0.333	0.667
Totally displaced sine current.............	1.0	1.333	0.333	2.667

*Average value of total electromagnetic force.

THE CURRENT DECREMENT

The current decrement, as already mentioned, causes a reduction, with time, of each of the electromagnetic force components, each component having its own rate of decrement. Obviously, the decrements must be considered in stress calculations, particularly in view of the fact that the peak stress frequently does not occur until several cycles after the beginning of the short circuit.

THE MECHANICAL CHARACTERISTICS OF BUSBAR STRUCTURES

The relative magnitude of the electromagnetic force components discussed would be of little practical significance in the determination of maximum support stresses were it not for the resilient and oscillatory characteristics of the mechanical elements of bus structures. It is well known for instance, that, a hard-drawn copper busbar, when deflected through the customary range of amplitudes occurring in practise, has substantially elastic properties, and is capable of oscillatory motion when suddenly impelled by an external force, such as a short-circuit electromagnetic force. Thus a copper bus one-quarter inch thick by four inches wide, rigidly clamped to supports forty-eight inches apart, has a natural frequency of 16 cycles per second, when suddenly impelled in the direction at right angles to its faces. The plain 16-cycle motion will occur, for example, when a direct-current short circuit is suddenly applied to a pair of busses of the kind described, if the two bars are placed face to face. Likewise, when the current is suddenly switched off, the bars will tend to spring back to their normal positions, and similar vibrations at 16 cycles per second will be set up. The mechanical damping, which, in the presence of the magnetic field set up by the current, includes the damping due to eddy currents, will gradually reduce the amplitude of the free vibrations.

The important points to be emphasized by this elementary example are; 1, that the reaction of the supports against the bar—a force which for the case in question is proportional to the deflection of the bar, if elastic and deflected through small amplitudes—will be a pulsating reaction (or stress) varying harmonically with gradually diminishing amplitudes, although the suddenly applied electromagnetic force is of constant value; 2, that the maximum support stress will be reached roughly 0.03 sec. after the application of the electromagnetic force; 3, that the value of the maximum support stress for all supports but the terminal ones will materially exceed (by nearly 100 per cent) the electromagnetic force per busbar span; and 4, that stress pulsations will continue for a considerable time after the electromagnetic force is removed. The fourth point has no direct bearing on the maximum

support stress during short circuits, but is brought out to indicate the most decided difference between the support stress and the electromagnetic force as observed in this simplest of illustrations.

If instead of the direct-current short circuit, an alternating-current 60-cycle short-circuit is suddenly applied to the busbars under discussion, there will be not only the 16-cycle free vibrations at the beginning but also forced vibrations at 60-cycles if the initial current is displaced, and 120-cycle vibrations of much smaller (in this case negligible) amplitude, all oscillations being superposed upon a direct component of deflection, the latter corresponding to the direct component of electromagnetic force. To put it in other words, the support stress has a natural-frequency component not present in the electromagnetic force and two forced-frequency components of relative magnitudes which differ from the corresponding components of electromagnetic force because the busbar responds rather selectively to impressed forces of various frequencies, being most partial to vibrations near its natural frequency.

In the preceding simple illustration, the resilient and vibratory characteristics of the support have been totally left out of consideration by assuming the busbar rigidly clamped at its points of support. Actually, however, most bus supports are appreciably flexible in the sense that a force applied at the point of support of the busbar, as under short-circuit conditions, will materially deflect the support. Moreover, most supports possess sufficient resilience, if deflected within the range of safe deflections, to have oscillatory characteristics similar to those of busbar spans, as has been demonstrated by numerous tests. For example, a typical porcelain busbar support, tested without a busbar, had a natural frequency of 45 cycles per second, the frequency being measureably modified by the mass of the busbar when clamped to the support.

When busbars are mounted on flexible supports, in the customary manner, the motion of the busbar span, as well as the motion of the support, shows *two dominant natural frequencies* which occur in combination in each of the two structural members when electromagnetic forces are suddenly applied. Accordingly, the support stress at the beginning of a short circuit contains two natural-frequency components in addition to the forced-frequency components. Furthermore, the forced-frequency support-stress components are related to the corresponding electromagnetic-force components by a modulating factor involving *both* of the natural frequencies.

To summarize:—the support stress during short circuits is, as a rule, materially affected by two natural frequencies due to the flexible and resilient characteristics of the busbar spans and of the supports. In view of the two natural frequencies mentioned, bus supports respond selectively to impressed electromagnetic forces at different frequencies; hence, the magnitude of the electromagnetic force and its mode of variation with time are not usually representative of the magnitude and mode of variation of the support stresses. The peak stresses depend most decidedly upon the natural frequencies of the bus structure.

Damping Due to Motional Resistance of Elements of Busbar Structure

In view of the importance of the natural-frequency components of support stress, the effect of damping on their amplitudes must be considered. The damping is easily determined by test and is readily incorporated in the stress calculations. The tendency of some types of bus supports not to return completely to their original positions, after a given stress has been applied and removed, has been shown to affect the amount of damping during vibrations. As a result of the various types of mechanical construction employed in bus supports, the magnitude of the damping and its effect on the peak stress differ for different types of supports, as demonstrated by test data. While the amount of damping is sufficiently appreciable to require consideration in ordinary stress calculations, there is not enough present in the customary structures to prevent, in some cases of resonance, stresses several times as great as those occurring at non-resonance, under otherwise similar conditions.

In connection with the foregoing, attention is called to the case of bus supports which do not clamp the busbar, but merely guide it loosely, so that a sudden thrust upon the busbar may cause it to be slapped with considerable impact against one side of the guides. The slapping effect is not generally desirable because of possible excess stresses, and when present must be allowed for in calculations.

The conclusion is therefore reached that, in a great many cases, both the busbar span and the support may be regarded as substantially elastic bodies for stress calculations, but the mechanical damping during oscillatory motion must be properly taken into account. The natural frequencies, as well as the damping effect, are readily determined by tests and have been obtained for a variety of structural members, not only when tested separately but also when fully assembled as in practise.

Resonance

Resonance occurs when one of the electromagnetic-force components has a frequency equal to one of the natural frequencies of the bus structure. Since the natural frequencies of busbar structures range from, say, 10 to 300 cycles per second, resonance is within common possibility in buses of 25-cycle circuits as well as in busses of 60-cycle circuits. While not all cases of resonance give rise to stresses greatly in excess of those at nonresonance, the stresses may, in some cases, be multiplied five or even ten times, because the effect of resonance on the maximum stress depends not only on the damping due to motional resistance of the struct-

ural elements, but also, and to an even greater extent,—on the magnitude of the non-resonant natural frequency. It is best, of course, to avoid the cases of resonance causing extra-heavy stresses by suitable design of bus structures.

Basis for Stress Determinations

An exact calculation of stresses taking into account the particular values of all the variables involved in any one problem would be extremely laborious, even if at all feasible. On the other hand, a method of approximately estimating maximum stresses on the basis of selected conditions and average representative constants has been established and is presented in this paper. The results so obtained are sufficiently accurate to be applicable to a large number of cases and have been found to be in reasonably good agreement with stresses observed in tests. Obviously, it would be a lengthy and costly procedure to make tests for the purpose of observing the stresses under the large variety of conditions met in practice.

The technical analysis of test data and the application of theoretical considerations gave the following results:

1. An analytical procedure for determining the support stress and its components in terms of the electrical and mechanical factors involved.

2. A simple routine formula, which, with the aid of practical stress curves, gives the maximum support-stress. The curves are calculated by the method indicated in No. 1, and with the aid of experimentally observed constants.

The analytical procedure for stress determinations involves an analysis of the mechanical forces reacting against the impelling electromagnetic forces during the vibrations of busbar and of support. In the stress calculations presented here elastic busbars and elastic supports were assumed and the two natural frequencies of the busbar structure were taken into account as well as the motional damping and current decrement. The specific circuit conditions selected for the stress calculations are a sine-wave short-circuit current,* the maximum amount of displacement of current from the symmetrical position at the beginning of the short circuit, and separate rates of current decrement for each of the short-circuit current components. The theory upon which the stress calculations are based is outlined in the Appendix.

Practical Formula for Maximum Stress Calculations

The stress formula and the stress curve presented here are based on the following selected conditions:

Two-wire short circuits with the maximum amount of initial current displacement.

Average initial rates of current decrement applicable without material error to maximum stress determinations for short circuits in systems for which the short-circuit reactance does not exceed, say, 30 per cent.

An average value of mechanical damping applicable to a variety of bus structures having copper bars and porcelain insulators.

The application of the formula and of practical stress curves calls for the following data:

1. Initial value of r. m. s. total short-circuit current I_0, as obtained from accepted short-circuit current decrement curves,† I_0 ampere.

2. Length of busbar span between centers of supports, l in.

3. Dimension of individual busbar lamination (measured in the direction parallel to plane of deflection) a in.

4. Dimension of busbar perpendicular to a, b in.

5. Center spacing between bars (or groups of bars) mounted on separate insulators, s in.

6. The two natural frequencies f_1 and f_2 of the busbar structure; they are most readily obtained by a simple test.

7. The frequency f of the current.

The procedure is to calculate F_0, the electromagnetic force exerted on a length of busbar span by the initial r. m. s. value of total short-circuit current, from the formula‡

$$F_0 = 4.5 \times 10^{-8} \times k \times I_0^2 \frac{l}{s} \text{ lb. per span§}$$

and to obtain the maximum support stress P from the formula

$$P = p\,F_0 \quad \text{lb. per support}$$

where p is the stress factor obtained from stress curves selecting the value of p corresponding to the two natural frequencies of the bus structure. Fig. 1 gives a sample stress curve for 60-cycle currents.

Additional working stress curves, similar to that of Fig. 1, but covering the full range of natural frequencies, or other ranges of conditions, may, of course, be prepared by the same procedure.

Examples of Stress Calculations

Example No. 1

Two-wire short circuit between phases A and B, in Fig. 3. Each bar 4 in. by ¼ in. copper.

I_0 = 15,000 amperes
l = 48 in.
s = 6 in.

*While the analysis, outlined in the Appendix, has been applied to the basic case of sine-wave currents, the procedure is, of course, readily applicable to currents having a number of harmonic components, such as, a two-wire short-circuit current having a decided second-harmonic component.

†Bibliography No. 14.

‡Assuming uniform current distribution in the conductors.

§The factor k is a shape correction factor. It depends on the width, thickness and spacing of the bars, and allows for the well-known fact that the electromagnetic forces between bars are not always the same as those obtained on the assumption that the entire current is concentrated at the center of each bus. The value of k frequently differs from 1.0, especially in cases of closely spaced bars. The necessary values of k have been calculated and plotted by H. B. Dwight, Bibliography No. 11, and are reproduced here in Fig. 2.

$a = \frac{1}{4}$ in.
$b = 4$ in.
$f_1 = 15$ cycle per sec.
$f_2 = 45$ cycle per sec.
$f = 60$ cycle per sec.

$$F_0 = 4.5 \times 10^{-8}\, k\, I_0^2 \frac{l}{s}$$

To get the shape-correction factor, k

$a' = a = 0.25$ in.
$b' = b = 4$

$$\frac{s - a'}{a' + b'} = \frac{5.75}{4.25} = 1.35 \quad \frac{a'}{b'} = \frac{0.25}{4} = 0.063$$

Then $k = 0.94$ from Fig. 2. Hence

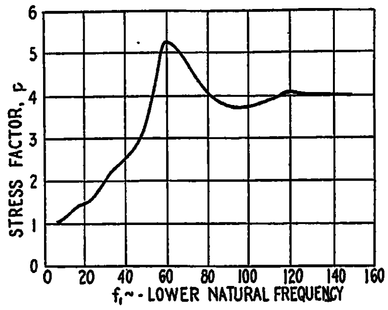

FIG. 1—CURVE OF STRESS FACTOR p

For the calculation of maximum support stress during 60-cycle short circuits, for values of f_1, lower natural frequency, ranging from 5 to 150 cyc. per sec. and for the value of f_2, higher natural frequency, equal to 180 cyc. per sec. The maximum support stress is pF_0, where F_0 is the electromagnetic force per busbar span for the initial r. m. s. (total) short-circuit current.

The curve of p is calculated for the following specific constants (see Appendix).

$$n_1 = n_2 = 5$$
$$g = 12.6$$
$$h = 2.2$$

Attention is called to the fact that the two natural frequencies f_1 and f_2 of the assembled busbar-insulator structure often differ very materially from the values of *busbar natural frequency for rigid supports* and of *support natural frequency without the busbar.* The differences in question are due to the support flexibility affecting busbar deflections and due to the busbar mass affecting support vibrations (compare, for example, equations (1) and (14) in the Appendix).

A useful formula and a simple chart for the determination of the natural frequency of busbars with rigid supports are given by L. F. Woodruff (Bibliography No. 34), but do not apply to busbar-insulator structures with flexible supports.

$$F_0 = 4.5 \times 10^{-8} \times 0.94 \times 15000^2 \times \frac{48}{6} = 76. \text{ lb. per span}$$

$P = \text{p}\, F_0$

$p = 1.6$ calculated by equation (33),* or from curves of stress factor similar to that in Fig. 1 plotted in accordance with (33).

Then the maximum stress is

$$P = 1.6 \times 76 = 122 \text{ lb. per support.}$$

The support must be designed to withstand this stress. The maximum electromagnetic force, however, is $\frac{8}{3} \times 76 \times 0.9^2 = 164$ lb. per span, where the factor $\frac{8}{3}$ is due to the relation between peak and average values of electromagnetic forces for totally displaced currents (see Table I), and the factor 0.9^2 allows for a 10 per cent current decrement during the first half-cycle of short-circuit current. It is seen that, in the case under discussion, the peak electromagnetic force is more than 30 per cent larger than the maximum support stress.

*Damping and current-decrement constants used are those given at the end of the appendix.

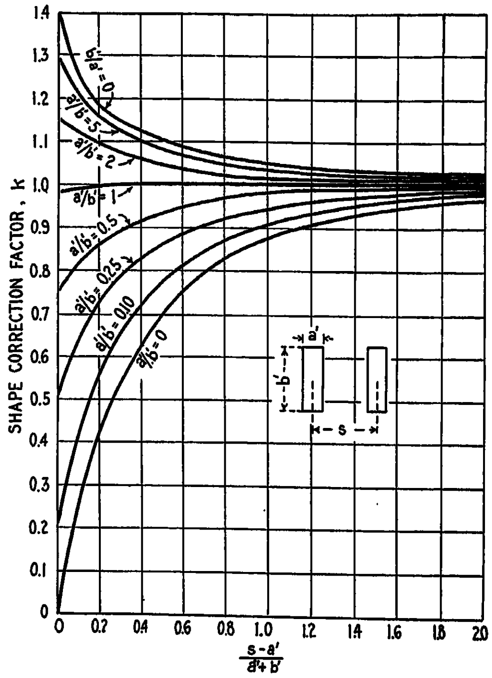

FIG. 2—SHAPE CORRECTION FACTOR k FOR THE CALCULATION OF ELECTROMAGNETIC FORCE

Prepared by H. B. Dwight and Published in the *Electrical World*, Vol. 70, p. 523

The electromagnetic force between parallel, rectangular bars is given by the formula

$$F = 4.5\, k\, I^2 \frac{l}{s} \cdot 10^{8-} \text{ lb. per span}$$

where l is the length of span in inches, s the spacing between conductors in inches, and I the current in amperes.

When the electromagnetic force is to be calculated between a going and a return conductor, each being a single rectangular bar of dimensions a by b, the values of a' and b' for the calculation of the shape correction factor k are:

$$a' = a \text{ and } b' = b$$

When several bars are clamped together in a group, the shape correction factor k may be computed approximately by considering the group to be replaced by a single solid conductor having the same outside dimensions as the group. Thus let the outside dimensions of the group be a' by b', and obtain k from Fig. 2. The approximation is usually very close when uniform current division between the laminations is provided—as, for instance, by proper transpositions—but may be less close when the current division is non-uniform.

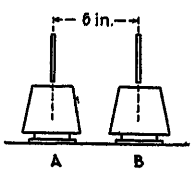

FIG. 3—THE BUS STRUCTURE CONSIDERED IN EXAMPLE 1

Example No. 2

Two-wire short circuit between phases A and B in Fig. 4, each phase having two copper bars 4 in. by ¼ in., with ¼ in. air space between bars.

$$I_0 = 16{,}200 \text{ amperes}$$
$$l = 56 \text{ in.}$$
$$s = 7.25 \text{ in.}$$
$$a = 4 \text{ in.}$$
$$b = \tfrac{1}{4} \text{ in.}$$
$$f_1 = 26.5 \text{ cycle per sec.}$$
$$f_2 = 280 \text{ cycle per sec.}$$
$$f = 60 \text{ cycle per sec.}$$

Then

$$F_0 = 4.5 \times 10^{-8} \times k \times I_0^2 \frac{l}{s}$$

where k is found from Fig. 2 with the aid of

$$a' = a = 4 \text{ in.}$$
$$b' = 0.75 \text{ in.}$$

In accordance with Fig. 2

$$\frac{s - a'}{a' + b'} = \frac{3.25}{4.75} = 0.69$$

$$\frac{a'}{b'} = \frac{4.0}{0.75} = 5.33$$

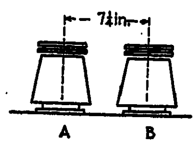

Fig. 4—The Bus Structure Considered in Example 2

and

$$k = 1.05 \text{ from Fig. 2}$$

Hence

$$F_0 = 4.5 \times 10^{-8} \times 1.05 \times 16{,}200^2 \times \frac{56}{7.25} = 96 \text{ lb. per span}$$

and the stress factor p, obtained from a curve similar to that of Fig. 1 (or by calculation from (33)) is 1.8

Thus the maximum stress per support is

$$P = 1.8 \times 96 = 173 \text{ lb.}$$

A test was made on the bus in question with a 25-cycle current, rather than a 60-cycle current. The test at 25-cycle per sec., gave a measured peak stress of 305 lb., for the same value of initial r. m. s. short-circuit current, *i. e.*, 16,200 amp., as indicated in Fig. 8. The greatly increased stress at 25 cycles is due to nearly perfect resonance, the natural frequency $f_1 = 26.5$ cycle per sec. being practically equal to the frequency of the fundamental component of electromagnetic force. It is therefore seen that in a given bus a short-circuit current of one frequency, say 25 cycle per sec., may produce a much greater stress than the same current of another frequency, say 60 cycles per sec.

Example 3

Busbar structure similar to that shown in Fig. 3, except that two 4 in. by ¼ in. copper bars are mounted on each support and that the length of the busbar spans is 28 in. The two bars per phase are separated by an air space of ¼ in. Calculate the maximum stress for a two-wire phase-to-phase short circuit.

$$I_0 = 25{,}000 \text{ ampere}$$
$$l = 28 \text{ in.}$$
$$s = 6 \text{ in.}$$
$$a = \tfrac{1}{4} \text{ in.}$$
$$b = 4 \text{ in.}$$
$$f_1 = 20 \text{ cycle per sec.}$$
$$f_2 = 60 \text{ cycle per sec.}$$
$$f = 60 \text{ cycle per sec.}$$

k is found from Fig. 2 with the aid of

$$a' = 0.75 \text{ in.}$$
$$b' = b = 4 \text{ in.}$$

In accordance with Fig. 2,

$$\frac{s - a'}{a' + b'} = \frac{5.25}{4.75} = 1.11$$

$$\frac{a'}{b'} = \frac{0.75}{4} = 0.188$$

and

$$k = 0.94 \text{ from Fig. 2}$$

Hence

$$F_0 = 4.5 \times 10^{-8} \times 0.94 \times 25{,}000^2 \times \frac{48}{6} = 212 \text{ lb. per span}$$

The calculated stress factor p is 1.9. Thus the maximum stress is

$$P = 1.9 \times 212 = 403 \text{ lb. per support.}$$

It is seen that the maximum stress is not excessive although resonance occurs, because the non-resonant natural frequency is well below the resonant frequency, as already indicated.

Results of Tests

A large number of tests were made to check the stress calculations: 1, on small-scale structures of definitely known and readily adjustable mechanical characteristics and 2, on full-size typical busbar-insulator structures with short-circuit currents up to 25,000 amperes. The results of the tests were in good agreement with the calculations. In the following will be given some of the results obtained in the full-size tests.

The support deflection curve (with time) as well as the busbar deflection curve (with time) were recorded by oscillograph, with the aid of specially designed displacement recorders. Moreover, the deflections of the insulators were measured for slowly applied constant loads, so that the support stresses could be calculated from the oscillographic support deflection records. The bus structures used had five or more uniform busbar spans per phase.

Test No. 1

The object of this test was to compare test results of support stress with calculated results for a bus structure employing porcelain insulators with a long busbar span (56 in.) in which the bars were mounted face-down on the supports, as shown in Fig. 4. The center spacing between phases was 7.25 in., two 4 in. by ¼ in. bars

Curve B: Calculated support-stress curve, by equation (**40**) and on the basis of the following constants: $f_1 = 25$ cyc. per sec., $f_2 = 280$ cyc. per sec., $f_c = 25$ cyc. per sec., $n_1 = n_2 = 5$, $g = 12.6$, $h = 2.2$

port deflection occurring at the level of the busbar. Fig. 6 shows, in the lower part, the support-stress curve, *A*, by test (from Fig. 5) together with a calculated support-stress curve, *B*, calculated for a lower natural frequency of 25 cycle per sec. (by equation (**40**) of the Appendix). In view of the almost perfect resonance obtained in the test, the stress factor for maximum support stress is 3.5, meaning that the maximum support stress is 3.5 times the initial average electromagnetic force per span. Moreover, the maximum support stress is 75 per cent greater than the electromagnetic force calculated from the maximum value of short-circuit current (21,500 amperes) measured at its first peak.

The load-deflection curve for the insulator appears in Fig. 7.

In Fig. 8 reasonably good agreement is shown between test points and a calculated curve of peak stress for short-circuit current values ranging from 8000 to 19,000 amperes, under the conditions of Test No. 1.

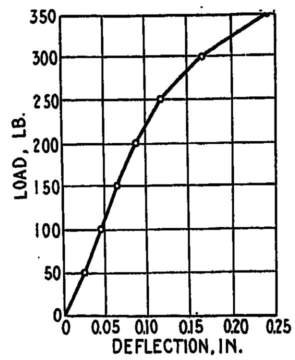

FIG. 7—LOAD-DEFLECTION CURVE FOR SUPPORT USED IN TEST NO. 1

Natural frequencies 26 cycle per sec. and 130 cycle per sec.

Test No. 2.

The object of Test No. 2 was to compare test results of support stress with calculated results for a bus structure employing porcelain insulators with a short busbar span (20 in.) in which the bars were mounted edgewise on the supports but face-to-face with respect to each other, as shown in Fig. 3.

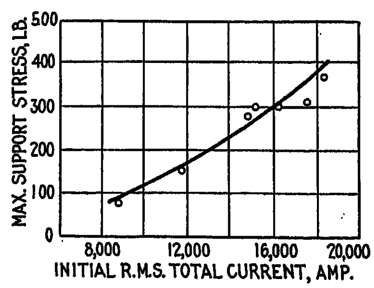

FIG. 8—COMPARISON OF MAXIMUM STRESSES BY TEST AND BY CALCULATION

For conditions of Test No. 1
Points obtained by test, curve by calculation

Current frequency 25 cycle per sec.

Initial r. m. s. current 19,900 amperes.

In Fig. 9, curve *A* shows the experimental stress-time curve. Curve *B* was calculated for perfect tuning by equation (**40**) in the appendix. The early dropping

off of the stress oscillations observed by test is probably due to the somewhat non-elastic behavior of the support at the heavier loads, as indicated in Fig. 10.

In Fig. 11, the calculated peak stress at the higher current values is materially above the test points—a result consistent with the larger values of damping to

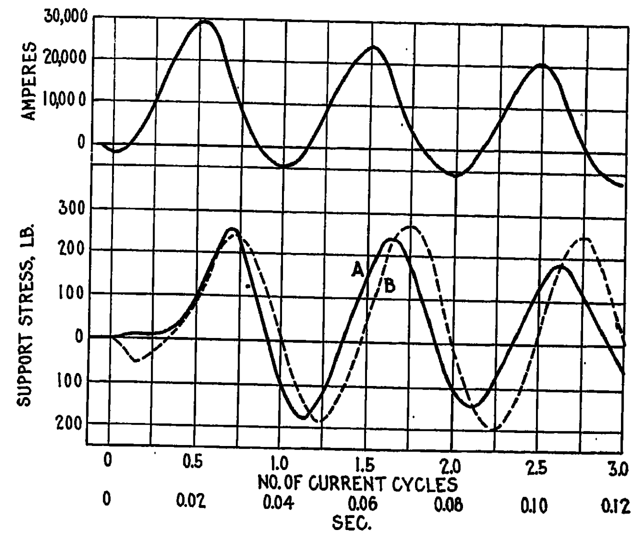

FIG. 9—CURRENT AND STRESS CURVES FOR TEST NO. 2

Upper curve: 25-cycle current, initial r. m. s. value 19900 amperes

be expected. At the lower currents, however, test results and calculations are in fairly good agreement.

Test No. 3.

The object of this test was to measure the stresses occurring in a structure having supports of the insulated-rod type, where the damping resistance is low.

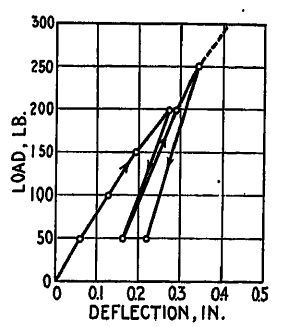

FIG. 10—LOAD-DEFLECTION CURVE FOR SUPPORT USED IN TEST NO. 2

Loads constant and slowly applied at the level of the busbar. Deflection measured at level of busbar. Where dips are shown, the load was reduced and subsequently increased.

Accordingly the bus structure of Fig. 12 was employed. Each conductor of the two-conductor loop was a 4 in. by 3/8 in. copper bus, the center spacing between conductors being 7.25 in. and the longitudinal spacing of supports being 45.5 in. The lower natural frequency of the structure was 27 cycle per sec., while the higher one was 60 cycle per sec.

Curve A of Fig. 13 shows the support stress variation, by test, from the beginning of the short circuit for an initial current of 22,800 amperes. The maximum stress peak did not occur until after the fourth current peak, on account of the low damping rate. Examination of free-vibration records for the structure of Fig. 12 showed

Curve B: Calculated support-stress curve, by equation (40) and on the basis of the following constants: $f_1 = 25$ cyc. per sec., $f_2 = 60$ cyc. per sec., $f_c = 25$ cyc. per sec., $n_1 = n_2 = 12$, $g = 9.7$, $h = 2.2$

that the resonance sharpness* (diminishing with increased damping) was more than double that found in Tests No. 1 and No. 2. With the aid of the higher value of resonance sharpness the calculated Curve B of Fig. 13 was obtained. The maximum experimental

*Defined by equations No. (30) and No. (31) in the appendix.

support stress by test was 6.3 times the initial average electromagnetic force, on account of (1) the nearly perfect resonance and (2) the reduced damping resistance.

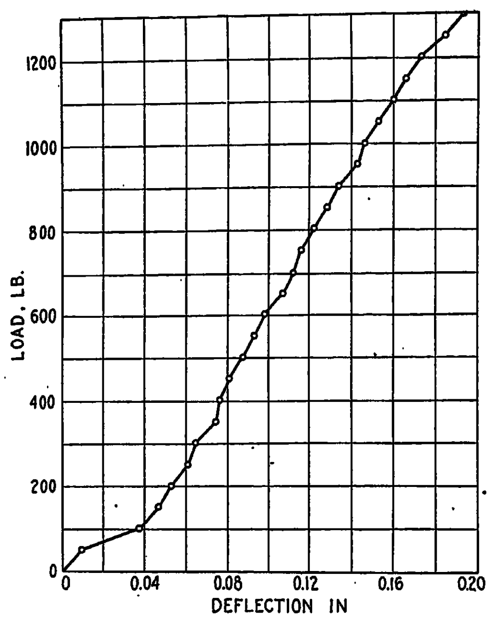

Fig. 14—Load-Deflection Curve for Support Used in Test No. 3

Loads constant and slowly applied at the level of the busbar. Deflection measured at the level of the busbar.

Attention is called to an insulator calibration curve given in Fig. 14.

Test results and a calculated curve of peak stresses for the structure of Fig. 12 are presented in Fig. 15,

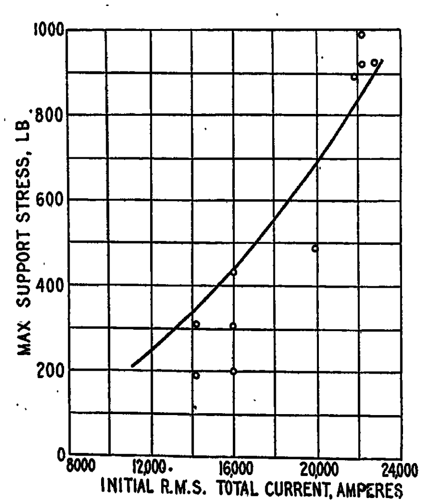

Fig. 15—Comparison of Maximum Stress by Test and by Calculation

For the conditions of Test No. 3
Points obtained by test, curve by calculation

for short-circuit current values ranging from 14,000 to 23,000 amperes.

Test No. 4.

In this test the elastic limit of a porcelain insulator, similar to those used in tests 1 and 2, was considerably exceeded.

The conductor consisted of two 4 in. by ¼ in. copper bars mounted in the same manner as the one bar shown in Fig. 3.

The bus structure when vibrating through small amplitudes had natural frequencies of 10 and 28 cycle per sec.

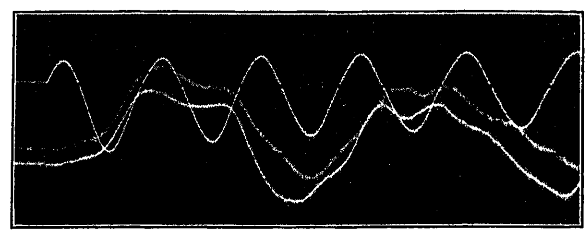

Fig. 16—Oscillogram Pertaining to Test No. 4

Upper curve: 25-cycle current, initial r. m. s. value 18200 amperes
Middle curve: Deflection of support A at level of busbar. 0.40 in. maximum
Lower curve: Deflection of support B at level of busbar. 0.36 in. maximum
Note: Supports A and B were adjacent insulators in the middle of the bus structure

Fig. 16 is a test record showing a 25-cycle short-circuit current of 18,200 initial r. m. s. amperes and two support-deflection curves (lower curves). The corresponding calculated stress curve, calculated for the two natural frequencies of 10 and 25 cycle per sec., is that

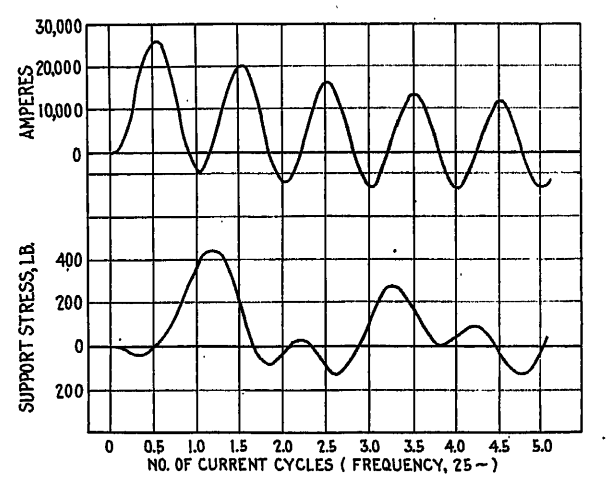

Fig. 17—Current and Stress Curves Relating to Test No. 4

Upper curve: 25-cycle current, initial r. m. s. value 18200 amperes; (assumed fully displaced); decrement factors: $g = 12.6$, $h = 2.2$
Lower curve: Calculated support-stress curve, for the current plotted in upper curve and on the basis of the following constants: $f_1 = 10$ cyc. per sec., $f_2 = 25$ cyc. per sec., $f_c = 25$ cyc. per sec., $n_1 = n_2 = 5$, $g = 12.6$, $h = 2.2$

of Fig. 17. The support load-deflection curve is given in Fig. 18. While the experimental deflections from Fig. 16 clearly show the 10-cycle natural-frequency component, the 25-cycle forced-frequency component of stress is present but less pronounced than that predicted from the calculated stress curve (Fig. 17). The discrepancy is due to the non-elastic behavior of the

support at the larger deflections which reached values as large as 0.4 in.

Attention is called to the deflections and stresses of considerable magnitudes occurring in a direction opposite to that of the electromagnetic force—an observation made in a number of tests and consistent with predictions by calculation. Bus supports must, therefore, be designed with reference to stresses of either direction. The maximum stress will be in the direction of the average electromagnetic force.

SUMMARY

1. A method of calculating the mechanical stresses in busbar supports during short circuits is developed and presented.

2. The method of stress calculation given here takes into account the following factors: The short-circuit current, its decrement rate, the electromagnetic force due to the current, the natural frequencies of busbar structures and their motional resistance.

3. The method of calculation differs from those employed in the past since the calculations used heretofore have only partially taken into account, or totally neglected, the oscillatory character of busbars and of supports.

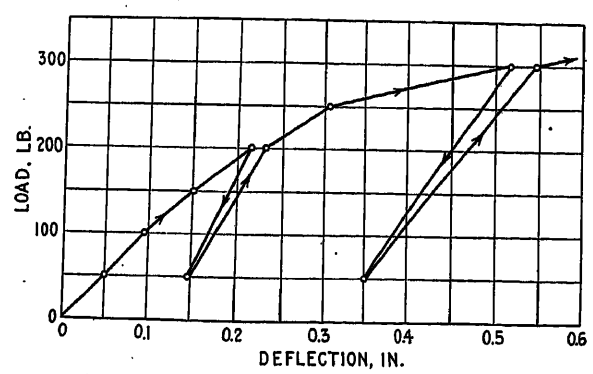

FIG. 18—LOAD-DEFLECTION CURVE FOR SUPPORT USED IN TEST NO. 4

Loads constant and slowly applied at the level of the busbar. Deflection measured at the level of the busbar. Where dips are shown, the load was reduced and subsequently increased.

4. Tests have demonstrated that not only the busbars, but also most types of supports are flexible and may be treated, for the purpose of estimating stresses, as having elastic properties.

5. When busbars are mounted on flexible supports, in the customary manner, the motion of the busbar span as well as the motion of the support show two dominant natural frequencies which occur in combination in each of the two structural members when electromagnetic forces are suddenly applied. The natural frequencies are determined by a simple test, when feasible, or by calculation from the mechanical constants of busbar and of support.

6. In view of the two natural frequencies mentioned, bus supports respond selectively to impressed electromagnetic forces at different frequencies; so that the magnitude of the electromagnetic force and its mode of variation with time are not usually representative of the magnitude and mode of variation of the support stresses.

7. Since the natural frequencies of busbar structures range from, say, 10 to 300 cycles per sec., mechanical resonance is within common possibility in buses of 25-cycle circuits as well as in buses of 60-cycle circuits. While not all cases of resonance give rise to stresses greatly in excess of those at non-resonance, resonance in some cases multiplies the stresses five or even ten times. It will often be possible by proper methods of design so to change the natural frequencies as to avoid the cases of resonance giving extra heavy stresses.

8. In the analysis of stresses presented the bus structure is treated as a two-element vibratory system, *i. e.*, as a mechanical system having two elastic oscillatory elements joined together—a composite structure resembling, for instance, the system comprising a turbine rotor keyed to a flexible shaft, the shaft bearings being attached to an elastic base.

The analysis of bus-support stresses presented here is applied to the basic case of a bus structure having long, straight, uniform, parallel busbars with equidistant, rigidly mounted supports of uniform characteristics. The method of calculation is a general one applicable to all cases of elastic busbars intermittently supported, irrespective of whether the busbars are placed face-on or edge-on with respect to the supports, and irrespective of whether the supports themselves are stressed in bending, in tension or in compression.

9. The transient motion and stresses obtained by tests on full-size structures were found in most cases to be in substantial agreement with the results calculated, proper allowance for damping and current decrement being made in the calculations. Special calculations, not covered by No. 8 will, however, be required in the following cases:

a. When a third pronounced natural frequency is introduced, due for example to a flexible foundation to which the insulators are bolted. A flexible foundation not only introduces additional possibilities of resonance, due to the third natural frequency, but also tends to alter the other two natural frequencies.

b. When the bus supports do not clamp the busbar but merely guide it loosely. Excess stresses may occur and must be allowed for in the calculation.

c. When the elastic limit of the supports or of the busbar is materially exceeded. As a rule the limit of safe stresses is not materially above the elastic limit of the structural members.

Moreover, consideration will sometimes have to be given to additional factors not covered in this paper, such as the effects, upon the stresses, of tap-connections, bends, unequal spans, non-uniform current division, and longitudinal tension set up along the busbars and stressing the insulators in a direction at right angles to the stresses covered by the formulas developed in this paper.

10. Approximate estimates of maximum support stresses in practical design may be made by multiplying the initial average electromagnetic force per busbar span, which force is that due to the initial r. m. s. (total) short-circuit current, by a "stress factor," equal to the maximum stress per support when the initial average electromagnetic force is unity. Representative curves of stress factor calculated from the equations derived may be plotted with respect to the natural frequencies. The curves in question are prepared on the basis of selected conditions and average representative constants so that one set of curves will be applicable with sufficient accuracy to a large number of cases. A sample curve of stress factor is presented in Fig. 1.

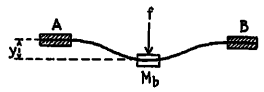

FIG. 19—BUSBAR REPRESENTED WITH CONCENTRATED MASS M AND MOUNTED ON RIGID SUPPORTS A, B

11. The maximum support stress may occur before the end of the first cycle of short-circuit current, or as late as 0.15 sec.

12. Attention is called to the deflections and stresses of considerable magnitudes occurring in a direction opposite to that of the electromagnetic force—an observation made in a number of tests and consistent with predictions by calculation. Bus supports must, therefore, be designed with reference to stresses of either direction. The maximum stress will be in the direction of the average electromagnetic force.

Appendix

Calculation of Stresses in Bus Supports

It is the object of this appendix to establish a procedure for estimating the maximum short-circuit stresses in busbar supports.

THE BUSBAR

With some restrictions and exceptions, the busbar with its distributed mass, may be treated, in regard to its vibratory behavior and support stresses, as a simple elastic beam of concentrated rigid mass, constant stiffness, and motional resistance.

a. Deflection of Support Neglected.

Theoretically, a uniform bar, clamped to a pair of rigid supports, may be expected to have a composite set of free vibrations having a fundamental frequency and a number of overtone frequencies. Practically, however, test records of vibrations of several kinds of busbars show the vibrations at overtone frequencies to be hardly noticeable in the free vibrations occurring when loads are suddenly applied or suddenly removed; *i. e.*, the free vibrations are practically the same as those of a concentrated mass supported by an elastic spring. If, then, M_b is the equivalent busbar mass and S_b its (constant) stiffness* an external force F, slowly applied, as in Fig. 19, to the mass originally at rest, will cause a deflection y of the mass M_b, so that $S_b y = F$. Thus, the stress upon each support will be $(\frac{1}{2}) S_b y$. If there are adjacent spans, similarly loaded, on each side of the first one, the stress on each support, except the end ones, will be $S_b y$. Similarly, during vibrations of an amplitude y, as will occur, for example, when the forces F on each span are suddenly and simultaneously removed (damping neglected), the maximum pressure on the supports will be $S_b y$ and the natural frequency f_b of the vibrations will be defined by

$$(2 \pi f_b)^2 = \omega_b^2 = \frac{S_b}{M_b} \tag{1}$$

For any given busbar, the values of S_b and M_b must satisfy (1), when f_b is the natural frequency of the actual busbar.

Assuming the busbar to be a vibratory element having a single natural frequency, as considered in the foregoing, Biermanns* calculated the busbar deflections in terms of the natural frequency of the busbar span for short-circuit currents on the assumption that the bus is rigidly clamped to non-flexible supports. Flexible supports were not considered.

b. Treatment of Busbars with Flexible Supports.

Busbar structures with flexible supports may be treated as a mechanical system comprising a busbar span of concentrated mass M_b, constant stiffness S_b, and motional resistance, the busbar being held by supports which also are represented by a concentrated mass M_s, a constant stiffness S_s, and motional resistance. The electromagnetic force f per span will be considered as applied to the equivalent busbar mass M_b; while the driving force acting on the support will be $S_b y_b$ where y_b is the deflection of the mass M_b with respect to the supports as indicated in Fig. 20. The system described has two inter-related natural frequencies. Both frequencies are present in the motion of the busbar as well as in the motion of the support, *i. e.*, neither frequency can be definitely assigned to either one of the elements alone.

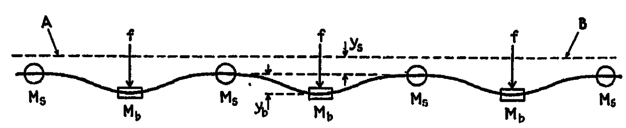

FIG. 20—BUSBAR-INSULATOR STRUCTURE WITH FLEXIBLE SUPPORTS

The busbar is represented with concentrated mass M_b and the support with concentrated mass M_s. Line A-B indicates the rest position of the busbar and of the supports before the electromagnetic forces are applied.

*The stiffness is the force per unit deflection, the force being slowly applied to the mass originally at rest.

*Bibliography No. 6.

The approximations involved in Fig. 20 are the following:

A. The portion of the electromagnetic force which acts directly on the support is neglected; *i. e.*, the entire force f is considered to be directly applied to the busbar span, since the width of the support, measured along the direction of the busbar, is less than 10 per cent of the spacing between supports in the majority of bus structures.

B. The overtone natural-frequency components of the busbar are neglected since they are rapidly damped out, and since the support stresses will be far less affected by any short-wave overtone busbar vibrations than by the fundamental vibrations involving the busbar as a whole.

C. There is a further approximation due to the effect of using the equivalent busbar mass, rather than the actual distributed mass, in a bus system having flexible supports. To investigate this point test values of the two natural frequencies obtained with actual bus structures were compared with values calculated on the basis of the concentrated busbar mass. The comparison showed good agreement, the discrepancies found being well within the limits of accuracy of the observed support constants themselves. It is concluded, therefore, that the approximation in question is allowable in stress calculations, particularly if test values of natural frequencies are used.

In view of the foregoing, the support-stress calculations will be based on the following conditions:

1. Straight, uniform, parallel busbars having equidistant supports of uniform characteristics.
2. All supports, are considered equally stressed, the stresses per support being those due to the electromagnetic force for a full busbar span. A number of similar spans are assumed to be acted on by the same electromagnetic force.
3. Busbar and support deflect when stressed and have elastic properties.
4. Two-wire short circuit, the two conductors carrying equal and opposite currents.
5. Busbars at rest and unstressed before application of the short circuit.
6. The deflection of the busbars is considered to be small in comparison with the spacing between conductors; thus the electromagnetic force is regarded as independent of the deflection of the bars. The longitudinal tension in the bars is neglected.
7. The base of each support is considered to be tightly bolted to a rigid foundation.
8. The assembled bus structure is assumed to have not more than two natural frequencies.
9. In the first analysis, the motional resistance of the structural elements as well as the current decrement will be neglected. The principles of motion and of stresses can adequately and most conveniently be derived from an analysis of the motional behavior of a (hypothetical) system of negligible resistance, in the absence of current decrement. Subsequently, suitable allowance will be made for current decrement and damping.

Support Deflections and Stresses without Damping and Without Current Decrement*

Since the driving electromagnetic force f per span is opposed during vibratory motion by a force due to the acceleration of the busbar mass, whose displacement at any instant is $y_b + y_s$, and by a restoring force due to the resilience of the busbar span, the following equation of busbar motion neglecting resistance is obtained, in accordance with Fig. 20.

$$M_b \left(\frac{d^2 y_b}{d t^2} + \frac{d^2 y_s}{d t^2} \right) + S_b y_b = f \qquad (2)$$

All forces are parallel and in one plane. The corresponding forces acting on the support, according to Fig. 20, define its motion as given in equation (3)†. Resistance is again neglected.

$$M_s \frac{d^2 y_s}{d t^2} + S_s y_s = S_b y_b \qquad (3)$$

In order to obtain the support stress, equations (2) and (3) will be solved for y_s in terms of the structural constants and the electromagnetic force. If equation (3) is differentiated twice, with respect to time, and the equation so found is then combined with (2) and (3) for eliminating y_b and the derivatives of y_b, equation (4), the differential equation for y_s, is obtained.

$$\frac{d^4 y_s}{d t^4} + \left(\frac{S_b}{M_b} + \frac{S_s}{M_s} + \frac{S_b}{M_s} \right) \frac{d^2 y_s}{d t^2} + \frac{S_b S_s}{M_b M_s} y_s = \frac{S_b}{M_b M_s} f \qquad (4)$$

The solution of (4) depends on the form of the electromagnetic force f. A symmetrical sine current of the form

$$I_m \sin \omega t$$

becomes, when totally displaced,

$$i = I_m (1 - \cos \omega t)$$

Thus the instantaneous electromagnetic force between two parallel bars each of which carries current i is, neglecting current decrement,

$$f = A I_m^2 (1 - \cos \omega t)^2$$

$$= 1.5 A I_m^2 \left(1 - \frac{4}{3} \cos \omega t + \frac{1}{3} \cos 2 \omega t \right) \qquad (5)$$

Equation (4) may then be written:

$$\frac{d^4 y_s}{d t^4} + g_0 \frac{d^2 y_s}{d t^2} + h_0^2 y_s = B F_0 \left(1 - \frac{4}{3} \cos \omega t + \frac{1}{3} \cos 2 \omega t \right) \qquad (6)$$

*C. g. s. absolute units are employed, unless otherwise mentioned.

†Equations similar to No. 2 and No. 3 were set up by Hort (Bibliography No. 15) for the vibrations of a system comprising a rotating machine on a flexible shaft held by two bearings which are resting on a yielding foundation.

where B is substituted for $\frac{S_b}{M_b M_s}$

Then y_s is of the form:*

$$y_s = y_1 + y_2 + y_3 + y_4$$

where

y_1 is the particular solution of (6) with the right-hand side equal to $B F_0$

y_2 is the particular solution of (6) with the right-hand side equal to $\left(-\frac{4}{3} B F_0\right) \cos \omega t$

y_3 is the particular solution of (6) with the right-hand side equal to $\left(+\frac{1}{3} B F_0\right) \cos 2 \omega t$

y_4 is the complementary function, with the right-hand side of (6) equal to zero.

Thus the solution for y_1 is

$$y_1 = \frac{B F_0}{h_0^2} \quad (7)$$

since the derivatives of equation (7) are zero. The solution for y_2† is

$$y_2 = \frac{-\frac{4}{3} B F_0 \cos \omega t}{\omega^4 - g_0 \omega^2 + h_0^2} \quad (8)$$

Similarly

$$y_3 = \frac{\frac{1}{3} B F_0 \cos 2 \omega t}{(2 \omega)^4 - g_o (2 \omega)^2 + h_0^2} \quad (9)$$

Finally, y_4 is found from

$$\frac{d^4 y_4}{d t^4} + g_0 \frac{d^2 y_4}{d t^2} + h_0^2 y_4 = 0 \quad (10)$$

The solution is of the form

$$y_4 = c_1 e^{\alpha_1 t} + c_2 e^{\alpha_2 t} + c_3 e^{\alpha_3 t} + c_4 e^{\alpha_4 t} \quad (11)$$

where c_1, c_2, c_3 and c_4 are constants dependent on the starting conditions, and α_1, α_2, α_3, α_4 are the four roots of the equation

$$\alpha^4 + g_0 \alpha^2 + h_0^2 = 0 \quad (12)$$

Thus all values of α are pure imaginaries:

$$\left.\begin{aligned} \alpha_1 &= j q_1 \\ \alpha_2 &= -j q_1 \\ \alpha_3 &= j q_2 \\ \alpha_4 &= -j q_2 \end{aligned}\right\} \quad (13)$$

where

$$\left.\begin{aligned} q_1 &= \sqrt{\frac{1}{2}\left(g_0 - \sqrt{g_0^2 - 4 h_0^2}\right)} \\ q_2 &= \sqrt{\frac{1}{2}\left(g_0 + \sqrt{g_0^2 - 4 h_0^2}\right)} \end{aligned}\right\} \quad (14)$$

q_1 and q_2 are the angular velocities of the two natural frequencies of the structure.

*See Bibliography 33, p. 214-218 and p. 240.

†See Bibliography 33, p. 215, equation (17‴).

Dividing q_1 and q_2, in equation (14), by 2π the two natural frequencies f_1 and f_2 of the busbar structure are obtained.

It is seen that q_1 cannot be larger than q_2.

Thus the solution for y_s is

$$y_s = c_1 e^{\alpha_1 t} + c_2 e^{\alpha_2 t} + c_3 e^{\alpha_3 t} + c_4 e^{\alpha_4 t} + \frac{B F_0}{h_0^2} - \frac{\frac{4}{3} B F_0 \cos \omega t}{\omega^4 - g_0 \omega^2 + h_0^2} + \frac{\frac{1}{3} B F_0 \cos 2 \omega t}{(2 \omega)^4 - (2 \omega)^2 g_0 + h_0^2} \quad (15)$$

Now the constants c_1, c_2, c_3 and c_4 in (15) will be determined from the initial conditions of motion. The constants will establish the amplitudes of the free-vibration components of motion. The initial condition to be considered is that the bus structure be at rest and unloaded at a time just before the occurrence of the short circuit or that, in mathematical terms,

$$\text{at the time } t = 0 \left\{\begin{aligned} y_b &= 0 && (16a) \\ \frac{d y_b}{d t} &= 0 && (16b) \\ y_s &= 0 && (16c) \\ \frac{d y_s}{d t} &= 0 && (16d) \end{aligned}\right.$$

The last two conditions will be applied directly to equation (15), while (16a) and (16b) will be applied to equation (3). In the use of (16a) and (16b) with equation (3) the expressions for $\frac{d^2 y_s}{d t^2}$ and $\frac{d^3 y_s}{d t^3}$ at the time $t = 0$ must be found from equation (15) by successive differentiations of (15). The procedure thus outlined gives the following constants:

$$\left.\begin{aligned} c_1 = c_2 &= \frac{y_0 u_2^2}{2 (u_2^2 - u_1^2)} \left[-1 - \frac{4}{3} \frac{u_1^2}{(1 - u_1^2)} + \frac{1}{3} \frac{u_1^2}{(4 - u_1^2)}\right] \\ c_3 = c_4 &= \frac{y_0 u_1^2}{2 (u_2^2 - u_1^2)} \left[1 + \frac{4}{3} \frac{u_2^2}{(1 - u_2^2)} - \frac{1}{3} \frac{u_2^2}{(4 - u_2^2)}\right] \end{aligned}\right\} \quad (17)$$

where

$$y_0 = \frac{B F_0}{h_0^2} = \frac{F_0}{S_s} \quad (18)$$

$$\left.\begin{aligned} u_1 &= \frac{q_1}{\omega} \\ u_2 &= \frac{q_2}{\omega} \end{aligned}\right\} \quad (19)$$

Then we obtain for y_4 from equation (11) with the aid of equation (13) and equation (17)

$$y_4 = 2 c_1 \cos q_1 t + 2 c_3 \cos q_2 t \quad (20)$$

The sum of $y_1 + y_2 + y_3 + y_4$ in accordance with (7), (8), (9) and (20) gives the full solution for y_s.

In practical stress calculations the ratio $\frac{y_s}{y_0} = p$ is convenient to use. The significance of p is due to the fact that y_0 is the support deflection due to a dead load equal to F_0, the electromagnetic force exerted on a busbar span by the r. m. s. initial asymmetrical short-circuit current. Hence, p multiplied by F_0 gives the support stress, and the maximum value of p is the maximum stress obtained when the initial average electromagnetic force per span is one. Accordingly, p will be called the stress factor. Thus the support stress factor, neglecting resistance and current decrement is

$$p = \frac{y_s}{y_o} = 1 + C_1 \cos q_1 t + C_2 \cos q_2 t + C' \cos \omega t + C'' \cos 2 \omega t \qquad (21)$$

where the coefficients C_1, C_2, C' and C'' are defined by

$$\left.\begin{aligned}
C_1 &= \frac{u_2^2}{u_2^2 - u_1^2} \left(-1 - \frac{4}{3} \frac{u_1^2}{(1 - u_1^2)} + \frac{1}{3} \frac{u_1^2}{(4 - u_1^2)} \right) \\
C_2 &= \frac{- u_1^2}{u_2^2 - u_1^2} \left(-1 - \frac{4}{3} \frac{u_2^2}{(1 - u_2^2)} + \frac{1}{3} \frac{u_2^2}{(4 - u_2^2)} \right) \\
C' &= - \frac{4}{3} \frac{u_1^2}{(1 - u_1^2)} \frac{u_2^2}{(1 - u_2^2)} \\
C'' &= \frac{1}{3} \frac{u_1^2}{(4 - u_1^2)} \frac{u_2^2}{(4 - u_2^2)}
\end{aligned}\right\} \qquad (22)$$

It is seen that all constants in equation **21** depend solely on the frequency ratios

$$u_1 = \frac{q_1}{\omega} = \frac{2 \pi f_1}{\omega} \text{ and } u_2 = \frac{q_2}{\omega} = \frac{2 \pi f_2}{\omega}$$

so that, if the two natural frequencies

$$\left.\begin{aligned}
f_1 &= \frac{q_1}{2 \pi} \text{ cycles per sec.} \\
f_2 &= \frac{q_2}{2 \pi} \text{ cycles per sec.}
\end{aligned}\right\} \qquad (23)$$

are known, the stress factor is readily calculated by (21) and (22), neglecting resistance and current decrement.

One of the questions of greatest practical importance is that of resonance. Resonance* occurs when an impressed force has a frequency equal to one of the two natural frequencies f_1 and f_2.

Since there are two natural frequencies and (for displaced short-circuit currents) harmonic electromagnetic force components at two frequencies, there are four possibilities of resonance, *i. e.*, either one of the two natural frequencies may be at resonance with either of the force frequencies. Thus the four conditions of resonance are:

$$u_1 = 1 \qquad \textbf{(24a)}$$

$$u_2 = 1 \qquad \textbf{(24b)}$$

$$u_1 = 2 \qquad \textbf{(24c)}$$

$$u_2 = 2 \qquad \textbf{(24d)}$$

To summarize the principal results derived so far:

Support stresses may be most conveniently expressed in terms of (1) the *initial average electromagnetic force* per busbar span, which force is that due to the r. m. s. initial value of asymmetrical short-circuit current, and (2) the *stress factor*, a value equal to the stress per support when the initial average electromagnetic force is unity.

Thus the maximum stress is obtained by multiplying the initial average electromagnetic force by the maximum stress factor.

For busbar and supports of elastic properties the stress factor, and hence the maximum stress, depend primarily on the two natural frequencies and on the current frequency except for the effects of damping and current decrement, to be considered below.

The two natural frequencies may be determined by calculation from the mechanical constants of busbar and of insulator, by equation (14), or preferably, where feasible, by direct measurement on the assembled bus structure.

Effects of Damping and of Current Decrement at Non-Resonance

Equation (21), derived for zero motional resistance, and for a totally displaced current without decrement, does not give the final values for practical stress calculations, because the damping of the structural elements and the current decrement do materially affect the maximum stresses during short circuits. Structures at non-resonance will be considered first. For the present purpose, "non-resonance" is to include all those cases in which the natural frequencies differ by 25% or more from the frequencies of the impressed electromagnetic force. The calculation of stresses at resonance is discussed later.

For practical calculations of maximum stresses at non-resonance, the following approximations have been made:

a. The electromagnetic force due to short-circuit currents is expressed in the form:

$$f = F_0 \left(\frac{2}{3} e^{-2gt} + \frac{1}{3} e^{-2ht} - \frac{4}{3} e^{(-g-h)t} \cos \omega t + \frac{1}{3} e^{-2ht} \cos 2 \omega t \right) \qquad (25)$$

which is approximately equal to the electromagnetic

*See Bibliography No. 31, pp. 152-155 and p. 175; also Bibliography No. 15, pp. 54-57.

force due to a two-wire short-circuit when the current is*

$$i = I_m e^{-gt} - [(I_m - I_s) e^{-ht} + I_s] \cos \omega t \qquad \mathbf{(26)}$$

where I_m and I_s are the maximum values of initial a-c. component and of sustained current, respectively, and g and h are the decrement constants of d-c. component and of a-c. component, respectively. It is seen that the electromagnetic force of equation (**25**) is obtained from a form of short-circuit current in which the value of I_s in equation (**26**) is neglected.

b. The non-harmonic component of the stress factor, which component is equal to unity without current decrement, is approximately

$$p_1 = \frac{2}{3} e^{-2gt} + \frac{1}{3} e^{-2h} \qquad \mathbf{(27)}$$

when the electromagnetic force defined by equation (**25**) is applied.

The approximation involved in equation (**27**) is very close at non-resonance in a single-element vibrating system having mass M, motional resistance R, and stiffness S, and moving in accordance with

$$M \frac{d^2 y}{d t^2} + R \frac{d y}{d t} + S y = f \qquad \mathbf{(28)}$$

c. The natural-frequency components of the stress factor are given in the following form when the electromagnetic force of equation (**25**) is applied to busbar structures for which the mechanical damping is known.

$$\left.\begin{aligned} p_2 &= C_1 e^{-0.5\alpha' t} \cos q_1 t \qquad \mathbf{(29a)} \\ p_3 &= C_2 e^{-0.5\alpha'' t} \cos q_2 t \qquad \mathbf{(29b)} \end{aligned}\right\}$$

where C_1 and C_2 are the constants of equation (**22**) while α' and α'' are damping decrement constants obtained from free-vibration tests. Observed values of the successive amplitudes of free vibrations may be used to solve numerically α' and α'' from equation (**29**). In calculations it is often convenient to use the term "sharpness of resonance" defined† as

$$\left.\begin{aligned} n_1 &= \frac{q_1}{\alpha'} \\ n_2 &= \frac{q_2}{\alpha''} \end{aligned}\right\} \qquad \mathbf{(30)}$$

Physically, the significance of the sharpness of resonance may be seen by considering, for example, a single-element vibratory system, such as that defined by (**28**), when acted on by a symmetrical harmonic force of amplitude F. The maximum resonant amplitude of vibration‡ is then, very nearly, n times the deflection obtained when a steady force F is slowly applied, where n is the sharpness of resonance defined by

$$n = \frac{\sqrt{\dfrac{S}{M}}}{\dfrac{R}{M}} \qquad \mathbf{(31)}$$

*See Bibliography No. 9 p. 1248.
†See Bibliography No. 17, p. 452.
‡Bibliography No. 31, p. 154.

the constants being those of equation **28.**

d. The forced-frequency components of the stress factor are approximated in the following form at non-resonance when the electromagnetic force of equation (**25**) is applied:

$$p_4 = C' e^{(-g-h)t} \cos \omega t \qquad \mathbf{(32\,a)}$$

$$p_5 = C'' e^{-2ht} \cos 2 \omega t \qquad \mathbf{(32\,b)}$$

Damping, such as encountered in busbar structures, affects the amplitudes in question only slightly at non-resonance.

e. The phases of the components of the stress factor are assumed to be those obtained without current decrement and for zero motional resistance, *i. e.*, in accordance with (**21**). The mechanical constants of busbar structures are such that the phase angles are sensitive to changes of motional resistance, or to the effect of current decrement, at impressed frequencies in the vicinity of resonance only.*

On the above basis, an approximate working formula, taking into account current decrement and damping, for estimating maximum short-circuit stresses in bus supports at non-resonance is then the following:

$$p = \frac{y_s}{y_0} = \frac{2}{3} e^{-2gt} + \frac{1}{3} e^{-2ht} + C_1 e^{-0.5\alpha' t} \cos q_1 t + C_2 e^{-0.5\alpha'' t} \cos q_2 t + C' e^{(-g-h)t} \cos \omega t + C'' e^{2ht} \cos 2 \omega t \qquad \mathbf{(33)}$$

where the constants C are those of (**22**). Equation (**33**) is not applicable to resonant cases in the form given, as already indicated. The practical use of (**33**) calls for the following data:

- the two natural frequencies f_1 and f_2
- the current frequency f_c
- the current decrement constants g and h
- the motional resistance decrement constants α' and α''

Stresses at Resonance

Definition of Resonance. Resonance will be defined as the condition of cyclically increasing stress amplitudes (or vibration amplitudes) occurring when a force of a frequency equal to one of the natural frequencies (f_1 and f_2) is impressed on the bus structure. The four cases of resonance for bus structures were stated in equation (**24**).

Condition for Maximum Stresses. It is well known that, strictly speaking, the maximum deflection due to sustained forced vibrations occurs at an impressed frequency slightly different from the resonant frequency above defined,† the difference depending on the damping constant. The magnitude of the difference, however, is less than one per cent in frequency and less than one per cent in deflection, for the constants coming into question in bus structures. For practical calculations, therefore, the differences mentioned may be ignored.

*Bibliography No. 26, p. 42.
†See Bibliography No. 17, p. 463; also Bibliography No. 26, pp. 41, 42.

(A) Resonance Without Resistance and Without Current Decrement

The four cases of resonance defined in (**24**) are fundamentally similar to one another. As an illustration of the theory, the case of $u_1 = 1$ will be worked out, which is the case of resonance between ω and q_1 in equation (**21**).

As ω approaches q_1 in equation (**21**) the amplitudes C_1 and C' approach infinity. The sum of the terms $C_1 \cos q_1 t + C' \cos \omega t$ must, however, be finite for finite values of time, even if the resistance is negligibly small, since the rate of increase of stress is limited depending on the magnitude of the impressed force at resonant frequency. Mathematically, we may determine the form of the resonant component of stress factor for the case when ω and q_1 become equal, by determining from equation (**21**)

$$\lim_{q_1 \doteq \omega} \left[C_1 \cos q_1 t + C' \cos \omega t \right] = \frac{y_r'}{y_0} \tag{34}$$

where y_r' is the component of support deflection at resonant angular velocity $\omega = q_1$. By evaluating the indeterminate form contained in equation (**34**), in the customary manner, it is found that

$$\frac{y_r'}{y_0} = \frac{4\, u_2^2\, (5 - 2\, u_2^2)}{9\, (1 - u_2^2)^2} \cos \omega t + \frac{2\, u_2^2}{3\, (1 - u_2^2)}\, \omega t \sin \omega t \tag{35}$$

In equation (**35**) the sine term, containing the factor ωt, is the one expressing the progressive increase of vibration amplitude characteristic of all cases of resonance. The expression shows that the amplitude of the resonant component of stress increases at the following rate:

$$\frac{2\, \pi\, u_2^2}{3\, (1 - u_2^2)} F_0 \quad \text{for each half cycle}$$

neglecting the effect of the cosine term which ceases to be of importance after a few cycles. The increase per half cycle may be written in the form

$$\frac{\pi}{2} \left(\frac{4}{3} \, \frac{u_2^2}{1 - u_2^2} \right) F_0 \tag{36}$$

indicating that the increase per half cycle of the support stress component at resonant frequency is equal to that which would be obtained if the support were impelled directly by a harmonic driving force of the amplitude*

$$\frac{4}{3} \left(\frac{u_2^2}{1 - u_2^2} \right) F_0 \tag{37}$$

where the ratio in brackets is a modulating ratio applied to the amplitude of the resonant component of the impressed electromagnetic force. The expression (**37**) may then be regarded as the amplitude of an equivalent driving force impelling the support.

*Obtained from (36) by analogy with the corresponding term for the single-element vibrating system whose motion is derived defined by 28, as indicated in Table II, item 4.

For resonance between q_2 and ω, expressions analogous to (**36**) and (**37**) are obtained with u_1 substituted for u_2.

Since it is desirable to keep the magnitude of the resonant stress as low as possible, the non-resonant natural frequency should be as far from resonance at possible, and preferably of lower value than the resonant natural frequency.

A special case of the equivalent driving force of equation (**37**) is that occurring when the frequency $\frac{q_2}{2\pi}$ becomes very large approaching infinity. Then (**37**) will reduce to

$$\frac{4}{3} F_0 \tag{38}$$

which is nothing else but the amplitude of the impressed electromagnetic force component at resonant frequency. The result (**38**) shows that the double-element system then behaves the same as a single-element system having a frequency equal to the lower natural frequency of the double-element system, as would be expected physically.

To summarize: The maximum rate of resonant stress increase per half cycle is given in (**36**) and is approximately $\frac{\pi}{2}$ times the equivalent driving force amplitude at resonant frequency, according to (**37**). This equivalent driving force is related to the amplitude of the resonant component of electromagnetic force by a simple modulating ratio dependent on the ratio of the non-resonant natural frequency to the current frequency. An expression is given in (**35**) for the stress component at resonant frequency and shows the growth of stress amplitude due to resonance from the instant at which the electromagnetic force is suddenly applied.

(B) Effect of Resistance on Resonant Stress. Current Decrement Neglected

The essential factors defining the resonant stress transient are the amplitude of the equivalent driving force at resonant frequency; the decrement rate due to damping and the current decrement. The equivalent driving force, given in (**37**) for the case $q_1 = \omega$, is practically independent of the resistance when q_2 is non-resonant, but the rate of resonant stress increase is dminished by resistance, so that the final amplitude of resonant stress component (neglecting the electromagnetic force decrement) is n times, rather than ∞ times, the amplitude of the equivalent driving force component at resonant frequency. The significance of n, the sharpness of resonance, has already been pointed out. Current decrement will be considered separately.

The resonant stress formula for the two-element vibratory system—one of the natural frequencies only

being at resonance, the other being outside of the resonance range—will then be worked out on the following basis, when damping resistance is included:

A. That the amplitude of the equivalent driving force component at resonant frequency has the same magnitude when damping is present as for the case when damping resistance is negligible. The damping will, however, materially affect the resonant stress component, and is taken into account in accordance with *B* and *C* which follow.

B. That the final amplitude of resonant stress component is n times the amplitude of the equivalent driving force component at resonant frequency, in accordance with the behavior of a single-element system.

C. That damping resistance reduces the resonant stress increase per half cycle at the same rate for the two-element system as for the single-element system.

A summary of the terms pertaining to resonance, in accordance with *A*, *B* and *C* above, is given in Table II. The principal object of the table is to point out the analogy existing between the behavior of the single-element system (column I), and the two-element system, (column II). It is seen, for instance, in items 3, 4 and 5, that the results previously derived for the two-element system, neglecting damping resistance, differ from the corresponding results for the single-element system by simple modulating factors depending on u_2. In items 6 and 7, column II, the analogy existing between I and II is further applied to the resonant stresses in bus supports when damping is present. Thus the resistance decrement terms

$$n_1 \left(1 - e^{-\frac{\alpha'}{2} t}\right) \text{ for the sine term, item 6,}$$

and

$$e^{-\frac{\alpha'}{2} t} \text{ for the cosine term, item 6,}$$

were adopted for the two-element system by analogy with the single-element system of column I. Consequently for either system the maximum amplitude of resonant stress component is n times the amplitude of the equivalent driving force component at resonant frequency neglecting current decrement, in accordance with proposition *B* above.

TABLE II.
SUMMARY OF TERMS PERTAINING TO RESONANCE
Current decrement not considered

	I Single-element M-R-S system. See Note	II Double-element system; resonance frequency is $\frac{q_1}{2\pi} = \frac{\omega}{2\pi}$
1. Electromagnetic force	$\frac{F_m}{2}(1 - \cos x\,t)$	$F_0\left(1 - \frac{4}{3}\cos\omega t + \frac{1}{3}\cos 2\,\omega t\right)$ (5)
2. Amplitude of harmonic electromagnetic force component at resonant frequency	$\frac{F_m}{2}$	$\frac{4}{3}F_0$ (5)
3. Harmonic stress component at resonant frequency without damping	$-\frac{F_m}{2}\left(\frac{1}{2}\,x\,t\sin x\,t + \cos x\,t\right)$	$\frac{4}{3}\frac{u_2^2}{(1-u_2^2)}F_0\left[\frac{1}{2}\,\omega\,t\sin\omega\,t + \frac{5-2\,u_2^2}{3\,(1-u_2^2)}\cos\omega\,t\right]$ (35)
4. Maximum increase of resonant stress amplitude per half cycle, no damping	$\frac{\pi}{2}\left(\frac{F_m}{2}\right)$	$\frac{\pi}{2}\left(\frac{4}{3}\frac{u_2^2}{(1-u_2^2)}F_0\right)$ (36)
5. Amplitude of equivalent driving force at resonant frequency	$\frac{F_m}{2}$	$\frac{4}{3}\frac{u_2^2}{(1-u_2^2)}$ (37)
6. Harmonic stress component at resonant frequency, damping considered; approximate values	$-\frac{F_m}{2}\left[n\left(1-e^{-\frac{\alpha}{2}t}\right)\sin x\,t + e^{-\frac{\alpha}{2}t}\cos x\,t\right]$	$\frac{4}{3}\frac{u_2^2}{(1-u_2^2)}F_0\left[n_1\left(1-e^{-\frac{\alpha'}{2}t}\right)\sin\omega\,t + \frac{5-2\,u_2^2}{3\,(1-u_2^2)}e^{-\frac{\alpha'}{2}t}\cos\omega\,t\right]^*$
7. Final amplitude of resonant stress component, damping considered; *i. e.* at $t = \infty$	$n\left(\frac{F_m}{2}\right)$	$n_1\left(\frac{4}{3}\frac{u_2^2}{(1-u_2^2)}F_0\right)$ †

*Derives from (35) by analogy with item 6, column I.
†Derived from (37) by analogy with items 4, 5, and 6 in column I.
NOTE: The single-element system dealt with in column I is that defined by (28) when impelled by a driving force F_m $(0.5 - 0.5\cos x\,t)$ at resonance; *i. e.* when $x^2 = \frac{S}{M}$.

(C) Resonant Stresses Including Resistance and Current Decrement

The current decrement will be applied, as in the case of non-resonant stresses, separately to each component of resonant stress, the decrement of each stress component being the same as that of the corresponding electromagnetic force component. In the case of the stress component at resonant frequency, when $q_1 = \omega$,

the decrement term at any time t is then approximately the average of

$$e^{(-g-h)t}$$

during the time interval from zero to t, which average is

$$\frac{1}{(g+h)\,t}\left(1 - e^{(-g-h)t}\right) \qquad (39)$$

Then the stress factor at resonance, including resistance and current decrements is obtained by adding the stress factor components from (27), (29b), (32b), and from Table II, column II item 6, the latter multiplied by the current decrement term (39):

$$p = \frac{y_s}{y_0} = \frac{2}{3}\,e^{-2gt} + \frac{1}{3}\,e^{-2ht} + C_2\,e^{-\frac{1}{2}\alpha'' t}\cos q_2 t$$

$$+ C''\,e^{-2ht}\cos 2\,\omega\,t + \frac{y_r'}{y_0} \qquad (40)$$

where

$$\frac{y_r'}{y_0} = \frac{4}{3}\,\frac{u_2^2}{(1-u_2^2)}\cdot\frac{(1-e^{-(g+h)t})}{(g+h)\,t}$$

$$\left[n_1\left(1-e^{-\frac{\alpha'}{2}t}\right)\sin\omega t + \frac{5-2\,u_2^2}{3\,(1-u_2^2)}\,e^{-\frac{\alpha'}{2}t}\cos\omega t\right] \qquad (41)$$

and C_2 and C'' are the factors defined in (22). Expressions (40) and (41) apply, of course, to resonance between q_1 and ω only, the expressions for the other three cases of resonance being similar.

To summarize: An approximate expression for the stress transient at resonance is worked out including effects of resistance and current decrements. Practical estimates of peak stresses occurring at resonance may thus be obtained when the two natural frequencies, the current frequency, the initial average electromagnetic force, and the decrement constants due to current decrement and due to motional resistance of the bus structure are known.

Stresses at Near Resonance

Two kinds of stress calculations have been considered so far, namely those at non-resonance and those at resonance proper. Non-resonance covers all the cases in which the working natural frequencies differ by 25 per cent or more from the frequencies of the electromagnetic force. There is thus a gap of frequencies 25 per cent above and 25 per cent below each resonance frequency, which gap is not bridged as far as the near-resonance component of stress is concerned. It is believed that in most cases coming within the gap, rough estimates of maximum stresses may be made on the basis of the cases already solved, by interpolation. Analytical calculation of the near-resonance component of stress will not be attempted. The omission mentioned is further justified by the fact that the resonant-frequency stress component is of relatively minor importance in the total stress for those cases in which the non-resonant natural frequency is kept low, as already stated.

Damping and Decrement Constants

A single value of the mechanical damping constant—a value applicable to all cases of busbar stress calculations—can, of course, not be given. Likewise, rates of short-circuit current decrement vary according to the circumstances. For approximate calculations, however, average constants applicable without serious error to a number of cases can be selected.

Damping Constant

As already mentioned, the effect of damping on resonant stresses may be taken into account by the use of the "sharpness of resonance" defined by (30) and (31). Obviously, an increased amount of damping gives a reduced value of resonance sharpness n. Tests performed on a variety of bus structures employing copper bars and porcelain insulators gave $n_1 = n_2 = 5$, on an average. This value was used in the preparation of the stress curve of Fig. 1. Other types of bus structures require, of course, different values of resonance sharpness, in some cases well above 5.

Current Decrement Constants

In (26), exponential rates of current decrement were assumed, different rates being applied to the direct component and to the alternating component. For approximate calculations of maximum short-circuit stresses in busbars, g and h in (26) may be given the values 12.6 and 2.2, respectively, provided 1, short-circuit currents with a maximum amount of initial displacement are considered; 2, the system reactance is within the range from, say five per cent to 30 per cent; and 3, the time of the maximum stress is not later than, say, 0.1 or 0.15 sec. after the beginning of the short-circuit. Tests have shown that the maximum in exceptional cases only, occurs later than 0.15 sec. after the beginning of the short circuit.

Symbols

$\alpha = \dfrac{R}{M}$

α', α'' resistance decrement constants in free vibrations

α_1, α_2, α_3, α_4 roots defined by (12) and (13)

A electromagnetic force per busbar span per unit current

a (in.) dimension of individual busbar lamination, measured in the direction of its deflection due to short-circuit electromagnetic force.

a' (in.) overall dimension of group of busbar laminations, measured in the direction of a.

B substitution for $\dfrac{S_b}{M_b\,M_s}$

b (in.) dimension of individual busbar lamination, measured in the direction perpendicular to its deflection due to short-circuit electromagnetic forces.

b' (in) over-all dimension of group of busbar laminations, measured in the direction of b.

c_1, c_2, c_3, c_4 constants of integration.

C_1, C_2, C', C'' amplitudes of harmonic components of stress factor for zero resistance and no decrement; see (**21**) and (**22**).

e $= 2.718$

l length of busbar span, measured between centers of supports.

F_0 electromagnetic force per span for a current of I_0 per conductor $= A\, I_0^2 = 1.5\, A\, I_m^2$.

F_m maximum value of a suddenly applied pulsating force $F_m \sin^2 \omega t$

f instantaneous value of electromagnetic force per busbar span.

f_c (cyc. per sec.) frequency of current

f_1 (cyc. per sec.) lower natural frequency of bus structure

f_2 (cyc. per sec.) higher natural frequency of bus structure.

f_b (cyc. per sec.) natural frequency of busbar when supports are totally rigid.

$$g_0 = \frac{S_b}{M_b} + \frac{S_s}{M_s} + \frac{S_b}{M_s}$$

g decrement constant of d-c. component of short-circuit current

$$h_0^2 = \frac{S_b}{M_b}\frac{S_s}{M_s}$$

h decrement constant of a-c. component of short-circuit current.

k shape correction factor for the calculation of electromagnetic force.

i instantaneous short-circuit current

I_0 r. m. s. value of initial asymmetrical short-circuit current at time $t = 0$; also $I_0 = 1.225 I_m$.

I_m maximum value of a-c. component of short-circuit current at time $t = 0$.

I_s maximum value of sustained current

j $= \sqrt{-1}$

M_b equivalent busbar mass, concentrated at the center of the busbar span.

M mass of a single-element vibratory system.

M_s equivalent support mass considered concentrated at center line of busbar over the center of the insulator; M_s includes the part of the busbar mass which follows with the support in its motion.

n, n_1, n_2 sharpness of resonance, defined by (**30**) and (**31**)

ω $= 2\pi f_c$ (radians per sec.)

ω_b $= 2\pi f_b$ (radians per sec.)

P (lb. per support) maximum support stress

p stress factor for calculation of support stress

p_1, p_2, p_3, p_4, p_5 components of the stress factor p

q_1, q_2 angular velocities of natural frequency vibrations, defined by (**14**); q_1 is smaller than q_2

R motional resistance of a vibratory system

S stiffness of a single-element vibratory system

S_b stiffness of equivalent busbar in direction parallel to deflection due to electromagnetic force

S_s stiffness of support

s center spacing of parallel busbars

t (sec.) time, measured from beginning of short circuit

$u_1 = \dfrac{q_1}{\omega}$ = ratio of lower natural frequency to current frequency

$u_2 = \dfrac{q_2}{\omega}$ = ratio of higher natural frequency to current frequency

x distance measured along the busbar from the support

x (also) substitution for 2ω

y deflection of a single-element vibratory system

y_b deflection of equivalent busbar span relative to supports.

y_s deflection of support in a direction parallel to the direction of the electromagnetic force

y_1, y_2, y_3, y_4 components of y_s

y_0 average support deflection $= \dfrac{B\, F_0}{h_0^2} = \dfrac{F_0}{S_s}$

y_r' component of support deflection at resonant angular velocity $q_1 = \omega$.

Electrical Measurement of Physical Values

The Determination by Electrical and Magnetic Means of Quantities not in Themselves of an Electrical Nature

BY PERRY A. BORDEN[1]

Member, A. I. E. E.

Synopsis.—This paper was prepared under instructions from the Committee on Instruments and Measurements, with a view to forming a basis for the Committee's work in connection with electrical measurements as applied outside of the strictly electrical field. The system of classification used is in accordance with the nature of the quantity under measurement, rather than with the principle involved; and the subject is treated under nine headings.

Measurement of Temperature: There are recognized two principal methods of electrically measuring temperature; the thermoelectric circuit, and the effect of temperature upon the resistance of many conducting materials. Outlines are given of the elementary applications of these, and a number of practical instruments embodying one or the other of the principles are described. Reference is made to several types of calorimeters embodying electrical methods of temperature measurement, and to hygrometers or humidity meters, in which the principle of the thermocouple has been applied. A brief description is also given of the optical pyrometer.

Measurement of Stress, Strain or Small Changes in Physical Dimensions: General reference is made to the changes which take place in both the electrical and magnetic characteristics of materials when exposed to mechanical stresses, with particular attention given to resistance effects. Several applications of the carbon pile in strain determination are mentioned. Recent developments in the use of the piezo-electric effect of certain crystals are described; and the use of the thermionic tube and its associated circuits for measuring very small dimensional changes is briefly treated. A description of the hot-wire micrometer is given, and a note on the Haigh alternating stress-testing machine. The use of both inductive and resistance circuits in conjunction with the oscillograph for study of vibrations is described: and a reference made to the use of electrical principles in the manometer and engine indicator.

Measurement of Flow: Flow meters are described, making use of the electrical conductivity, the heat capacity and the velocity-head of the fluid under investigation. Prof. Allen's salt-water-velocity method of determining speed of flow in penstocks and conduits is treated. Descriptions are given of a number of flow meters, both for gases and liquids, in which the principle of cooling of a heated conductor is employed, and reference is made to experiments which have been carried out with a view to establishing a definite relationship between the electrical resistance of an electrolyte and its linear velocity past electrodes. Electrical methods of measuring and recording the pressure head due to velocity in a pipe are found in the "Republic" and the General Electric flow meters, both of which are briefly described. Mention is made of a recently developed method of plotting stream-flow diagrams, by reproducing the physical conditions by an electrical system and locating equipotential lines with an alternating current potentiometer.

Measurement of Velocities: The stroboscopic methods of measuring velocities, while not fundamentally electrical, are so closely associated with electrical practise as to receive considerable attention, and the "oscilloscope" for visualizing reciprocating motions is touched upon. The magnetic tachometer and the squirrel-cage speed-indicator are mentioned, as well as the ordinary electrical speed indicators, wherein measurement is made upon the current of a small generator driven by the shaft under measurement. The condenser method of determining linear velocities, and the several inductive methods used in ballistics are treated.

Measurement of Work: No fine distinction is made between work force and energy: and the standard methods of measuring electrical energy with the wattmeter are omitted, as being outside the scope of the paper. Six types of electrical transmission and absorption dynamometers are described, and a reference made to recent tests, in which the characteristics of a steam locomotive were determined by causing it to pull an electric locomotive, measurement being performed upon the regenerated current of the latter. The Gilson device for determining over-all efficiency of a power plant, by balancing in an instrument two electrical forces, one representing the fuel input, and the other the electrical output is briefly treated.

The Measurement of Radiant Energy: Many measurements of radiant energy are made by determining the heat generated when that energy impinges upon a surface; and these would strictly come under the head of temperature measurement. It is realized that it is difficult to apply the term "non-electrical" or "non-magnetic" to any radiant phenomenon: and this section of the paper confines itself to a bare mention of a number of the best known photoelectric cells, used principally in photometry and closely allied work.

Chemical Measurement: The Electrical determination of concentration of the hydrogen ion is treated in some detail. The various electrical and magnetic methods of studying and treating the ferrous metals are described, with particular reference to the "hump" method of steel treating. The application of the cooling properties of various gases upon heated wires, is mentioned, and descriptions are given of the CO_2 and CO recorders. Note is made of the fire-damp detector, and the dionic water tester.

Navigational Measurements: Coupled with measurements used in navigation are found those used in the detection of hidden conditions, such as the locating of ore bodies and water pockets. The mariner's compass is given as the oldest application of magnetic principles to physical measurements, and mention is made of the very recent application of the earth-inductor both as a compass and as an inclimometer. Special attention is given to those electrical aids to navigation developed under the stimulus of the great war, including the leader cable, radio direction-finding and methods for locating mines, submarines and icebergs, as well as sound-ranging and acoustic methods of measuring ocean depths.

Among the devices for detecting unseen conditions are mentioned the water-vapour detector, the magnetic method of locating flaws in steel, and systems which have been employed in the detection of theft or of the presence of unauthorized persons in certain places. A number of methods, more or less sound, for locating ore, oil or water deposits, are described in some detail, and under the same head are mentioned such devices as egg testers and sex detectors.

Physiological Measurements: Attention is called to the rapid advances which have lately been made in the application of electrical measurements to the diagnosis of pathological conditions. The method of diagnosing disease by the so-called "method of electronic reactions" is dismissed as not meriting the attention of electrical men until its proponents are prepared to submit a description couched in intelligible terms. Note is made of the value of electrical measurements of temperature in diagnostic work: and the electrocardiograph is treated fully, both in its application to actual studies of heart performance and in the investigation of psychological conditions. Brief descriptions are given of the "Stethophone" and the "Audiometer," both of which seem destined to fill an import-

Presented at Midwinter Convention of the A. I. E. E., New York, N. Y., February 9-12, 1925.

ant place in diagnosis and medical investigations in general.

In conclusion it is pointed out that the art of applying electrical methods of measurement to work outside of the electrical field is advancing so rapidly as to make it practically impossible that one could keep absolutely up-to-date in his knowledge of all the branches. The general effect is one of bringing together technicians in varied branches of scientific pursuit and finding for them a common ground of thought. Wide and diversified as are the practises of measurement in these branches, it is felt that the Institute forms the natural clearing house for such information; and it is to be hoped now that the ground is fairly well cleared, that the Committee on Instruments and Measurements will be kept cognizant of as many as possible of the new developments which will be made in the application of electrical principles to the measurement of non-electrical quantities.

Acknowledgment is made of the valuable help which has been rendered the author by men both within and without the electrical sphere: and a bibliography of over 300 references is appended.

* * * * *

Introduction

While the duties of the Institute's Committee on Instruments and Measurements have to do primarily with the measurement of electrical quantities used in the work of the electrical engineer, they also cover the cognizance of all electrical measurements, including the determination by electrical methods of quantities which in themselves may be far removed from the field of electrical engineering. Technicians in all branches of science and engineering have been quick to realize the advantages obtainable in performing their quantitative measurements by electrical means; and, more or less independently, these workers have developed and adopted such methods and have announced their successes through such channels as would most readily reach their interested confreres.

Electrical men have, for some time, felt that a number of important applications of their principles of measurement were thus escaping the notice of those whom they should most concern; and with a view to bringing these diverse practises under one head, the author was instructed to collect all possible information in respect to the work which had been done, and to compile the material as a basis of reference, so that the Committee might henceforth fulfil its several duties with a fair knowledge of the use which was being made of the art of electrical measurement by specialists in other fields of scientific pursuit.

The principal published sources from which information has been drawn appear in the appended Bibliography; and while this cannot, in any sense, be considered as complete, an endeavour has been made to collect such references as are available—mostly in the English language—to enable those interested to gain a working knowledge of the use which has been made of electrical principles in the developments described.

General

It is doubtful if there is any physical quantity subject to measurement, upon which that measurement has not been performed or attempted by electrical or magnetic means. Aside from all determinations of purely electrical quantities such as voltage, current and power, the electric current, by virtue of its ease of transmission, its infinite divisibility, lack of inertia, and the facility with which it may be measured, recorded or integrated, furnishes a medium almost ideal for the quantitative expression of other physical values. It is to be expected, then, that we should have a host of counting devices, time-measuring mechanisms, position indicators and kindred appliances for adding convenience to measurements already performed by other means. The principal purpose of this paper, however, is not to discuss these, but rather to consider those methods in which some inherent property of the electrical circuit is made use of to actually perform the quantitative measurement and translate the measured value into definite terms. While the greatest number of these are of an electrical nature, there are some which embody the principles of the magnetic circuit; and, because of the close association, it is only logical that they should here be classed along with the electrical methods.

The system of classification used is in accordance with the nature of the quantity under measurement, rather than with the principle involved; but the overlapping which must necessarily follow, in cases where the same principle is applied in work of differing types, has, as far as possible, been reduced to a minimum.

The types of measurement which are performed by electrical means have been divided into nine classes; and while it may seem that this system has resulted in the association of some strange neighbors, it is felt that fundamentally the grouping is that of methods basically kindred in their nature.

1. Measurement of Temperature.
2. Measurement of Stress, Strain or Small Changes in Physical Dimensions.
3. Measurement of Flow of Liquids and Gases.
4. Measurement of Angular and Linear Velocity.
5. Measurement of Work.
6. Measurement of Radiant Energy.
7. Determination of Chemical and Molecular Condition.
8. Navigational Measurement, and Detection of Hidden Conditions.
9. Physiological and Allied Measurements.

I. Measurement of Temperature

While one of the earliest applications of the electric current to measurement outside of the electrical field lies in determination of heat effects, it probably still remains the branch in which the greatest advances and developments have been made within recent years. Since temperature effects play an important

part in other electrical measurements it is fitting that this association of electrical quantities should receive the first attention. Whether the problem be one of detecting temperature changes of a microscopic part of a degree or of controling and recording the performance of industrial furnaces and boilers, the electrical method usually furnishes the most workable solution, and usually at a minimum of cost.

Until late years, the importance of accurate temperature measurement seems to have been overlooked by many branches of industry. For instance, in the treatment of steels, much was left to the judgment of the operator, with a consequent lack of uniformity in the product. And what may be said for the metal industry may be applied to almost every branch of activities wherein temperatures other than atmospheric were concerned. Recently, however, there seems to have been an awakening to the importance of accurate temperature determination, with the result that there have appeared a large number of excellent temperature measuring devices, giving not only rapid and accurate results, but making possible the reading and recording at a central location of temperature at a large number of different points.[1, 2, 3]

Most electrical thermometers are based upon one or the other of two principles, either the potential difference at a junction of two dissimilar metals maintained at a temperature differing from that of the rest of the circuit, a property discovered by Seebeck in 1821; or upon the change in electrical resistance accompanying change in the temperature of any pure metal. A very recent development depends in its operation upon the change with temperature of the magnetic permeability of certain ferrous alloys.[4]

In 1833 the thermopile was combined with the galvanometer by Nobili and Melloni to produce a temperature-measuring instrument of great sensitivity. In 1887, Boys greatly increased the sensitivity of this apparatus by combining the two elements in one instrument, so that the thermo-junction formed a part of the galvanometer loop, and swung with it in the field of a magnet. In 1881 Langley contrived another instrument of very great delicacy for measuring radiations, which he called a *bolometer*. This consisted of four very fine platinum or iron wires, forming the arms of a Wheatstone bridge connection. Alternate strips were exposed to radiation, and a measurement made of the unbalance of the bridge due to changes in the temperature, (and consequently of the resistance) of the arms. The thermo-galvanometer of Boys was estimated to indicate the one hundred-millionth of a degree, while the bolometer was capable of about one-tenth of that sensitivity.

In measurements embodying the use of the thermoelectric principle, it is usual to place one couple in as close association as possible with the body under measurement, and the "cold junction," necessary to complete the circuit, in a location where its temperature can be conveniently determined or regulated. The voltage set up in the circuit is then a measure of the temperature difference between the junctions, and therefore of the temperature of the "hot junction." Measurement of this voltage may be directly made with an instrument of the d'Arsonval type, or it may be performed with a potentiometer, which may be either indicating or recording. Where the direct deflecting instrument is used, a current in proportion to the measured voltage will flow through the circuit; and this, by the Peltier effect, will tend to equalize the temperature of the junctions, thus crowding the scale in its upper ranges. The selection of metals employed will vary with the conditions under which the measurement is made, depending upon the precision and permanency required, upon the temperature range through which the couple may be carried, and upon the possibility of corrosive effects in the atmosphere surrounding the thermo-junction.[5, 6, 7, 8, 9, 10, 11]

In one form of temperature-measuring instrument operating upon this principle, known as the radiation pyrometer, developed by C. Fery, the junction is not placed in direct contact with the heated body, but is used in combination with an optical focusing device,

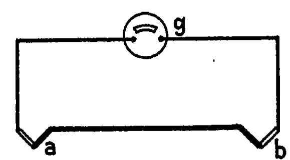

Fig. 1—Elementary Circuit of Thermo-Electric Pyrometer

(a) "Cold" couple, at standard temperature
(b) "Hot" couple, exposed to temperature under measurement
(g) Galvanometer

so that when a certain image of the incandescent surface is obtained in the telescope field, the exposure of the couple is such that the indication of an associated galvanometer is a measure of the temperature. Fery has also produced a bomb calorimeter of interesting construction, in which the steel body of the bomb is plated with copper and supported by two constantin disks. The change of temperature attendant upon combustion of the charge produces a thermo-electromotive force in the structure; and the value of this voltage is read upon a suitable galvanometer directly graduated in calories. An amplification of this principle is found in an isothermal calorimeter exhibited in 1924 by the Research Department of the Arsenal at Woolwich, England. The bomb or container in which combustion takes place is associated with a double set of thermo-junctions, one serving as a source of measurement and regulation, and the other, using the Peltier effect, to neutralize the temperature rise due to the combustion under measurement. The current in the Peltier junctions is regulated, through the agency of the thermocouples, to maintain the tem-

1. For all references see bibliography.

perature of the bomb constant within 0.0001 deg. cent. and a measurement of this current furnishes a direct indication of the rate of heat evolution.[12, 13, 14, 15, 16]

It is characteristic of all pure metals that they change their electrical resistance with changes in temperature; and this property has been widely used in measurement of temperatures. As a rule the detector employed in this class of work consists in a small coil of wire (usually copper, platinum or iron), forming one arm of a Wheatstone bridge, the remainder of the bridge circuit being at or near the point where the indication is required. (see Fig. 2). As in the case of the thermo-

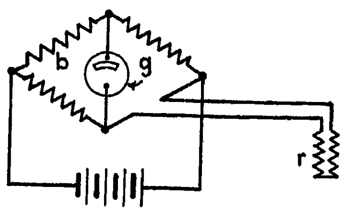

FIG. 2—ELEMENTARY CIRCUIT OF RESISTANCE THERMOMETER
(b) Wheatstone bridge circuit
(r) Resistance coil, exposed to temperature under measurement
(g) Galvanometer

electric system, the indicator may be either direct reading, in which the galvanometer in the bridge circuit is graduated in thermal units, or the galvanometer may be incorporated in a zero-reading device, either indicating or recording. In either case the simplest arrangement is that embodying the direct reading instrument; but far greater accuracy and higher precision are obtained when zero methods are used. In determination of temperatures of small areas the thermo-electric method is usually the more satisfactory; while if the

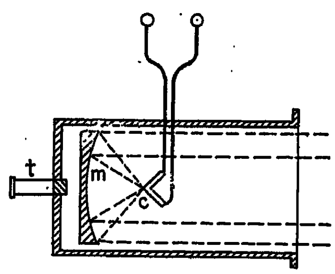

FIG. 3—RADIATION PYROMETER
(m) Concave mirror
(c) Thermocouple
(t) Focusing telescope

average temperature of a considerable mass or area is required, the resistance method is often the better. This is particularly evident in the determination of the temperatures of the windings of electrical apparatus. "Hot spots" are better located by thermocouples placed in proximity to the windings, while average temperatures of coils may be measured by closely associated resistance units or by direct measurement of the resistance of the windings themselves.[17, 18, 20, 21, 22, 23]

Another application of the electric current in temperature measurement is found in the optical pyrometer used in the determination of temperatures in the luminous range (Fig. 4). Here the heated body or surface is viewed in contrast with the filament of an incandescent electric lamp, and the current through the latter adjusted until the filament diasppears against the heated background. A reading is then made of the current, from which the temperature of the filament and consequently of the heated body may be determined (Fig. 5).[24, 25, 26, 27]

Since both the thermo-electric effect and the resistance method are particularly suited to the measurement of temperature difference, use has been made of them in determining quantities which depend primarily

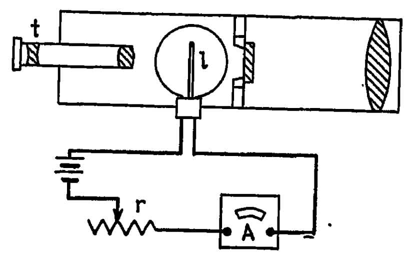

FIG. 4—OPTICAL, OR DISAPPEARING-FILAMENT PYROMETER

(r) Adjusting rheostat
(t) Viewing telescope
(a) Ammeter in lamp circuit

upon this difference. A heat-flow meter dependent upon temperature gradient in a known mass, has been developed for study of boiler-room conditions; and a humidity recorder, depending for its action upon an electrical measurement of the difference in temperature of a wet and a dry-bulb thermometer, has recently made its appearance in several forms. Another form of

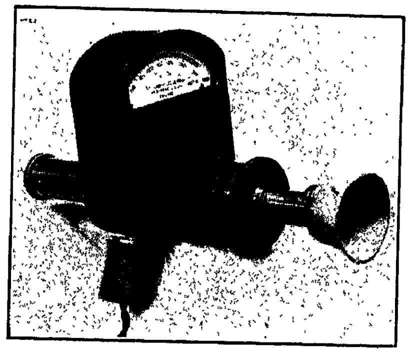

FIG. 5—OPTICAL, OR DISAPPEARING-FILAMENT PYROMETER

hygrometer, lately exhibited in England, directly determines the percentage of moisture in the air by measurement of the dew point. Radiant heat from a small lamp falls upon a polished metal surface, whose temperature is regulated by a brine coil, whence it is reflected and focussed upon a small thermo-junction in the circuit of a galvanometer. When dew forms upon the polished surface the thermo-electric current is reduced; and a distinct disturbance of the galvanometer indication takes place. The sharpness of indication and the essential simplicity of this apparatus make its use highly desirable in hygrometric work, particularly

at low temperatures. Many other applications of electrical methods of measuring temperature and temperature difference will be found in the subsequent sections of this paper.[28, 29, 30, 31, 32, 33, 34]

II. Measurement of Stress, Strain or Small Changes in Physical Dimensions

While it has long been known that molecular strain has the effect of producing measurable changes in the electrical and magnetic characteristics of many materials, the principal uses which have so far been made of these properties in measurement of the stress responsible for distortion are associated more with contact surfaces and air-gaps than with the masses of the stressed materials. The change in contact resistance accompanying change of pressure is well known in its application to the carbon pile, long used for rheostats, where smooth regulation is required. It is only recently, however, that this property has been used in precise quantitative measurement; and in a "Telemeter," lately developed in the Bureau of Standards, the inherent objections to the use of the carbon pile for quantitative work seems to have been removed by a simple system of compensation, and the principle made available for measurements requiring a considerable degree of precision. The basic idea of the tele-

(g) Galvanometer

meter lies in the use of two similar carbon stacks, built up of rings, carefully selected and ground, placed under a predetermined stress, and connected as adjacent arms of a Wheatstone bridge circuit (Fig. 6). With this arrangement, changes in temperature, or over-all pressure and other disturbing factors tend to balance out; and the force under investigation, producing a difference in pressure of the two piles, is the only external influence reflected in the electrical circuit. This principle has been used in the study of not only slowly changing stresses, but, in conjunction with the oscillograph, of vibratory forces of considerable frequency. During the last few months, experiments have been carried out by the Bureau of Standards, in which carbon piles are permanently cast into concrete structures, so that stress determinations may be made at any future time desired.[35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45]

The piezo-electric effect in cyrstals of quartz and certain salts has been employed with great success in many studies of stresses and mechanical vibrations. The best exemplification of this property is probably that found in Rochelle salt. Though its characteristic of exhibiting certain electrical potentials when under stress has been known for some time, it remained for engineers in the laboratories of the Western Electric Company in 1917 to bring this property to practical application in engineering work. By proper prepara-

tion and treatment of the crystal it was possible to greatly magnify the weak effects which had been observed; and, in general, it was found that the best effects are obtained when the crystal is submitted to torsional forces, when, under proper conditions, a potential difference of several volts may be obtained between points on the crystal before the elastic limit of the material is reached. While the earlier experiments with the piezo-electric effect were directed principally toward the development of sound transmitting and reproducing apparatus, considerable recent work has been done in its use for the measurement of stresses and vibrations in machinery and mechanical structures. The freedom from frictional or inertia effects makes the principle particularly desirable in the study of rapidly changing stresses, and the property has been used with great success in obtaining indicator diagrams of explosion pressures in heavy ordnance.[46, 47, 48, 49, 50, 51]

In the measurement of very small distances or changes of length, there has been found a valuable application of the thermionic tube and its associated circuits. In general the two points between which the measurement is to be made are attached to, or themselves become, the plates of a condenser which is a part of a tuned circuit. A microscopic change in the distance between the points is enough to materially change the capacity of the condenser, and by disturbing the tuning of the system, to introduce beat sounds or other

effects by which the change in dimensions may be gaged. [52, 53, 54, 55, 56, 57]

A novel application of combined temperature and resistance effects to the measurement of small deflections is found in a hot-wire micrometer recently exhibited in England. Two small enclosing cells each contain a loosely wound helix of copper wire. These coils are connected mechanically and electrically by a fine straight wire which holds them in a slight degree of tension. This wire forms the point of attachment of the member the motion of which it is desired to detect, and incidentally of the galvanometer in a Wheatstone bridge circuit. The two coils thus form adjacent arms of the bridge, which is balanced by two other arms in the ordinary way. Any movement of the connecting wire between the coils, in the direction of its length will lengthen one coil and shorten the other, thus changing the ratio between radiating surface and heat generated by the bridge current, and altering the relative temperature of the coils. (See Fig. 7). This, in turn, produces a change in the resistance ratio, with a subsequent unbalancing of the bridge; which unbalance may either be read directly on the galvanometer or compensated by one of the standard types of recording instruments. This arrangement has been devised particularly for application to the measurement of small deflections, such as are produced in specimens under mechanical stress and for application to bourdon tubes. It is claimed for the device, that there may be obtained a magnification of one thousand times between the original motion and the deflection of the indicator. An entirely different application of the convection of heat from small wires to the measurement of pressures is found in a thermal vacuum gage employed by some investigators. A fine electrically heated wire is placed in the evacuated space, and observations made of its resistance, as affected by temperature. As this temperature is a function of the generation and dissipation of heat, it is thus made possible to determine with great accuracy the density of the gaseous medium. [58, 59, 60]

A flexible system of studying small deflections has recently been developed by a German engineer. The points between which measurement is to be made are connected by fine stretched wires, forming a bridge circuit. This circuit feeds an oscillograph, and enables records to be obtained of movements both sustained and oscillatory. Oscillographic records of vibrations in machinery have also been obtained by connecting inductive circuits to the vibrating parts and supplying to the instrument the small currents set up in these circuits by vibratory action. [61, 62, 63, 64, 65]

A unique application of the two-phase current to mechanical testing is found in the alternating stress-testing machine, developed by Professor Haigh of the Royal Naval College, Greenwich, England. This device is used in the performance of fatigue tests on specimens which are required to withstand a great number of successive stresses. The vibrating element of the machine is excited by two-phase currents having a periodicity of about 1000 cycles per minute, and the stresses in opposite directions are equalized by balancing these currents in a differential ammeter. The armature to which the vibratory forces are transmitted carries a set of small search coils; and the average value of the stress is determined by measurements made of the voltage induced in these coils. [66]

In the "Low" oscillograph manograph, use is made of a microphone and a special very heavy design of telephone receiver, in the determination of phenomena attending the performance of internal combustion engines; and with it, it is possible to obtain indicator diagrams, as well as to determine general operation conditions, under very exacting and severe circumstances. [67, 68, 69, 70]

III. Measurement of Flow of Liquids and Gases

The flow of both liquids and gases can be determined by a number of electrical methods; and several of these have become standardized in modern engineering practice. In liquid flow meters use is made of either the electrical conductivity or heat capacity of the fluid, or electrical measuring devices may be employed as auxiliaries in the determination of the pressure head developed by the flow of the liquid through an orifice or a Venturi tube.

A highly satisfactory means of determining the velocity of flow of water, particularly applicable to large conduits, such as penstocks, is found in Prof. C. M. Allen's recently developed "salt-velocity" method. There is injected into the penstock a quantity of saline solution, the presence of which has a marked effect upon the electrical conductivity of the water. The passage of the solution is detected by means of an electrode consisting of a pair of parallel plates projecting well into the liquid and connected in series with a detector circuit. A number of schemes have been used for determining, from the current flow across the electrodes, the velocity of the water in the pipe. One is to measure the time lapse between the injection of the salt solution and the time of maximum conductivity between the electrodes situated a measured distance along the conduit. Another employs two similar pairs of electrodes, and the time interval is taken between the instants of maximum conductivity at the respective stations. While the electrical readings may be obtained with ordinary ammeters, there has been developed an ingenious recording arrangement, wherein the record appears on a graphic chart as two series of dots from which the time interval may be scaled off at leisure. [71, 72, 73]

Experiments have been carried out with a view to establishing a definite relationship between the resistance to passage of an electric current between two electrodes and the velocity of motion of the water in which they are immersed; but in the present stage of development, this relationship, while it unquestionably

exists, has been found to be of too erratic a nature to justify its employment for flow determination.[74, 75, 76]

A device designed particularly for measuring oil-flow in transformers consists in a very small ball of copper wire which is inserted in the pipe. This ball forms one arm of a bridge circuit, the other arms being varied in such a way as to maintain a condition of balance. By this means a determination is made of the number of watts necessary to keep the

little ball at a constant temperature. Referring these values to a calibration curve, it is possible to read off the flow of oil in the transformer cooling system. A somewhat similar application is found in the Griffith's depth gage, used for measuring the amount of liquid in tanks. Here the radiating conductor takes the form of a straight slender wire reaching down into the liquid

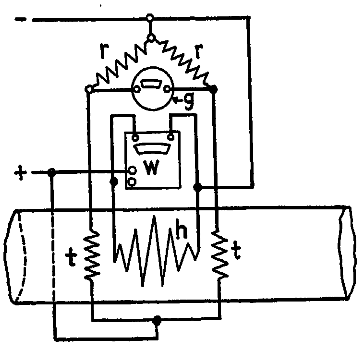

FIG. 9—THOMAS GAS METER
(h) Heating elements

(g) Galvanometer in bridge circuit
(w) Wattmeter in heater circuit

from above. A similar wire, parallel to the other, but shielded by a tube from actual contact with the liquid, serves to compensate for changes in the temperature of the liquid. The cooling of the exposed conductor is proportional to its immersion, and the unbalance so introduced is read on a galvanometer or recorded by a graphic instrument. A device of this nature, used in connection with a calibrated weir forms a very convenient flow meter.[77, 78, 79]

In the measurement of gas-flow, a wide use has been made of the principle known as the hot-wire anemometer, in which a heated wire is exposed to the flow, and an electrical determination made of the cooling effect upon the wire. For most practical conditions the indications of the anemometer depend upon the product of density and velocity. In the meter developed by Dr. L. V. King, an electrically heated wire reaches across the pipe in which the measurement is to be made and means are provided for adjusting the current so as to maintain the wire at a fixed value of resistance (Fig. 8). A measurement of this current gives the instantaneous value of the flow of gas, and the results may be obtained in an indicating, graphic or integrated form. A very similar device has been used to measure the air-intake on internal combustion engines.[80, 81, 82, 83, 84]

The cooling effect of the gas stream is made use of in a somewhat different way in the Thomas gas meter, which is based upon the measurement of the amount of heat required to raise the temperature of the gas

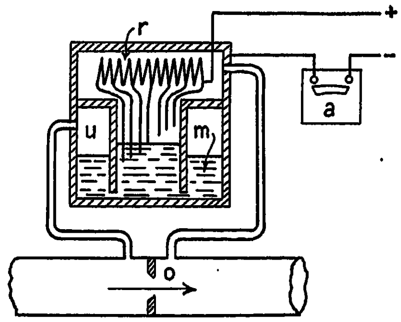

FIG. 10—REPUBLIC FLOW-METER

through a known range. Two similar resistance thermometers, forming two arms of a bridge are inserted in the main, and between these is placed a heating element. Both the heater and the resistance thermometers are well distributed over the cross section of the pipe (Fig. 9). While this meter has a number of forms, its commercial arrangement is such that a constant temperature difference is maintained between the two resistance thermometers by means of adjustment of the current flowing in the heater, and measurement is made of the power represented by this heating current. The meter is made in a recording form, and may be made to read either in pounds or in cubic feet at any desired pressure and temperature.[85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97]

The importance of knowing the amount of steam consumed in power plants has led to the development of a number of practical flow meters, which have now become standard equipment in all large steam-driven stations. The pressures, temperatures and velocities here met with prohibit the methods which are appli-

cable to ordinary gas-flow measurements and recourse is had to the orifice or the Venturi tube. The pressure-head, so developed, may then be determined by electrical means. One of the best known is the Republic flow-meter, in which the U-tube normally found as an accessory of the Venturi meter is developed into a reservoir containing mercury, which, as it rises, short-circuits the ends of a number of vertical rods of different lengths forming the terminals of resistances (see Fig. 10). Changes in the mercury level thus serve to operate a rheostat, this rheostat forming a part of a circuit supplied from a source of constant voltage. Thus, the value of current flowing in the circuit depends upon the flow through the pipe, and by properly proportioning the resistance between rods, it may be made directly proportional to the flow. The current may be made to actuate an indicator or a recording instrument; or, if desired, it may be passed through an integrating meter to produce a record of the volume of fluid which has passed through the pipe. [98, 99, 100, 101]

(m) Mercury, forming secondary of measuring transformer
(a) Ammeter in A. C. supply circuit

A development somewhat similar to the above is found in the flow-meter recently announced by the General Electric Company, shown in Fig. 11. In this, the column of mercury, instead of bridging the points of a rheostat, forms a short-circuited secondary to a small transformer. As the height of the mercury changes, the cross-section of the ring varies, and with it, the secondary conductivity. This produces a variation in the primary current which may then be measured by any of the standard methods for metering alternating current quantities. The same apparatus has been applied in the indication of vacuum and water level. [102, 103, 104]

As an illustration of the ease with which the properties of the electrical circuit lend themselves to the investigation of problems in other branches of science, there may be mentioned a method of tracing the steam-lines of flow about a ship or other diverting body placed in the path of a fluid. Use is made of the fact that the stream lines for flow past an obstacle are coincident with the equipotentials for a conductor of the same shape in an electrostatic field. A model of the figure to be investigated is placed in a rectangular tank full of water, and containing two sheets of aluminum mounted on its longer sides. Alternating-current of audible frequency is supplied to the sheets, and two electrodes, one fixed and the other movable and attached to a pantagraph which allows it's position to be recorded on a sheet of paper, dip into the water. These electrodes are connected to a low frequency amplifier and a telephone. By moving one electrode to balance out the sound, it is possible to establish a series of equipotential lines corresponding to various settings of the fixed electrode, and thus to very faithfully duplicate the conformation of stream lines in a fluid body. [105]

IV. Measurement of Angular and Linear Velocities

Where alternating-current generators are attached to rotating shafts the electrical measurement of angular velocity consists simply in determination of the frequency of the generated electromotive force which may be accomplished with one of the many forms of electrical frequency meter. In cases where the frequency meter does not possess the requisite accuracy or precision, use may be made of the alternating-voltage as an element in some more precise type of measurement. Where the problem is one of determining the relationship between two speeds, as in the measurement of slip in an induction motor, there are available a large number of stroboscopic methods either partially or wholly electrical. Some part of the revolving part of one machine may be viewed, either through a slit operated synchronously with the other, or by illumination from a source which flickers at a speed definitely related to the velocity of the other. In this conncetion the neon lamp has proved particularly valuable. Or one machine may be caused to operate a synchronous contactor in the circuit of a current which is either generated or commutated by the other. In any of these stroboscopic methods the result is a beating effect, whose period represents the difference in speeds of the machines, and which may be determined with far greater precision than could either speed alone. [106, 107, 108, 109, 110, 111, 112, 113]

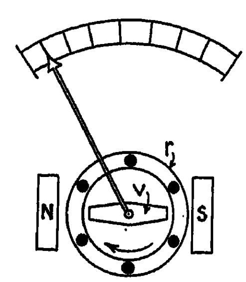

Fig. 12—Squirrel-Cage Tachometer

(n, s,) Permanent magnet
(v) Pivoted vane
(r) Rotor

Where absolute measurement of the speed of one machine is required, a stroboscopic method may still be used, the standard velocity being obtained from a pendulum or tuning fork. When comparatively low angular velocities, such as those of large generators, are to be determined, the measurement may conveniently be made by having a contactor on the shaft operate one pen on a chronograph, in comparison with another operated from a standard pendulum. An interesting application of the stroboscopic principle lies in the Elverson "Oscilloscope," a device designed for visualizing rapidly reciprocating parts of machinery.[114, 115, 116, 117]

A speed indicator depending for its action upon the modification of the main field by the cross-magnetizing effect of the armature current in a small generator is that known as the squirrel-cage type (Fig. 12). The field is produced by a permanent magnet, between the pole-pieces of which rotates a squirrel-cage very similar to the electrical circuit of an induction motor secondary. Within this cage, pivoted upon the main axis of rotation, floats on a small soft iron vane, to which is attached the pointer of the instrument. With the rotor at rest,

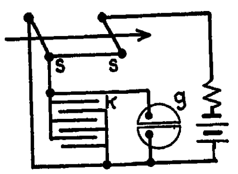

FIG. 13—CONDENSER METHOD OF DETERMINING VELOCITY

(s, s) Strips successively broken by projectile
(k) Calibrated condenser
(g) Ballistic galvanometer

the vane lies along the magnetic axis, and the pointer indicates zero. As the rotor revolves eddy currents flow in the bars, tending to set up a cross-field in the air-gap of the magnet, thus modifying the resultant direction of the field, and causing the vane to take up a new position of equilibrium. The extent of deflection of the vane depends upon the amount of field distortion, and hence is representative of the velocity of the rotor.[118]

Not unlike the squirrel-cage indicator is the well-known magnetic tachometer widely used on automobiles. Here a small permanent magnet rotates within a metal cylinder, inducing eddy-currents and dragging the cylinder around, against the counter-torque of a spring, so that the deflection is proportional to the velocity of rotation. The graduations are marked upon the outer surface of the drum, and are observed through a small window in the casing of the instrument.

The electrical tachometer, in which speed measurement is obtained by means of a small generator driven from the shaft, is standard equipment supplied by a number of manufacturers. In some forms of this type the generator produces alternating-current, and measurement is made on the frequency; but the most common form generates a direct-current the pressure of which is measured with an ordinary voltmeter graduated in revolutions per minute.

There have been developed a number of essentially electrical methods of measuring linear velocities, particularly at very high speeds such as are found in studies of projectile flight. In one of these the projectile is caused to pass through two solenoids in succession, the time interval being determined by timing the impulses set up in a current flowing in the coils. A more precise method employs the discharge of a condenser whose circuits are successively interrupted by the passage of the bullet. (see Fig. 13.) Two strips of tinfoil are placed in the line of flight, and connected in such a way that the rupture of the first removes a short-circuit from the condenser, while the breakage of the second open-circuits the source of supply. The charge accumulated in the condenser in the interval is then measured by an electrometer or otherwise; and from the characteristic curve of charge the value of the time interval may be determined with great precision. It is claimed for this method that the velocity of an ordinary rifle bullet may be determined when the strips are only an inch apart. The method has also been applied to measuring the duration of very short intervals of contact; and a similar device has been adapted for the determination of angular velocities.[119, 120, 121, 122, 123, 124, 125, 126, 127, 128, 129, 130]

In an apparatus developed by Mr. R. Ferguson of the Research Department, Woolwich Arsenal, for determining flash velocity and pressure factors of ignitory detonators, the detonator is placed on the top of a vertical tube. The hot ionized gases rushing down the tube close successively two circuits of a battery, condenser valve and one string of an Einthoven galvanometer, from which records of the speed can be obtained. Between the tube and the steel block upon which it rests is placed a turmaline crystal in circuit with a valve and a ballistic galvanometer to measure the piezo-electric current generated by the pressure of the explosion.

V. MEASUREMENT OF WORK

In a general study of the measurement of work, it is not necessary that hair-splitting distinctions be made between *work, force* and *energy*; and some of the methods particularly applicable to the one quantity, are so principally because of their adaptability to the other. Since energy may, itself, be an electrical quantity, the wattmeter and the watthour-meter may be looked upon as instruments performing measurements of work; but, leaving these, which lie outside the scope of this study, there remain a number of devices for measuring physical work by electrical means.

The most common device for direct measurement of work is the dynamometer; and both the transmission and absorption dynamometer have appeared in electrical forms. The transmission type usually takes the form of a torsion meter, measurement being performed

either upon a portion of the main shaft of the unit under test or upon a prepared member of known resiliency.

In the Moore dynamometer, a special spring is inserted in the shaft upon each element of which is mounted a small alternating-current generator. The two generators are identical in design, and are excited with their fields in series from a common source of direct-current. When there is no torque in the shaft, and consequently no twist in the spring, the adjustment of the machines is such that they are of exactly opposite polarity. However, as soon as any angular displacement occurs, a resultant voltage appears, the two generated voltages being no longer in opposition; and since this voltage is a function of torque multiplied by speed, a properly calibrated voltmeter will give a direct measurement of the energy being transmitted by the dynamometer. By measuring either of the component voltages alone, a direct determination of the velocity of the shaft may be obtained.[131]

An interesting form of dynamometer, developed by Messrs. Johnson and Denny, operates on the induction principle, using a differentially wound telephone as a detector. On the shaft in which the torsion is to be measured there are fixed at a suitable distance apart, two light non-magnetic wheels, each carrying a permanent magnet with a rather sharp point. Fixed near the periphery of these wheels are inductor units consisting of sets of little coils arranged about a small angle of the arc of rotation. Each coil of the inductor may be separately connected to the detector circuit by means of dial switches, so that it is possible to oppose any coil in one unit to any coil in the other, through the telephone detector. By using different numbers of coils on the respective inductors a vernier arrangement is obtained, so that by setting the dial switches, coils varying by small angular increments on the two wheels may be opposed. In operation the dials are manipulated until a condition of least noise in the telephone is obtained, when the angle represented by the setting is that of torsion of the shaft, from which value the transmitted power may be computed.[132]

Another electrical type of torsion meter developed by the same investigators depends upon the variation of the constants of a transformer with change in the air-gap. Two iron sleeves, carried on the two ends of the shaft under test, form a part of the magnetic circuit of a small transformer. As the torsion of the shaft varies, the air-gap between these sleeves changes, with the consequent result, that owing to the redistribution of flux, there is a change in secondary voltage. The torque is then determined from the indications of a voltmeter in the secondary circuit. A modification of this arrangement, due to Moullin, includes a generator driven from the same shaft, so that, the frequency changing with the velocity, the current through the magnetizing coil is independent of the speed of rotation and gives a direct measure of the twist or torque in the shaft. This current, bearing a linear relationship to the torque, may be measured either directly in an ammeter or recorded by an oscillograph. This form of the instrument has been found particularly useful in measuring the torque in Diesel engines and other prime movers.[133, 134, 135, 136, 137]

In the absorption dynamometer, the energy transmitted from the shaft is all converted into heat or electrical energy, the measurement performed upon the factors controlling the conversion. There are two principal electrical forms of this dynamometer, known respectively as the eddy-current, and the generator types. In the eddy-current dynamometer the power under measurement is delivered to a disk or other form of short-circuited conductor rotating in an adjustable magnetic field. The torque is opposed by weights, as in the prony brake, but the retardation is adjusted by regulating the field current to a value where a condition of equilibrium exists. The actual quantitative measurement is made upon the weights, and the electro-magnetic effects may be said to serve only as a convenient means of absorbing the energy. The generator type of dynamometer has provision for making a direct measurement of either the mechanical torque or the electrical energy produced. The best-known form of this apparatus consists in a direct-current generator, having its field structure carried on knife-edges, allowing it to rotate through a small angle against a measured force. The output of the generator may be regulated and also metered, thus providing two independent means of determining the value of the power. In many instances an added advantage of this scheme lies in the possible regenerative use of the dynamometer, the power being returned to the main circuits of the plant or employed for other useful purposes. Perhaps the most recent development in electrical dynamometers is that in which an electric locomotive is made use of in testing a steam locomotive. The latter pulls the former along the track; and load is supplied by making use of the regenerative feature of the electric unit, electrical power being back-fed into the trolley and measured with ordinary electrical instruments.[138, 139, 140, 141, 142, 143, 144]

An interesting though hardly precise form of power plant instrument recently developed in England is the Gilson "Efficiency meter," devised for the purpose of giving, at any time, an indication of the efficiency at which a steam-driven plant is operating. The metering element consists in a movement similar to that used in the power-factor meter, wherein a pointer takes up a position representative of the ratio of two currents flowing in separate windings. One of these windings is supplied with current whose value is controlled by the rate of fuel supply to the boiler, while the other receives its current from a transformer or shunt on the main bus. The ratio of these two quantities, as shown on the indicator, will then be a rough measure of the over-all efficiency of the unit under consideration, or of the whole plant, according to the arrangement of the

electrical circuits. The limitation of this type of instrument would appear to lie in the precision with which the input energy may be measured; and it would seem that in hydroelectric plants or in stations using powdered or liquid fuel, where a fairly accurate and continuous measure of the input may be obtained, it might find considerable application, particularly if a differential instrument instead of a ratio type of indicator were employed, the final measurement being one of over-all losses rather than of efficiency.[145]

VI. The Measurement of Radiant Energy

The close association which exists between radiant and electrical effects, as we now understand the terms, gives rise to a host of points of contact between the two classes of measurable quantities. But because of the difficulty of definitely applying the term "non-electrical" or "non-magnetic" to any radiant phenomenon, we are limited in this study to a few of the more outstanding measurements where we may safely feel that we are not too far trespassing upon the preserves of the physicist.

The effect of light upon the electrical resistance of selenium and similar metals is familiar to all; and while many uses have been made of this property, it can not be said that any great progress has been made in the quantitative measurement of illumination by this means. This is due principally to the selective quality of these materials for various wave-lengths differing from that of the retina of the eye, to such an extent as to render impracticable, the replacement of the eye in photometry. A lack of constancy which further characterizes selenium precludes its use for measurements where there is need for any degree of maintained accuracy. Recent researches have placed before us a mass of valuable material in regard to the relations between radiant energy and electric-current phenomena; and the new developments in photo-electric cells already in evidence point to a great expansion in the application of electrical principles to the practice of photometry and allied measurements. The photoelectrical properties of the materials which have been investigated may manifest themselves in a change of electrical resistance or of thermo-electro-motive forces, a change in the electron discharge in an evacuated tube or by a definite electrical potential difference between parts of the specimen under exposure to the radiant energy. A photo-electric cell developed in 1923 by the General Electric Laboratories utilizes the principle of electronic discharge, and has already found wide application in the sorting of materials according to colour.[146.........179 incl.]

The best-known methods of measuring radiant energy are, however, those which employ the thermal effect due to the impinging of the energy upon a surface to be heated; but these are more properly discussed under the head of "Temperature Measurement," and as such have been briefly touched upon in their elementary forms, as the thermo-galvanometer and the bolometer, and will be further referred to in the discussion of iceberg detectors under the heading of "Navigational Measurements."

VII. Determination of Chemical and Molecular Conditions

The rapidly closing gap between the phenomena of chemistry and those of electricity has been bridged be electrical measurement so often as to make it probable that the writer of a few years hence will not be able to class measurements in the field of chemistry as applying to "non-electrical" quantities. Electrical measurements have so intruded themselves into the work of the chemist as to make it appear that in the very near future his voltmeter, his potentiometer, and his oscillograph will be as much a part of his standard equipment as are his present-day reagents and balances.[180]

An electrical measurement which has found very wide application in both organic and inorganic chemistry is the determination of hydrogen ion concentration. The essential characteristic of an acid is its replaceable hydrogen atom, or, in terms of the theory of electrolytic dissociation, its ability to give off hydrogen ions in water solution. In general it may be said that the amount and the speed of the action of an acid is dependent only upon the concentration of the hydrogen ions. When a metal is dipped into an acid solution there at once takes place an interchange of ions, resulting in the establishment of a definite electrical potential between the metal and the solution. If two similar electrodes are dipped into two solutions of different concentration, and these solutions be electrically connected, the potentials will be different; and if an external circuit be provided there will be a tendency for current to flow between electrodes. The potential difference will be proportional to the concentration of the ions of the electrodes in the respective solutions. If, then, an electrode of hydrogen is used, there will be developed, in such a cell, a potential representative in its value of the concentration of hydrogen ions in the electrolytes. Such an electrode may be prepared by depositing a film of finely divided platinum, palladium or iridium upon an inert metal and saturating it with hydrogen gas at a definite pressure. The metal is inert as regards hydrogen ions; hence any electrical potential developed between electrodes is due to the respective concentrations of hydrogen ions in the solutions.[181, 182, 183, 184, 185, 186, 187, 188]

As any flow of current at the time of measurement will have an effect sufficiently disturbing to vitiate the results it is necessary that the measurement of potential be made by some method wherein no current is drawn at the time of reading. There are three general methods whereby this may be done, embodying the use respectively of the quadrant electrometer, the condenser and the potentiometer. Of these the last named is capable

of giving the greatest accuracy, and is probably more convenient in its operation than either of the others. Any of the standard laboratory types of potentiometer may be used; and, if required, the apparatus can be obtained in a continuously recording form. The electrometric method has been successfully applied in determining the acid content of lubricating and transformer oils.

An interesting use of the oscillograph in chemical work is found in a recently published study of the rate of diffusion of certain metals in solutions of their salts. This work, carried on by Professors Miller and Burt-Gerrans, of Toronto University, consists in a detailed study of the intensity of concentration of electrolytes during short time intervals after the application. While it is essentially a fundamental investigation in pure science, it is one whose results should have immediate application in such work as battery charging from rectified currents, and electrolytic processes in general.[189, 190, 191, 192, 193]

Much has been accomplished in the adaptation of electrical measurements to studies of the chemical and molecular properties of steel and ferrous metals in general. A rather indirect method of determining

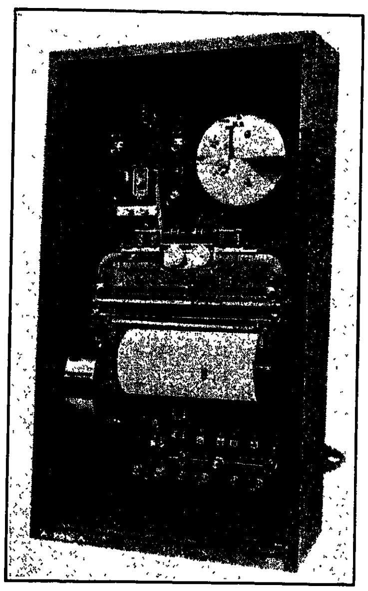

FIG. 14—CALLENDAR (CAMBRIDGE) RECORDER

the carbon content of a steel consists in passing the carbon dioxide produced by direct combustion of the metal into a solution of barium-hydroxide of known resistance and basing the results upon a determination of the increased resistance of the solution due to the precipitation of barium ions. In a practical development of this method, as worked out by Messrs. Cain and Maxwell, of the Bureau of Standards, great accuracy has been obtained, and results can be produced in a very short time. The products of combustion are passed through a special absorption vessel, and the electrical resistance measured by means of an alternating-current bridge operating on commercial frequency. The resistance values are then applied in a special nomographic chart which compensates for temperature conditions and gives a direct reading of the percentage of carbon in the steel.[194]

Through a system of magnetic analysis, the percentage of carbon in steel is determined in the "Carbometer" developed by Messrs. Malmberg and Holmstroem. The method requires a test piece cast in a special mold to fit a space provided in the apparatus so that it be-

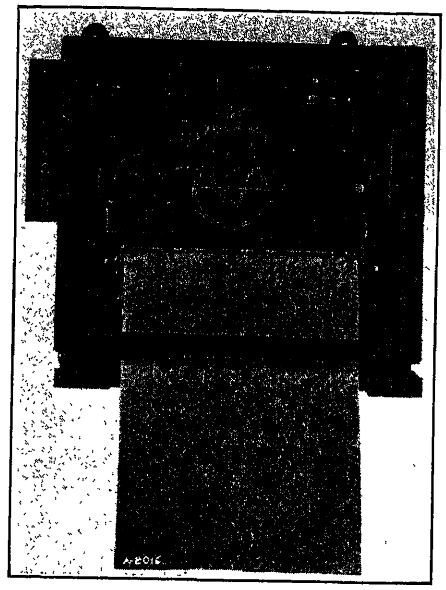

FIG. 15—LEEDS & NORTHRUP RECORDER

comes a part of the magnetic circuit of a special type of generator. The action of the generator, which is operated by clockwork, is to expose the specimen to the alternate action of two magnetic fields of different intensity. After a few cycles of magnetization the relation between the greater and the lesser induction becomes practically constant, and the armature of the generator comes to rest in the position which gives the stronger field through the specimen. By depressing a button, the armature is then caused to rotate to the position of weaker field and the change of flux determined by a coil linked with the magnetic circuit and connected to a ballistic galvanometer. Since the reading is representative of the difference of the two fluxes in the one specimen it has been found that slight flaws, cracks or roughnesses have but little effect upon the final results. With the same treatment it is found that a very definite relationship exists between the readings of the galvanometer and the percentage of carbon in the specimen, enabling determinations of carbon to be made with an accuracy equivalent to that obtaining with the most careful chemical analysis. The carbometer has also been applied in the determination of the amount of other metals such as aluminum, silicon, manganese and chromium in the iron.[195, 196, 197, 198]

Certain operations in the treatment of steel and ferrous alloys in general should take place at definite temperatures which are closely related to what are known as the "transformation points" of the metal. At these critical points there occur important changes in the internal characteristics of the steel; and these, being reflected in a number of electrical and magnetic phenomena, may be determined with great accuracy by electrical means. The critical points have been studied by observations of the thermo-electric effect, the electrical resistance, the magnetic permeability and the heating and cooling curves; and while there does not as yet seem to obtain a perfect agreement among the several methods, there has been collected a vast amount of data, enabling heat treatment to be carried out with an accuracy and precision quite sufficient for the most exacting requirements of modern industry.[199]

The thermo-electric method of determining the transformation points of iron-carbon alloys consists in making up a combination of thermo-couples in which the iron under investigation in the form of a fine wire, forms a part. To the two ends of the wire specimen are welded thermo-junctions, usually platinum, platinum-rhodium; and the wire is placed in a furnace in such a way that there is a slight temperature gradient between its ends. The thermo-couples give the temperatures at the ends of the wire, while the voltage between the platinum leads represents the thermo-electromotive force of the iron against platinum for the temperature and temperature range indicated. The results of these measurements, when plotted graphically, show a distinct discontinuity in the relationship of the respective curves as the critical ranges of the alloys are reached, and make possible the accurate determination of the temperature at which the transformations take place.[200, 201, 202]

In studying the critical ranges of iron by the resistance method, a curve is plotted of electrical resistance against temperature, when it is found that distinct points of inflection make their appearance at temperatures corresponding to the transformation points. When the magnetic method is employed curves of permeability are plotted against temperature, giving very precise results until the magnetic characteristic of the iron almost disappears, at a temperature of about 780 deg. cent.[203]

The method which seems to have found the greatest use as a basis of heat treatment in industry is that based upon a study of the heating or cooling curves of the material. As the changes which occur at the critical points are accompanied by an absorption or evolution of heat, it follows that under the condition of heat being supplied to or abstracted from the specimen at a uniform rate, the temperature of the metal will not follow a uniform law of change, but will pause at a more or less constant value until the change in the structure of the material is completed, when it will resume its change in proportion to the transfer of heat. As a result of this characteristic a curve of temperature of the metal will exhibit a "hump," which indicates the transformation point of the material, and thus gives a very definite point of reference for the control of tempering or hardening operations. A practical apparatus utilizing this principle for the treatment of steel employs a standard type of potentiometer-pyrometer, making its record upon a strip of coordinate paper. The record takes the form of a series of temperature cycles as the furnace is heated and cooled, and as each batch approaches its maximum temperature, there is noted a distinct "hump" in the curve, as the transformation point is reached. (Fig. 16) By carrying the heating to a specified amount beyond this point, and then quenching, (or annealing, as the case may require) a very high degree of uniformity of product in various batches is virtually assured. This method in the past few years has found a wide application both in the heat treatment of tools and dies, and in production work, such as the hardening of gears, ball-races and small parts for automobiles and other machinery.[204, 205, 206, 207]

Certain phases of the chemical analysis of gases may be performed by electrical methods based upon thermal conductivity. Some of the earliest work on this principle was done in England by Mr. G. A. Shakespear; and his method has since made its appearance in a practical form of carbon dioxide recorder, produced both in England and America. The fundamental action of the device is in reality that of the hot-wire anemometer. In practise there are usually two similar heated wires, enclosed in adjacent cavities in a metal block, forming two arms of a Wheatstone bridge. One of the wires is exposed to air or some standard gas, while the other operates in an atmosphere of the gas to be measured. (Fig. 17.) Any difference of temperature, as indicated by an unbalance of the bridge, must then be due to a difference in the thermal conductivity of the gases, from which the characteristics of the gas under investigation may be determined. This apparatus is available in a graphic form, so that a continuous record may be obtained where desired, as in the case of flue gas analysis in power plants. The principle of this device has also been successfully applied in the following measurements: Hydrogen in electrolytic oxygen, Oxygen in electrolytic hydrogen, SO_2 in contact gases and the permeability of fabrics. Another electrical method of determining the percentage of CO_2 in a flue gas bases its results upon the change of resistance of solution through which a sample of the gas is passed. This has already been discussed among the methods for determining the carbon content of steel.[208, 209, 210]

As an accessory to the carbon dioxide recorder, there is sometimes furnished a carbon monoxide recorder, which, while of very similar construction to the former, operates upon a somewhat different prin-

ciple. (Fig. 18.) As in the CO_2 recorder, there are found the two wires in adjacent chambers, forming a part of a similar circuit. Here, however, the wires are kept at a much higher temperature than in the CO_2 recorder, so that the conductor in the active chamber serves as a catalyzer and ignites any CO, which may be present. The rise in temperature due to the combustion is much greater than that which is produced in the CO_2 meter by the change in heat conductivity of the

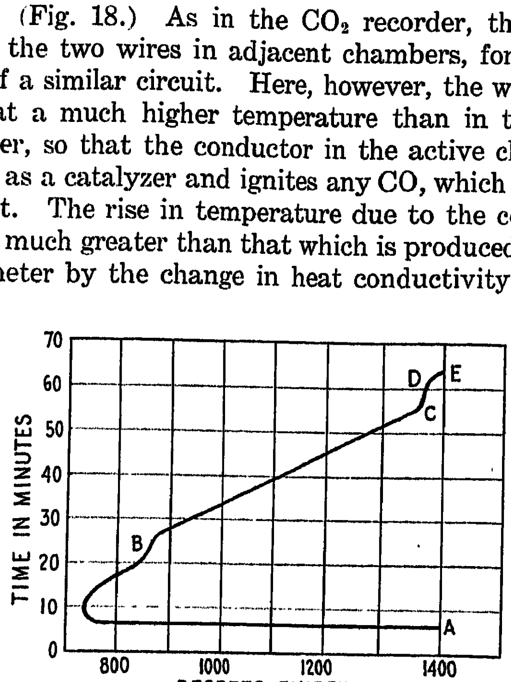

Fig. 16—Chart Showing the "Hump" Method of Steel Treatment

gases, completely overshadowing any change due to the presence of incombustible components and furnishing an almost perfect indication of the presence of CO, or, to be more precise, of ($CO + H_2$), in which terms the instrument is sometimes calibrated. Or, as is sometimes done, a determination of CO may be made by

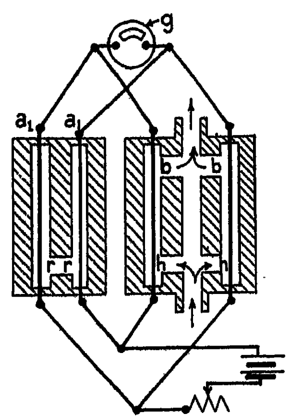

Fig. 17—Electrical CO_2 Meter

(a, a) Chambers containing inert gas or air

(r, r) Balance resistances
(h, h) Variable resistances
(g) Galvanometer in bridge circuit

converting it into CO_2 and passing the gas a second time through a CO_2 meter. Another form of CO recorder uses the electric current as a catalyzing agent only, leaving the final determination to a measurement of the change in volume between the incoming and outgoing gases.[211, 212]

The catalytic property of heated platinum in the presence of certain combustible gases has found an important use in the fire-damp detector used in coal mines. The principle of the several forms is essentially that of a Wheatstone bridge containing in its circuit one or more arms of platinum wire. In an atmosphere containing fire-damp local combustion raises the temperature, and consequently the resistance of the platinum arms, and produces an unbalance which may be read quantitatively on a galvanometer, or may be made to operate a relay, giving an alarm of the presence of the combustible gas.[213, 214, 215, 216, 217]

In the Dionic water tester of Messrs. Digby and Biggs, produced by Evershed, we have a very interesting application of the use of the electrical conductivity of water as a basis in the determination of the percentage of impurities. The instrument consists in a form of direct reading ohm-meter, similar to the well-known Megger, supplied with a specially designed water cell and graduated upon its scale in units of conductivity. By means of tables furnished by the makers

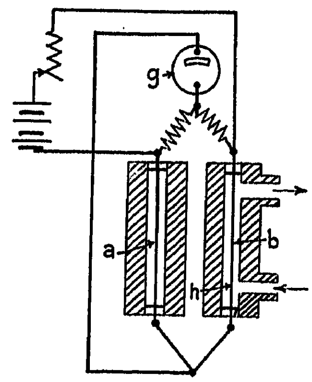

Fig. 18—Electrical C O Meter

(r) Fixed resistance
(h) Variable resistance and ignition
(g) Galvanometer in bridge circuit

of the instrument, it is possible to determine and measure almost infinitesimal quantities of dissolved substances. The principal uses of this instrument are found in the testing of water supplies for cities and for use in power plants, as well as in determination of leakage in surface condensers. Similar applications have very recently been made of electrical conductivity measurement in the determination of the characteristics of organic solutions; and probably the most recent lies in the electrical measurement of the percentage of butter fat in cream.[218, 219, 220, 221, 222, 223, 224, 225]

VIII. Navigational Measurements and Detection of Hidden Conditions

The earliest application of magnetic principles to physical measurement lies undoubtedly in the mariner's compass. The fact that the earth is surrounded by a field, so that a magnetic needle takes up an approximately north and south position seems to have been known to the Chinese at least a thousand years before

the beginning of the Christian era, and two thousand years before this property was known in Europe. Indeed as early as the third or fourth century "Chinese vessels navigated the Indian Ocean under the direction of floating magnetic needles pointing to the south." (Humboldt.) For centuries the magnetic compass has changed but little in form; and until very late years there was found no substitute for the simple structure of a small magnet carried on a frictionless bearing and kept in a reasonably level plane. The prime cause of recent improvements in the magnetic compass is the extremely disturbing condition to which aviation instruments are exposed. This has led to the utilization of the earth-inductor, in which a coil of wire is caused to rotate in the earth's field, the magnitude of the voltage so generated being a function of the orientation of the coil with respect to the earth. The earth inductor has been used thus, not only as a compass but as an inclinometer.[226, 227, 228]

Like many other branches of science, the use of electrical and magnetic aids to navigation received a powerful stimulus in the great war, and for many months the rivalry, not only between contending forces but among friendly navies in their efforts to outstrip one another in the development of these methods of guiding themselves through unchartered waters, knew a keeness which has never been equalled in times of peace. While many of the results of such work have been strangled with red tape, a goodly proportion actually found their way into actual use, and rendered great service; and some have survived to the extent of becoming standard practise, not only in our navies but with the merchant marine of the present day. Leaving aside the gyroscopic compass, a pre-war development employing electromagnetic principles in only an auxiliary sense, there may be mentioned under this head the leader gear, the several systems of radio direction-finding and beacons, as well as electrical applications in depth-sounding and the location of icebergs and other obstructions.[229]

The leader-cable, now permanently installed in several important waterways, was originally developed by Drs. L. A. Herdt and R. B. Owens of McGill University, and a trial installation successfully operated near Sorel, on the St. Lawrence River in 1903 and 1904. The cable is usually laid in the navigable channel; and the ships which make use of it are equipped with sensitive detecting apparatus whereby they may be kept in a position directly over the course of the cable. The particular use of the leader-gear lies in enabling ships to find and enter an estuary in foggy weather, and when usual aids to navigation, such as buoys, light-ships and landmarks, are obscured. The scheme embodies an inversion of some of the systems which have been used for locating faults in defective circuits, in that an alternating current carried in the cable induces effects in the detector circuit at the point of observation. A signaling key is inserted in the cable circuit at the transmitting station; and this enables the current to be interrupted, so that messages may be transmitted if desired. The distortion of magnetic field from the cable, due to the iron in the construction of the ship has a favorable effect, in that it greatly increases the closeness with which the ship may be kept over the line of the cable. With receiving coils mounted on the side of the ship, signals are good up to about 400 yards; and with an auxiliary system of towed electrodes, the cable may be detected at more than 1200 yards.[230, 231, 232, 233, 234, 235]

Quite apart from its sphere of communication, the principle of the wireless telegraph has been employed in a number of systems of direction-finding by radio; and these are proving of inestimable value, particularly in the navigation of coastal waters. There are at present three principal methods by which radio is applied in direction-finding. The best-known of these, the Bellini-Tosi, system employs two land stations or "beacons," sending more or less continuous signals of prearranged characteristics. The ship, equipped with a rotatable loop-antenna, is able to determine the directions from which the respective signals emanate, as well as the angle subtended by them. It is then possible, either by communication with these stations or by direct computation, to quickly and precisely determine the position and course of the vessel. Several modifications of the rotatable-loop receiving antenna are in use.[236, 237, 238, 239, 240, 241]

In the short-wave Marconi system, transmission is made from a coil instead of from the usual aerial and the coil is maintained in rotation at a constant rate about a vertical axis. A maximum amount of energy is radiated in the plane of the coil; and in a perfect system no signals can be obtained in a plane perpendicular to this. The result is a rotating radio beacon. The ship picks up the signals on its ordinary aerial system; and as the transmitting coil rotates, the intensity of the signal varies from a maximum to zero twice for each revolution. When the intensity is zero, the navigating officer knows that the plane of the coil is at right angles to him. A system of distinguishing signals transmitted by the coil when it is due east and west, and when due north and south serves to establish a time upon which the officer may base his calculations and determine the direction from the transmitting station. Two such beacons determine the position of the ship.[229]

Another type of beacon carries two coil-aerials with their planes displaced through an angle of about 135 degrees, a signal being sent alternately from one and the other coil. A ship located on the bisector of the angle between the coils will receive the two signals with equal intensity. Thus a definite course may be held simply by navigating so that the signal strength from the two coils remains balanced.[242, 243, 244]

During the war there were developed numerous electrical and magnetic methods of locating submarines and floating mines; and while, for some of these, most extravagant claims were made, and others, owing to

the sudden cessation of hostilities, proved abortive, there yet remain a number which rendered yeoman service under actual warfare conditions. Apparatus employing the piezo-electric effect of crystals was developed, depending for its operation upon the response of the crystals to vibrations set up by the propeller of the submarine; but the best known, and probably the most useful were those schemes using the alternating magnetic field, and operating on a principle basically that of the Hughes induction balance of 1879.

As an outstanding example of this application, may be mentioned the work done by Messrs. J. B. Whitehead and L. O. Grondahl, first at Johns Hopkins University and later, on vessels afloat, under the jurisdiction of the U. S. Navy. The elementary construction of the device used consists in a long alternating electromagnet, having within its field, but some distance away, a detecting coil, so placed that normally no electromotive force is set up by the field of the magnet. If a considerable mass of magnetic material comes within the range of the magnet, the disturbance of the field is sufficient to upset the balance, causing in the detector circuit a voltage, which not only reveals the presence of the distrubing element, but may also give an indication of its direction.[245]

In measuring the depth of navigable water, as well as in detecting the presence of icebergs or other obstructions, in foggy weather, advantage has been taken of the known speed of propagation of sound waves through the medium. A characteristic sound wave is produced, and the distance determined by the time elapsing until its echo is received. While this is not primarily an electrical method, the success which has attended its use has been due almost entirely to the use of electrical means both for the production of the sound and for the sensitive and accurate determination of the instant of its return. Employing the linear induction motor developed by Professor Fessenden for this purpose, it has been possible to establish communication between moving ships by telegraph, and even for short distances by telephone.[246, 247, 248, 249]

Considerable work has been done in various quarters in the detection of invisible objects by heat radiation. In general, a sensitive thermo-electric cell is used in the focus of a parabolic reflector and the presence of any object of a temperature differing from that of the background of the field of the reflector sets up electromotive forces which are detected by a sensitive galvanometer in the circuit of the cell. During the war this device was made use of in such work as detecting the presence of reconnoitering and working parties in "No-man's land." A similar development is that of A. Larigaldi of Paris for detecting icebergs at sea. In this he makes use of a tellurium cell, very sensitive to a band of heat waves in the infra-red, which have a peculiar property of traveling through fog with little loss of intensity. The cell is protected from air currents and stray radiation by being mounted in a small glass housing fitted with a window of sylvinite, (a crystal transparent to this particular band of radiation), the whole being mounted at the focus of a searchlight mirror about three feet in diameter. The resistance of the tellurium element is balanced in the usual way; but an innovation is introduced in the use of currents of telephonic frequency, and the detection of a condition of unbalance by the use of thermionic amplifiers and a telephone. The mirror is mounted so as to sweep the horizon, and an adjustment is made for minimum disturbance in the telephone. If, for some reason, radiation from the horizon is interrupted by an iceberg (or other obstacle), a sound will be heard in the telephone every time the searchlight is turned toward that particular direction. By this means, large icebergs have been detected as far as six miles away.[250, 251]

An interesting application of the electrical resistance thermometer to navigational purposes is found in a method of iceberg detection developed by L. V. King and H. T. Barnes of McGill University. A continuous record, to a very small part of a degree, being obtained of the temperature of the water through which the vessel is passing; the presence of an iceberg manifests itself by a lowering of this temperature due to the surface layer of recently melted water which has not yet mixed with that of the ocean. While in conditions of calm weather this method has much to recommend it, it has been found that disturbing conditions, such as introduced by ocean currents, are too great to make it infallible in its results. Experiments are still in progress in connection with the applications of this method of recording ocean temperatures to various practical applications, such as meterology.[252, 253]

Much valuable work was done during the great war in the practise of sound-ranging on land. In general there were placed at predetermined locations two or more sound detectors, circuits being carried from these to a central point, where records were made by an Einthoven string-galvanometer or an oscillograph. One form of detector was made up of a bolometer placed behind a very thin rubber diaphragm. A sound wave impinging upon this film caused a momentary condensation and rarefaction of the air about the bolometer, with a consequent impulse in the electrical circuit. By scaling the spacing of the several impulses as recorded by the galvanometer, it was possible to triangulate for the location of the origin of the actuating sound. In this way enemy guns were located with a high degree of accuracy.

The principle of the hot-wire anemometer has been applied in a form of inclinometer for use in aviation. The heated conductor is enclosed within a tight tube, and its cooling depends upon the convection currents in the enclosed air, which currents are much modified by the position of the tube with respect to the horizontal. It is thus possible to obtain from the instruments in the bridge circuit of the anemometer a direct indication of the inclination of the machine. The earth-inductor

referred to in an earlier paragraph, has also been used as an inclinometer.[254, 255, 256]

A very sensitive device for the detection of water vapour in closed pipes has been developed by Messrs. Weaver and Ledig of the Bureau of Standards. A small glass cell is coated on the outside with a platinized surface having its electrical conductivity broken by an etched line. The two areas of metal are connected to separate leads sealed into the glass. The line of separation is painted over with some hygroscopic electrolyte, and the outside of the cell is exposed to the gas whose purity it is desired to observe. The leads are connected into the circuit of an alternating-current bridge; and measurements of the resistance of the cell furnish a very precise indication of the quantity of water vapour which may be present in the gas.[257]

A method originally developed in the Bureau of Standards for the determination of the uniformity of specimens for magnetic tests was turned to a very practical application during the war, in the location of flaws in steel for rifle barrels. In this apparatus the iron under investigation forms a part of the magnetic circuit of a form of continuously operating permeameter; and as the specimen passes slowly through the instrument, irregularities in its structure make their presence very evident by marked changes in the reluctance of the material. It is possible that this method may find application in the testing of such materials as steel rails and cables.[258 ...... 278 incl.]

Many ways have been proposed for the location of ore bodies beneath the surface of the ground, of water pockets, and of buried treasures in general; and these, like methods of producing rain, may be classed as either religious, magical or scientific; and, as in rainmaking, while a study of the first two does not come within the sphere of this paper, an analysis of the so-called scientific methods is generally productive of the most disappointing results. Most of the electrical methods which have been suggested embody either an application of the Hughes induction balance or some most delicate system of electrostatic measurements; and it is very difficult to establish authentic records of metal-bearing ores or other valuable material having been definitely located by such means.[279]

One scheme which has received some note in the technical press is that of H. Lewis, which embodies an application of Kirchoff's laws of potential distribution. An electric field is generated in the area to be investigated; and, with a telephone, a series of level lines is determined on the surface. By observing the disturbances in these lines, it is claimed that the presence and location of deep-lying ores of conducting material or of water may be determined.[280, 281]

Devices purporting to make use of magnetic disturbances due to earth currents in the vicinity of deposits of ore, oil or water have from time to time made their appearance; and some of them show great ingenuity in their design and construction. Probably the best known of these are the instruments of Schmidt, and of Mansfield, which are essentially similar in their arrangement. The general construction, as described in one of the patents, is as follows:

> A horizontal hollow glass cylinder is surrounded by a layer of paper impregnated with paraffin. Around this layer of paper a well annealed iron wire is spirally wound, the successive windings of the same spiral line not being in contact, and the successive layers of wire being separated from one another by a layer of paper impregnated with paraffin. Here and there a layer of paper treated with paraffin is covered with tin-foil over which the wire is wound. The outside layer of wire of the coil thus formed is covered with paper. The coil is open and completely insulated, that is to say, not connected with any source of current. Above this coil a glass plate is placed, in the middle of which is a fine point which supports a needle. The needle is feebly magnetized and turns easily on the point.

It is stated that the instrument will

> Indicate certain atmospheric changes, the nature and cause of which are not yet understood but which manifest themselves in a peculiar way in the neighborhood of the source and course of subterranean waters by rapid oscillations of the pointer of the device.

It is claimed that when the instrument is in the vicinity of a source or a stream of subterranean water the needle will after a time oscillate rapidly. Whether designed for ores, water or oil, there is little structural difference in the instruments.[282, 283]

It was the writer's privilege to take an examination of one of these devices, known as a "water finder," and to study in detail the functioning of the various parts. Structurally the instrument agreed closely with the description given above, and the workmanship was of the highest order. The suspension of the needle was so delicate that slightly magnetized tools some distance away would produce a noticeable disturbance. As no known laws of electricity or magnetism are applicable to the coil beneath, it would appear that any movement of the needle which may take place must be due to changes in the external magnetic field, modified perhaps by the presence of the iron coil, which would represent a magnetic cylinder of comparatively low permeability.

While the instructions accompanying the device very particularly state that it should be protected from the direct rays of sunlight and that it is not effective in locating streams that have "sprung up to daylight," no mention is made of the necessity of shielding the delicately poised needle from nearby magnetic bodies, such as tools, other electrical instruments, or telephone receivers, or from electric currents due either to neighboring conductors or to ground returns. In view of the numerous vitiating influences admitted by the makers of the instrument and of the fact that systematic magnetic surveys of the earth have not shown any local earth or air currents upon which its operation could be based, it can only be concluded that the invention is unsound in principle, and to be classified along with magnetic egg testers, sex detectors, and other devices calculated to prey upon the credulity of those who are

susceptible to impression by high-sounding terms.[284, 285, 286, 287]

Cases are on record where principles of electrical measurement have been made use of in the detection of theft or the presence of unauthorized persons in certain places. In one instance, an electrical manufacturer had noted the disappearance of coils of magnet wire from his stock, and undertook to detect the thief by establishment of a circuit similar to that of the induction balance about a passageway through which all employees were required to pass on leaving the premises. The spools of wire in the stock shelves having been carefully short-circuited, it became an easy matter to detect the presence of the guilty person by observing the unbalance set up by eddy currents in the short-circuited coils concealed beneath his clothing as he left for home in the evening. According to a recently published article it has been proposed to make an electrical investigation of the continuity of the iron chain which lies embedded in the massonry around the base of the dome of St. Paul's Cathedral, London.[288]

IX. Physiological and Allied Measurements

While the attitude of the medical profession toward exact quantitative methods of measurement in diagnosis would to the layman appear characterized by the utmost conservatism, it may, without question, be said that there is at present no field of scientific work wherein there are being made more rapid expansions of the use of electrical measurement than in that of the investigation of physiological and psychological phenomena. In studying the functions of living matter it has been difficult to identify processes which would lend themselves to quantitative expression; and, had it not been for the startling advances but lately made in applying electrical measurements to the diagnosis of disease, the expression "When doctors disagree" might yet have been due for a long lease of life. Recently, however, electrical methods of measurement have made an intrusion into the work of the medical profession which bids fair to place the findings and decisions of this group of technicians upon a basis of precision comparable with that long enjoyed by the devotees of the more exact sciences.[289, 290]

The popular press has of late contained considerable reference to a method of diagnosis wherein it is claimed that perfectly definite results may be obtained upon the basis of measurements of an electrical nature performed upon electronic emissions of the patient under investigation, and that a complete diagnosis of his affliction may be made in absentia by the electronic reactions of a drop of blood. If there be any merit to this system it is one which should most intimately concern the electrical engineer; but until the proponents of the method are in a position to expound their procedure openly, and in terms intelligible to electrical men, it can hardly be said that it need be recognized as an added application of electrical methods of measurement.[291, 292, 293, 294]

Electrical determination of the concentration of the hydrogen ion has found a wide use in the study of biology, but since this has already been referred to in an earlier part of this paper its repetition here will not be necessary. The convenience and precision with which temperature may electrically be determined has proved a great boon in the accurate measurement of body temperatures in pathological work. Both the thermocouple and the resistance coil have been employed in these measurements, the former where extreme precision or observation of rapidly varying values is required, and the latter for ordinary clinical work. The thermocouple can be made to give an accuracy of 0.02 deg. cent. while the resistance thermometer can be relied upon to 0.1 deg. cent. The detector is made in several forms, suited either for contact with the skin or for insertion into the natural cavities of the body. It is usually employed with some form of automatic recorder, so that continuous charts may be obtained. While these temperature measurements find their basic application in the observance of pathological conditions, researches are now under way with a view to correlating the patient's emotional condition with rapid changes of skin temperature, and the results as far as these tests have been carried, go to show that there may be thus obtained much valuable material in psychological investigations.[295, 296, 297, 298]

The outstanding example of electrical measurement of physiological conditions lies in the electrocardiograph, an instrument applying the Einthoven string galvanometer to the direct measurement of electromotive forces set up in the human body, particularly by the functioning of the heart. It is well known that all muscle movements are accompanied by changes in electric potential of the active part, relative to the passive part, the former becoming negative. If, then, a record of the electrical phenomena attending the action of the heart can be obtained, it follows that this must give reliable information regarding the various phases in the performance of this organ. While the theoretical possibility of this had long been appreciated, it was not until Einthoven in 1903 developed the string galvanometer, that it became an accomplished fact. In practise it is customary to make the electrical connections to the patient through non-polarizing electrodes attached to his limbs; and it has been found that the most complete information is obtained from three electrocardiograms taken with the following circuits:

I. Right arm and left arm:
II. Right arm and left leg:
III. Left arm and left leg. (Fig. 19.)

In the use of this device it is necessary not only to guard against polarization at the electrodes but to balance out the potential difference caused by glandular activities of the skin, and usually known as "skin current." An interesting and important feature of the

electrocardiograph as applied to diagnosis lies in the fact that the patient need not be brought into the presence of the instrument, but may have records taken at a remote point, perhaps several miles away, and, in fact, need not know that a study is being made of the performance of his heart.[299, 300, 301, 302, 303, 304, 305, 306, 307]

Studies of heart action are greatly facilitated by the use of the "Stethophone," lately developed by the Western Electric Laboratories, not only replacing the long-familiar stethoscope, but far surpassing it in the volume of information obtained. By the combination of an electromagnetic transmitter with a selected group of filter circuits it is possible not only to faithfully reproduce heart and other body sounds, but to mask out those to which it is not necessary to listen. The sound upon which it is desired to concentrate may then be heard in one telephone or in several hundred. An interesting feature of the device, in connection with its application to lecture room work lies in the fact that where the lecturer wishes to communicate with his audience he need only direct his remarks toward the

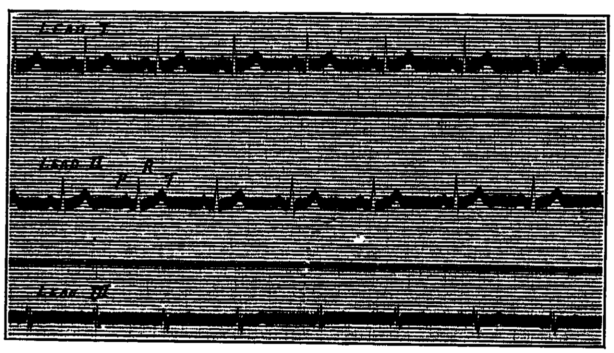

FIG. 19—ELECTROCARDIOGRAM

body of the patient, when the sound vibrations will be picked up and carried to the listeners. Like the cardiograph, the stethophone may be used at a point remote from the patient; and the electrical circuit may, as in that instrument, be associated with the recording features of the string galvanometer.[308, 309, 310]

Another Western Electric development is found in the "Audiometer" a precision instrument capable of measuring the acuity and quality of hearing. While the original purpose of this device was investigation connected with telephone work, it has been adapted to the medical field, and should without question prove a most valuable addition to the equipment of that profession. By means of a special vaccum tube there are produced continuously pure tones, which may be controlled and measured, both as to pitch and intensity; and these are delivered through a telephone receiver directly to the ear. By applying in a standard diagram the values representing the limits for a particular patient, there is obtained an exact index of the condition of his hearing; and this, in the hands of a specialist, furnishes material upon which a very complete diagnosis may be based. This instrument should prove of great usefulness, not only in the study of defective ears, but in all cases where complete physical examinations are required.[311 .... 323 incl.]

Amazing results have been obtained in the association of measurable electrical phenomena with the emotional condition of the human subject. While the "psycho-galvanic" action has been known, though rather imperfectly, for a number of years, it is only lately that there has been made any systematized and definite collection of measurements of the electrical effects which appear in conjunction with emotional conditions. For some time there has been in use an instrument known as the "emotometer," (Gambrell, London), which is a Wheatstone bridge, in whose circuit a portion of the patient's anatomy,—the hand, for instance,—is included. It is found that sudden changes of emotion, resultant upon predetermined stimuli, such as a sensation of falling, produce marked disturbances in the electrical balance of the circuit; and investigations have been carried out with a view to establishing a series of "standard emotions." While the possibilities of the device in its simple form have in no way been exhausted, its field has been immensely widened by the association of the string galvanometer, either as a detector in the bridge circuit, or independently, as in the cardiograph. This development is too recent to have made available any conclusive data; but such records as have been obtained from experimental work at present in progress go to show that, awaiting only the skill of the interpreter, there is at hand a mass of information on the functions of the human mind which will go far toward standardizing the study of psychologic processes, and the host of dependent manifestations of mental activity.[324, 325, 326, 327, 328, 329, 330]

CONCLUSION

Little that bespeaks finality can be found in the application of electrical principles to the innumerable measurements confronting engineers, scientists, navigators or medical men. In some branches of activity there have been adopted fairly well standardized systems for the performance of measurement by electrical means; but in general it may be said that there is apparent a state of development so rapid that in the few weeks which must necessarily elapse between the preparation and the presentation of this material, methods which have been described as modern will have been rendered obsolete and superseded by still more efficient electrical devices for making the required measurements. The phenomenal expansion of electrical practise to include, or to bear most closely upon almost every other field of human endeavor,—the continual breaking down of the barriers between electrical manifestations and the supposedly remote processes of other sciences, is having the effect of narrowing the meaning of the term "non-electrical quantities"

to the extent that the problem of their measurement, while today of interest to the electrical engineer as an appreciation of his working tools by other craftsmen, will very shortly be his problem by right of inheritance.

In collecting material used in this work it has been the privilege of the writer to come into contact with many specialists in fields where the electrical engineer seldom dares to tread. The cheerful cooperation shown, whether by the chemist, the physicist, the physiologist, the psychologist or the brother engineer, has been most encouraging; and the general spirit has been one of realization of the mutual benefit which must result when the engineer compares notes with his fellows in other spheres of technical activity. Space limitations preclude individual acknowledgement to the many who have assisted in the rounding out of the work; and the only tribute here practicable is seen in the liberal use of the results of their studies, as described in the text, and as referred to in the bibliography, which, may perhaps, like imitation, be looked upon as the sincerest form of flattery.

Associate, A. I. E. E.

I. Introduction

THE oscillograph is an instrument which has been extensively employed by electrical engineers in electrical measurements. It has been used not only in connection with electrical oscillations, such as alternating electromotive forces and alternating currents, but also in connection with acyclic electrical phenomena, such as the current required to blow a fuse, or the discharge current of a condenser. This paper describes methods by which the oscillograph may be used in mechanical measurements. This requires that the mechanical phenomena must affect an electric current which is being continuously recorded on the oscillograph.

II. The Oscillograph

The oscillograph can be briefly described as a galvanometer having a short period and critical damping, which is so arranged that its deflections can be recorded on a moving photographic film. Several models have been brought out by different manufacturers. For the work described in this paper a General Electric oscillograph has been modified to meet the requirements of the special investigations. The most important of these modifications are: (1) A special arc lamp; (2) a large drum which will take a five-foot film; (3) a special table on which is mounted a switchboard and suitable control instruments; (4) a new shutter and shutter control mechanism; (5) a rotating mirror; (6) a tuning fork for measuring the speed of the film.

1. *Special Arc Lamp.* Experiments have been made with several different sources of light, but for the highest film speeds it is necessary to use an arc lamp. For this purpose it is essential that the end of the positive carbon shall lie in the axis of the lens which is used to direct the light beam onto the oscillograph mirrors and very near to the focal point of the lens. It must be possible to advance this carbon without disturbing its adjustment. To accomplish this a special arc lamp was constructed in which the carbon holders slide on metallic ways. The carbons are held in V-shaped grooves which are parallel to the direction of the ways. The carbon holders are advanced by means of racks and pinions. The carbons can be maintained in a desired position by keeping their images, formed by a pinhole camera, at definite points on a screen which is provided for this purpose.

2. *Large Drum which Will Take a Five-Foot Film.* It is often desirable to use films of considerable length and whose motion is uniform during the time that the record is being made. For this purpose drums have been constructed which will take a five-foot film. This length was selected as it corresponds with standard films which can be universally purchased. The rotating portion has a large moment of inertia which insures that the speed will not change rapidly. The opening of the shutter does not appreciably change the speed of the drum.

3. *Special Table on Which is Mounted a Switchboard and Suitable Control Instruments.* Another useful modification was the design of a special table on which there is mounted not only the oscillograph itself but also a switchboard and suitable measuring instruments. This table was especially constructed for field use. The legs are made of two-inch pipe which screw into floor flanges that are mounted on the underside of the table top. The switchboard is hinged to the table apron in such a way that when the legs are removed it will swing into the bottom of the table, where it can be fastened for shipment. The instruments are mounted at a convenient point at the back of the table. These instruments consist of a 25-ampere ammeter for reading the current through the arc, a one-ampere ammeter for reading the current in the field magnet, and three milliammeters, range 150-0-150, which are connected in series with the oscillograph elements. These latter instruments have proven to be especially useful, since most of the difficulties in oscillograph operation occur in the element circuits. These difficulties can readily be traced by means of these milliammeters. In addition, there is a small resistance box in each element circuit, variable from 1 to 1000 ohms in steps of one ohm.

In Fig. 1 is shown an illustration of a complete oscillograph with arc lamp, large drum, instruments, and switchboard. At the right in this picture is the table with switchboard as prepared for shown shipment.

4. *New Shutter and Shutter Control Mechanism.* There are many advantages to be gained by placing the shutter mechanism as near the film as possible. By doing this all of the optical parts can be continuously illuminated so that one can readily see whether they are in proper adjustment. Moreover, by placing the shutter at this position, the time required to open it is reduced to a minimum. Another advantage of placing the shutter in this position will be discussed in connection with the rotating mirror which will be

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 9-12, 1925.

described in the next section. A diagram showing the location of the shutter and its method of operation is shown in Fig. 2.

It is important to have a mechanism which will close the shutter when the film drum has made a complete revolution, and it is desirable that it shall do this regardless of the speed of the drum. It should also be as nearly automatic as possible so that it will require little or no attention from the operator. This has been accomplished by the mechanism shown in Fig. 3. A brass gear is mounted either directly on the shaft of the drum or connected therewith through a train of gears so that no slipping can occur. A fiber gear is mounted on an arm in such a way that it is normally held out of mesh from this brass gear by means of a spring, but can be pulled into mesh by means of an electromagnet. This fiber gear has a small portion cut away. When it is rotated to the point where this portion is cut away, it presses against the brass gear and stops rotating, remaining in this position until the operator releases the key. Then as the fiber gear is drawn back by the spring to its normal position, a ratchet attached thereto (not shown in the drawing) turns it through a small angle so that no attention is required to make it ready for the next operation.

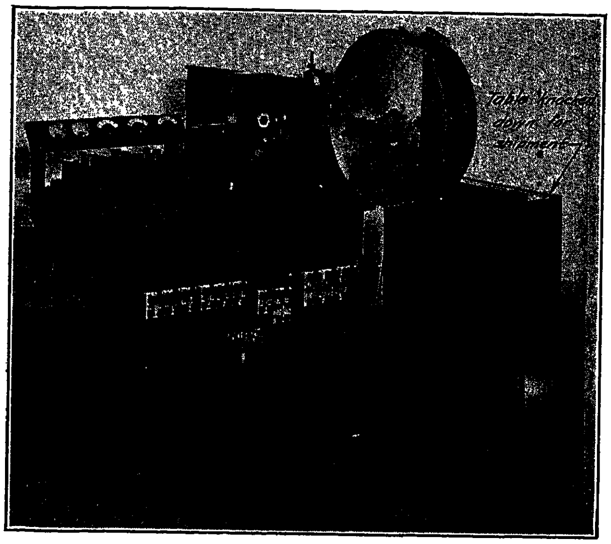

Fig. 1
The oscillograph with large drum, arc lamp, ammeters, resistances, and switchboard mounted on a special table. To prepare the table for shipment, the legs are removed and the switchboard, which is hinged to the apron of the table, is folded against the bottom of the table top without disturbing the wiring.

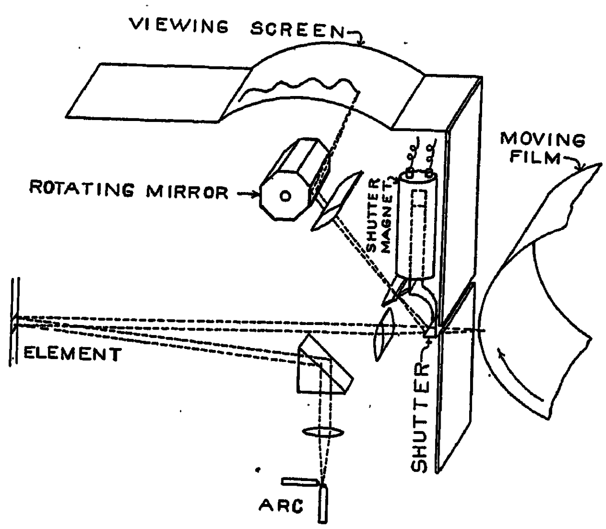

Fig. 2
Diagram to show the optical system when the shutter is placed near the film. A mirror is mounted on the shutter so that the light from an element can be seen on the viewing screen whenever the shutter is closed.

Attached to the fiber gear there is an adjustable cam which opens a contact in the circuit of the shutter magnet. This contact is closed when the fiber gear is in its normal position, but is opened after the gear has rotated a definite amount. By proper adjustment of the cam, the shutter can, for any given speed of the drum, be made to close when the drum has made one revolution.

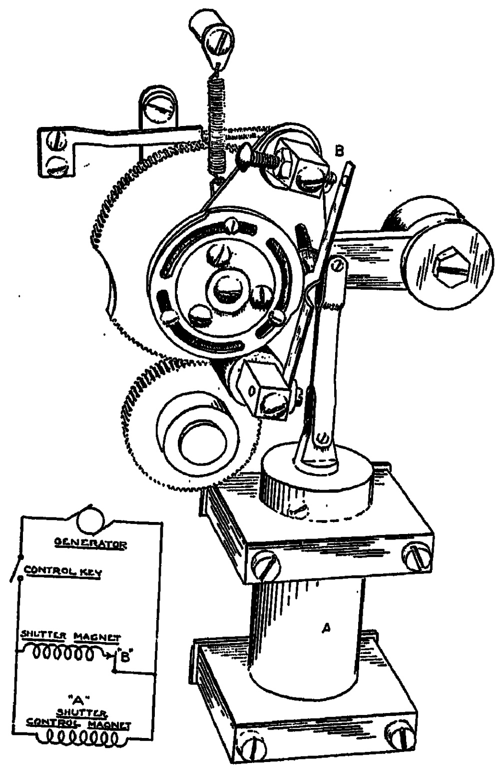

Fig. 3
The shutter-control mechanism for closing the shutter when the drum has made a complete revolution. The figure shows the gears held in mesh by the electromagnet A. The fiber gear (upper in the figure) has made about three-quarters of a revolution. The contact B is open, having been closed during the first part of the revolution.

The adjustment of the shutter mechanism will, in general, depend on the speed of the drum, and is more difficult for high speeds than low speeds. When the drum is rotating rapidly, the time required for the shutter to open, the time required for it to close, and the time required for the fiber gear to be drawn into mesh, are each a large fraction of the time of a revo-

lution of the drum. That the adjustment of the shutter mechanism will depend on each of these can be seen by considering a simple case. Suppose that the gear is drawn into mesh at the same instant that the shutter is opened. Then the shutter circuit will be broken when the drum has made a definite part of a revolution, at which time the shutter starts to close. In the time required for the shutter to close, the drum will rotate through an angle which depends upon its speed of rotation. Hence with this arrangement, if the shutter mechanism was adjusted to work correctly at low speeds, there would be overlapping at high speeds.

The adjustment of the shutter mechanism will be independent of the speed of the drum if the time of closing the shutter is shorter than the time of opening the shutter by the time required for the shutter-closing mechanism to operate. Another way of stating this is that the shutter must open so slowly that it will be closed for a time after the fiber gear comes into mesh, and this time must equal the time required to close the shutter. Up to the present time, it has been found necessary, in order to accomplish the above results, to make the time of opening the shutter about five-hundredths of a second. As this is not satisfactory for some kinds of work, it is frequently more desirable to adjust the shutter to open as rapidly as possible, and then adjust the shutter closing time for a definite speed of the drum. When the speed of the drum is materially changed, it is then necessary to readjust the time of closing the shutter.

5. *Rotating Mirror.* As indicated in Fig. 2, a mirror set at an angle is mounted directly on the shutter so that whenever the shutter is closed the light is reflected through a slit and a second cylindrical lens onto one of the faces of a hexagonal rotating mirror. This mirror reflects the light onto a translucent viewing screen. When used with acyclic phenomena, this hexagonal mirror is not rotated but can be turned to bring the spots of light at a convenient place on the viewing screen. Its principal value is that it enables the operator to see that the spots of light reflected from the element mirrors are in adjustment and are sufficiently brilliant. With cyclic phenomena the rotating mirror can be driven by any variable speed motor, the speed being adjusted so that suitable waves appear on the viewing screen. It should be observed that these waves are slightly distorted and that they do not have quite the same amplitude as the waves which will be photographed on the moving film. In any case, the spots of light which are about to be photographed can be observed up to the instant that the shutter is opened, and they come into view again as soon as the shutter is closed.

6. *Tuning Fork for Measuring the Speed of the Film.* In many experiments it is important to measure the speed of the film with greater accuracy than can be done by the use of a 60-cycle wave. This has been accomplished by means of a tuning fork which is installed in the oscillograph. The principle involved in the use of the tuning fork is shown in Fig. 4. On each prong of the tuning fork there is mounted a vane, these vanes being of such length that they overlap when the tuning fork is at rest. Slits are then cut through these vanes so that, when the tuning fork is at rest, the slits in the two vanes coincide. When the tuning fork

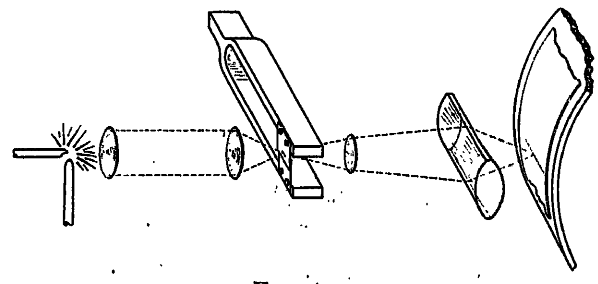

FIG. 4

Diagram showing optical system by which a tuning fork can produce timing lines on a moving film.

vibrates, the slits coincide at the center of the swing, giving momentarily the effect of a single slit. When this slit is brilliantly illuminated, its image, formed by a suitable optical system, can be photographed on a moving film. This gives lines on the film,[2] the distance

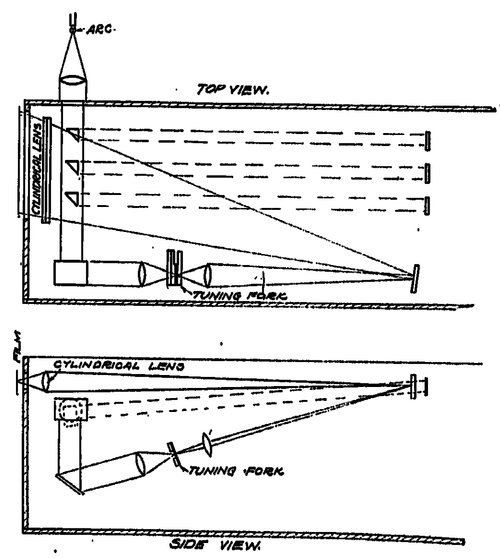

FIG. 5

Diagram showing method of installing a tuning fork in an oscillograph. By means of the tuning fork, the velocity of the oscillograph film can be accurately determined.

between them being the distance that the film travels in the time of a half vibration of the fork. A suitable size for the slits is 0.003 in. width and 0.2 in. length.

For rapidly moving films a 500-cycle fork giving lines one one-thousandth of a second apart has been found

2. A more complete description of this method of timing a moving photograph film is given in Scientific Paper 470 of the Bureau of Standards by H. L. Curtis and R. C. Duncan, entitled "A Method for the Accurate Measurement of Short-Time Intervals."

satisfactory. For slower film speeds a 50-cycle fork giving lines one one-hundredth of a second apart has been useful. A diagram showing the optical system used is given in Fig. 5. Examples of timing lines will be found in Fig. 8.

III. Measurement of Short Time Intervals

When it is desired to study the time of occurrence of a number of events, where order of occurrence is known, it is generally possible to arrange electrical circuits in such a way as to record all of these events with one oscillograph element. An example of this is the recording of the events which take place in a gun at the time it is fired. The electric circuits by which it is possible to record six different events with a single element are shown in Fig. 6.

As shown in this figure, two batteries, one of 6 and one of 12 volts, are connected in opposition so that a continuous current is sent through the resistance, R, and the oscillograph element, E. The series of events is started by the closing of the firing key, S. This ener-

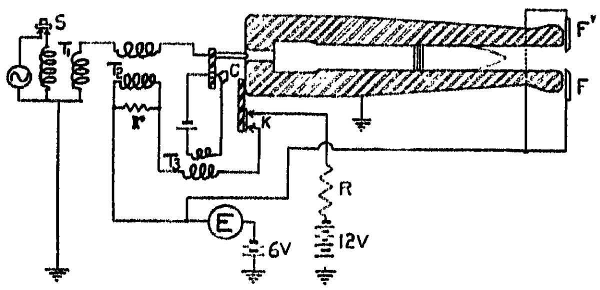

Fig. 6

Diagram showing the electrical connections for recording the important events in the firing of a gun. By circuits not shown, the oscillograph shutter is opened a few hundredths of a second before the firing circuit is closed at S. A description of the sequence of events after the closing of the firing key, and of the consequent variations in current through the element E of the oscillograph, is given in the text.

gizes the firing circuit, sending an alternating current through a fine wire inside of the primer. This wire soon fuses, thus opening the firing circuit. By means of a small current transformer, T_2, called the primer transformer, an alternating current is superposed on the direct current which is already flowing through the oscillograph element. The amount of the alternating current which flows through the oscillograph element is is regulated by a resistance, r , in parallel with the secondary of the transformer. This resistance also serves as a non-inductive path when other current changes are produced in the circuit. By means of this alternating current the time of the closing of the firing circuit and the time at which it opens are recorded on the oscillograph film. Soon after the explosive in the primer is ignited, enough pressure is generated inside the primer to cause it to explode, sending a flame into the powder chamber, and at the same time causing a sudden kick of the firing pin. As this firing pin reacts suddenly, it opens the contacts on the explosion indicator, C, causing the current through the primary of the explosion indicator transformer, T_3, to become zero. This produces in the secondary circuit of T_3 a momentary current which is registered on the oscillograph film, thus giving the time at which the explosion occurred. When the gun starts to recoil, it opens the start-of-recoil contacts, K, thus breaking the continuous current which up to this time has been flowing through the oscillograph element. When the projectile reaches the muzzle, it makes contact with the ogive finger, F', causing a relatively large current to flow through the oscillograph element. This ogive finger is swept away

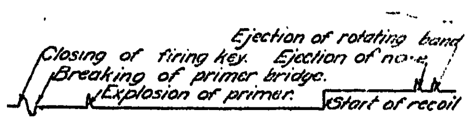

Fig. 7

Diagram showing type of record given by the circuits of Fig. 6.

when the circuit has been closed for only a few ten-thousandths of a second, thus again opening the circuit. This same process is repeated when the rotating band makes contact on the rotating band finger, F.

As these events must occur in a definite order, there is no possibility of one record interfering with any other. Moreover, since all the deflections are of a different type, if one apparatus should fail to record, no uncertainty is introduced regarding the other events. The only exception is in the case of the ogive finger and rotating band finger, whose records are practically

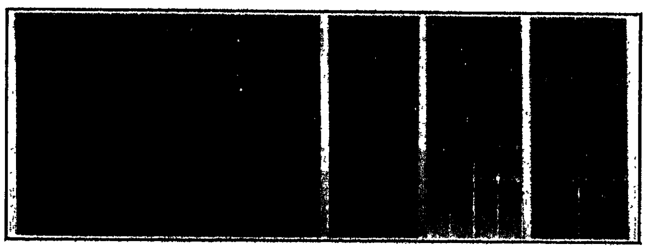

Fig. 8

Four portions of a record taken during the firing of a gun, with the circuits arranged as in Fig. 6. In the first portion is shown the alternating-current wave: in the second portion, the current change caused by the explosion indicator: in the third portion, the displacement of the record caused by the breaking of the start-of-recoil contacts: in the fourth portion, the current changes caused by the grounding of the ogive and rotating band fingers. The distance between timing lines corresponds to one one-thousandth of a second.

identical. As pointed out later, this is necessary for other reasons. It would be very simple to introduce some resistance in one of the circuits so that they could be distinguished.

The record obtained by such an arrangement is so long that it is not feasible to reproduce it. However, the kind of record which this apparatus gives is shown in Fig. 7. Portions of an actual record are shown in Fig. 8. These portions were selected to show the deflections at the times of the different events. In this record the events are shown as recorded by the element

whose trace appears at the top of the figure. The other two elements were used for other purposes. The timing lines are one one-thousandth of a second apart.

When it is desired to obtain the time of occurrence of several events, the order of the occurrence of which cannot be predetermined, it is sometimes feasible to arrange a series of circuits like that described above, so that each event gives a distinctive record on the film. Then the order of occurrence and time of occurrence can be determined from a single record. However, there is always the possibility of two events occurring approximately simultaneously so that the time at which these events occur cannot be accurately determined. When it is important to avoid such a possibility of confusion, it is necessary to record each one of the events on a separate element. If it is necessary to use more than one oscillograph, then some common event must be recorded on all films, so that the time of each event can be determined.

It is sometimes possible, when it is reasonably sure that the events will not all occur simultaneously, to so arrange the electric circuits that at least two independent values of the time interval can be obtained on two different elements, and yet have only a very slight probability that any event will fail to be recorded. As an example, suppose that it is desired to determine with accuracy the time between the contact on the ogive finger and that on the rotating band finger in each of three guns which are fired simultaneously. As explained later, this time difference can be used to get the velocity of the projectile. But since the experimental errors are relatively large, it is important to get as many independent determinations as possible. By using three elements for three guns and connecting them so that the records from gun No. 1 are recorded by both elements 1 and 2, from gun No. 2 are recorded by elements 2 and 3, and gun No. 3 by elements 3 and 1, we are able to obtain two values for the velocity of each projectile, and there can be no uncertainty regarding the value for each gun. Should the times at which two projectiles reach the muzzles differ by less than one one-thousandth of a second, then the record of one element would be of no value, but the records of the other two would be sufficient to give one value for two guns and two values for one gun. Should all three guns react simultaneously, then the records would be valueless, but the probability of such a contingency is very remote.

IV. Measurement of Velocity

If at definite points in its path a moving object changes the electric current in a circuit, then by recording the changes in current on an oscillograph film whose speed is known, it is possible to determine the velocity of the moving object. Since the oscillograph can measure short time intervals, this method has been used chiefly in measurements on objects moving at very high velocities. Perhaps the highest velocities with which engineers at present have to deal are those of projectiles fired from modern guns. Their velocity is of the order of 3000 ft. per second or 3 ft. in one one-thousandth of a second. With an oscillograph film running at 50 ft. per second, the film moves approximately one-half inch in one one-thousandth of a second. With a suitable record, this distance can be measured by means of a comparator with an accuracy of one-fifth of one per cent. However, to obtain this accuracy in the time measurement it is necessary to record both events on one element and to arrange the circuits for recording the two events so that the electrical constants are practically identical in the two cases.

The necessity for using a single element arises from two causes; first, the spots from two elements cannot be adjusted so that they lie exactly on a line parallel to the axis of the drum, and second, the rotational constants of the two elements cannot be made identical. Neither of these causes will introduce errors of more than one or two hundred-thousandths of a second, but in the short interval under consideration, this might produce an error of one or two per cent in the final result.

The necessity for the identity of the electrical constants of the circuits for recording the two events arises from the necessity of a time correlation of the element deflection with the change of current in the circuit. When the projectile closes an electric circuit, the current starts at zero and rises to its maximum by means of an exponential curve, the shape of which depends on the resistance and inductance of the circuit as well as on the applied electromotive force. The element deflects slowly at first, but with a rapidly increasing velocity, partly because the current is increasing and partly because of its own inertia. Hence it is difficult to determine on the film the exact time that a deflection starts. The time difference between two events can, however, be determined with accuracy by taking as the time of the first event the time that the element has deflected one centimeter, say, and an equal deflection for the time of the second event. However, this will accurately determine the time interval only when the electric circuits for the two events have the same constants, and when the rotational constants of the two recording elements are the same. This last is completely met by recording both events on one element. The desirability of measuring from a deflected position is apparent from the center trace of Fig. 8, but it is not to be expected that this will be so apparent in a reproduction as in the original film.

The measurement of the distance between contacts generally introduces a greater error in the velocity when measured by an oscillograph than does the measurement of time. Two methods of obtaining a measurable distance have been used. In the first, each contact consists of two insulated metal plates or screens, so that the projectiles short-circuits them. It is

desirable to put a quick acting fuse in the circuits with the first contact so that if a short circuit persists the fuse will melt and the element will have returned to its zero position before the second contact is closed. In the practical application of this method, it is not generally feasible to measure the distance between the contacts with an accuracy as great as one-tenth per cent. As they are generally thirty or more feet apart, so that the time interval is of the order of a hundredth of a second, little difficulty is experienced in measuring the time to a greater accuracy than is possible in measuring the distance.

In the second method, two contacts are mounted in

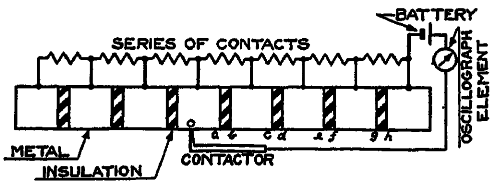

Fig. 9
Diagram to illustrate the step-by-step method.

the same plane to make contact at definite points on the projectile. This is illustrated in Fig. 6 where the ogive finger and rotating band finger are in the same plane, the one making contact on the ogive of the projectile and the other on the rotating band. This method, which is applicable only to projectiles of large size, requires that the distance on the projectile shall be measured before the projectile is loaded and that the path of the projectile shall be known so that the contacts will be made at the measured positions. This last difficulty may introduce errors as great as one per cent. Hence this method should be used only when no other method is available.

V. Measurement of Displacement by the Step-by-Step Method

It is sometimes desirable to determine the time-displacement curve of a moving body. This is readily accomplished by means of the oscillograph by so arranging an electric circuit that the current is changed as the body passes certain definite points. This step-by-step method is shown diagrammatically in Fig. 9, which shows the principles involved in a displaceometer. This instrument is designed to obtain time-displacement curves of the motion of a body in one direction. The series of contacts is mounted on a fixed support while the contactor is attached to the body whose displacement is to be measured. When the body moves, the contact point is drawn over the contacts, thus altering the resistance of the circuit and producing a definite record on the oscillograph film. When the contact point is on an insulating segment, the current goes to zero but rises to a definite value as it comes onto one of the contacts. A record obtained with such an instrument is shown in Fig. 10.

One advantage of this method is the great accuracy which can be obtained by its use. Both time and distances can be measured with high precision. Also, the method is very flexible. For example, in determining the recoil of a gun, the motion is slow at first but changes rapidly. At the beginning, contacts may be made to advantage every one-tenth inch. However, with increasing velocity, these could not be recorded satisfactorily, so that after the first inch it is desirable to have the contacts made every one-half inch, and later when the velocity becomes more uniform, contacts which are made every two and one-half inches have been found satisfactory. This permits greater accuracy in those parts of the curve where accuracy is needed.

The method has, however, certain disadvantages. It is obvious that one can never tell the exact instant that the motion starts. However, if the apparatus is well made so that the first contact occurs one one-thousandth of an inch or less after the motion begins, this is not a serious difficulty. In fact, by such an arrangement it may be possible to determine the time at which the motion begins with greater accuracy than can be done by some method which records the motion directly. Another disadvantage of the instrument is the fact that, if the time-displacement curve has a maximum value, this maximum value is not recorded by this method but must be determined from the plotted curve. The error in the maximum value can be diminished by arranging the apparatus so that contacts occur at frequent intervals near this point. However, when the maximum value of the occurrence is a matter of importance, care must be exercised in designing the apparatus in order that it will give the necessary accuracy.

Fig. 10
Portion of a record obtained by a recoilmeter using the step-by-step method. The distance between timing lines corresponds to one one-thousandth of a second. Contacts were one-tenth of an inch apart.

The fact that the time-displacement curve can be be obtained only by plotting the data which is read from the oscillograph film is, in some cases, a disadvantage. This becomes, however, an advantage when great accuracy is desired, since the films can be read with such accuracy that a very large sized plot can be made. This is very necessary if the time-displacement curve is to be graphically differentiated to obtain a time-velocity curve. Moreover, the time-acceleration curve, which can be obtained by a graphical differentiation of the time-velocity curves is of value only if the time-displacement curve is constructed with

the highest accuracy. In Fig. 11 is shown the time-displacement curve of a gun during the first seven inches of recoil, together with the velocity-time curve and the acceleration-time curve. The last two curves were obtained from the first by graphical differentiation.

In analyzing the motion of a moving body, it is

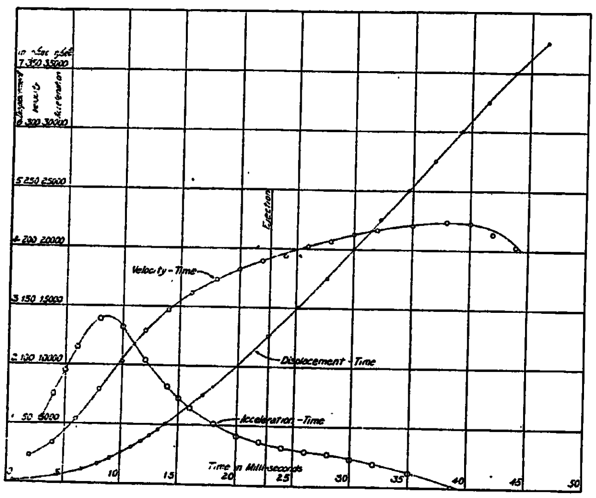

Fig. 11

Curves obtained by means of a recoilmeter during the firing of a large gun. The displacement-time curve is plotted from data obtained from an oscillograph record, together with the calibration data of the recoilmeter. By differentiating this curve graphically, the velocity-time curve is obtained. The acceleration-time curve is obtained by graphical differentiation of the velocity-time curve.

sometimes desirable to obtain time-displacement curves of two different parts of the mechanism from which the displacement of one part relative to the other can be determined. An interesting application of this was in determining the instantaneous torsion of the shaft of

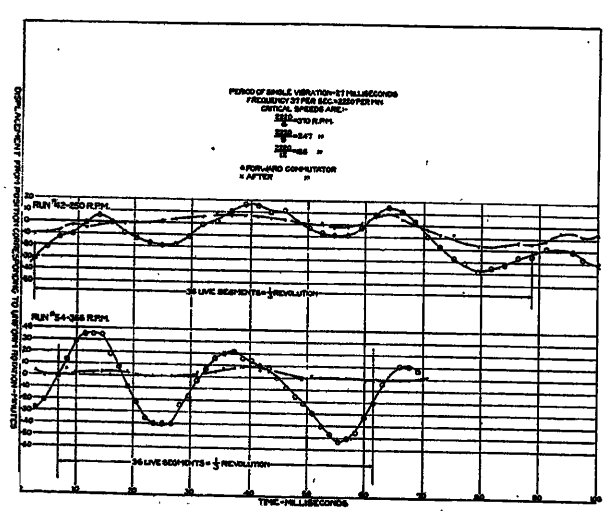

Fig. 12

Torsional vibrations of an engine shaft at two critical speeds.

a large Diesel engine. At certain speeds the shaft of the engine showed large torsional vibrations. By placing accurately made commutators on the two ends of the shaft and recording on the oscillograph the times when the segments passed a definite position, it was possible to plot curves which showed the torsion of the shaft at any instant. Two such curves are shown in Fig. 12. It will be noted that one end of the shaft showed almost uniform rotation, whereas there is a very pronounced sine wave at the opposite end.

The same principle can be applied in the simultaneous measurement of several displacements. If these are recorded by one or more oscillographs so that the relative times can be determined, a very complete knowledge of the motion of the body can be obtained. This has been applied to the study of the motions of the turret and turret structures on a battleship when the

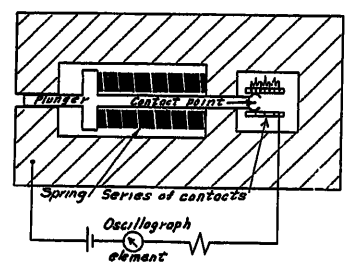

Fig. 13

Diagram of a pressure gage by means of which a pressure-time curve can be obtained when the pressure on the plunger is changing rapidly.

guns of this turret are fired. In this case eight oscillographs were used, giving twenty-four separate records. These showed not only the displacement of the turret in three perpendicular directions but also the rotation about three perpendicular axes. They likewise gave the distortions of the structures which support the turret. This complete analysis was possible not only

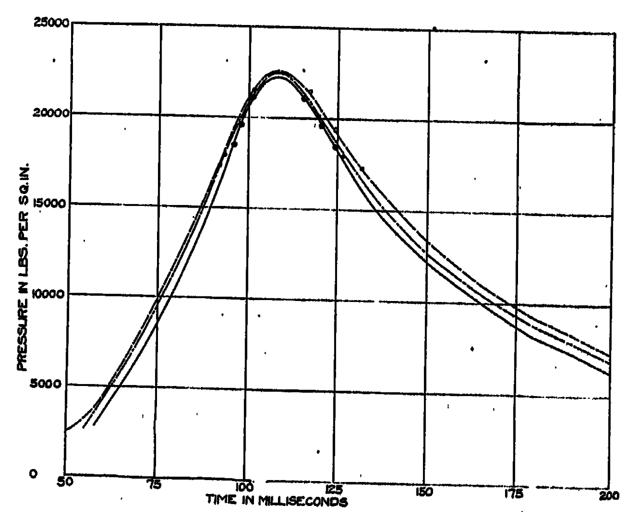

Fig. 14

Curves of pressure obtained simultaneously by three independent gages, mounted in a bomb which had a small vent. The pressure was produced by igniting a charge of powder.

because of the accurate timing which could be obtained through the use of the oscillograph, but also because all times could be referred to the same zero.

VI. Application of Step-by-Step Method to a Phenomenon Which Can be Registered as a Displacement

There are many phenomena whose magnitude can be determined by means of a displacement, and hence they can be recorded on an oscillograph by the method described above. We shall indicate only one application, namely, the measurement of a rapidly varying pressure. A diagram showing the principles involved in such an instrument is given in Fig. 13. The pressure which is applied to the plunger compresses the spring. This causes the contact point to move over a series of contacts, producing a record which is identical in form with that of the displaceometer described above. In Fig. 14 are shown curves obtained by three separate pressure gages which were placed in a bomb. The pressure rose to over 20,000 lb. per square inch in approximately one-tenth of a second. A satisfactory time-pressure curve was obtained.

The illustrations in this article have been drawn from the experience of the author and details are given only in so far as it is thought necessary to make clear the principles involved. There are many other ways in which the oscillograph can be used in measuring mechanical phenomena of short duration. It should be considered whenever it is necessary to investigate a phenomenon whose duration lies between one second and one millisecond.

Several physicists and engineers have been associated with the author in redesigning the oscillograph and in developing the experimental methods herein presented. Particular mention should be made of Dr. R. C. Duncan and Mr. H. H. Moore.

Discussion

J. R. Craighead: Mr. Curtis has given a great deal of attention to pushing the use of the oscillograph into fields decidedly beyond that for which the device was originally designed. The fundamentals of the oscillograph (that is, the natural frequency of the vibrator, and the photographic ability of light which can be placed upon the film) are such that values of the order that Mr. Curtis speaks of can be attained, but the general mechanical construction, and details, have been laid out with a view to practical operation in the shop and in power stations, rather than reaching the extreme values which Mr. Curtis has attained.

I made a few comparisons from the figures given in Mr. Curtis' paper. The width of the beam actually photographed on the film is usually of the order of $^1/_{16}$ in. It can be brought down considerably below that, but in the same oscillogram, the actual width of the beam photographed is dependent on the rate at which the beam is displaced; in other words, the same spot of light displaced somewhat slowly will produce a much wider beam than it will when displaced with extreme rapidity, because of the varying photographic effect proceeding from the center of the beam outward.

Mr. Curtis is measuring, according to the text of the paper, by means of a comparator, distances of approximately 0.001 in. and these distances are being measured on a beam such as I have described which ordinarily would be $^1/_{16}$ in. wide, but which as his oscillogram shows he has been able to get down to much less width. Will he give us a word or two regarding the type of comparator he uses which enables him to place these beams in such a way that distances as small as 0.001 in., or less, as implied in some of his statements, can be correctly measured.

There is no difficulty, of course, in reading that distance on the comparator. What I am trying to get at is the question as to how he can apply the comparator to a somewhat indefinite line and get the accuracy mentioned. It is, of course, essential to place on the film the timing lines to which he refers.

In regard to the actual correctness of the observation, after the photograph has been made, one further consideration of importance comes in. The ordinary kodak film expands when you put it in the developer and contracts when you dry it, after taking it out. The amount of expansion and of contraction and the exact size of the film at the time the photograph is taken are all quantities which depend upon the exact atmospheric conditions and the exact method of treatment. Because of conditions of this kind, timing by lines very closely in the vicinity in which measurement is to be made becomes essential. These lines which Mr. Curtis has placed on his films, it seems to me, should be extended all the way across the film, if he is going to get correct measurements for some of the values which he has indicated as going to the extreme opposite side of the film.

F. V. Magalhaes: Mr. Curtis makes the statement: "Experiments have been made with different sources of light, but for the highest film speeds it is necessary to use an arc lamp."

No question is raised with regard to that particular statement, but it would be of interest to know what measure of success he may have obtained with other sources of light, presumably incandescent lamps, for use with the oscillograph.

In the laboratory, where the particular function which is being measured can be repeated until a proper record is obtained, it is quite possible to use the arc which provides an intensity and a quality of light which is very satisfactory for high-speed films. In the field it is sometimes necessary to use an oscillograph under conditions where it is difficult, if not impossible to repeat the function. The arc under these conditions introduces variables such that consistently good oscillograms are hard to obtain. It is an accomplishment, to my mind, to operate an oscillograph continuously and without failure in the field. It means a careful watch on about a half dozen different factors or parts of the oscillograph, including the arc. When you get the results with the arc, they are very satisfactory, but it is difficult to handle, and it would be valuable indeed to have a satisfactory source of light such as an incandescent lamp, free from the mechanical and electrical variabilities that exist in the arc.

C. E. Skinner: Mr. Magalhaes has suggested the desirability of a light source easier to operate than the arc lamp. Mr. J. W. Legg's work has been done with an incandescent lamp, usually flashed at the instant of the taking of the picture, and I think his discussion will show that he has accomplished considerable in the way of speed in connection with the use of this device.

J. W. Legg: Practically all of the mechanical measurements made by Mr. Curtis have been made by electrical engineers in connection with electrical testing but have not been heretofore so fully described, and in some cases have not been so carefully worked out.

The writer's article in the Transactions A. I. E. E., 1923, Vol. 42, p. 381 on "Expansion of Oscillography," states: "Many purely mechanical movements can be detected and studied only through the medium of electricity and the oscillograph. Undesirable vibrations in machinery, noises, minute movements, momentary pressures, disturbances in the atmosphere, properties of materials and many other non-electrical functions have been studied with the oscillograph. Force or movement has to be transformed into a change in electric current through the medium of the carbon microphone, a special generator, a varying capacity or reactance, or the action of the piezo-electric crystal. The resulting current may be recorded directly by the oscillograph, or first amplified to suitable strength by the

three-electrode vacuum tube." These various mechanical measurements have been made by electrical-apparatus manufacturers in conjunction with electrical tests on quick-acting circuit breakers, electric locomotives, synchronous-converter sets, and the like, but heretofore, have not been taken up by non-electrical apparatus manufacturers, except where the manufacturer is in close touch with the electrical industry, as is the case with some steam-turbine manufacturers.

The value of the various attachments which were made by Mr. Curtis for his particular oscillograph was realized by the writer when designing the oscillograph described in the July 1920 JOURNAL (Vol. XXXIX page 674). An improved optical efficiency and an incandescent lamp were substituted for the old arc lamp; all control apparatus was included in the main unit; a mechanical shutter and control mechanism were designed to cause transients to appear on desired parts of the film, and a fourth optical system was provided for the timing lines. A simultaneous-viewing scheme was proposed but not adopted at that time. The oscillograph described in the February 1923 JOURNAL has been furnished, for particular non-electrical work, with a simultaneous-viewing attachment which has one great advantage over that described by Mr. Curtis, in that viewing continues during the photographic exposure as well as just previous to it. The incandescent lamp is operated on abnormal voltage only during the photographic exposure, hence if the particular transient required does not appear during the extra-bright wave period, then the operator can be sure that it was not successfully photographed and may repeat the test without waiting to develop the film to find the failure.

The increased optical efficiency of the new portable oscillographs, including the six-element instrument, would have been a help to Mr. Curtis with his high-speed films. By arranging the film on the drum to come closer to the oscillograph optical slot, it was possible to use a much wider angle of convergence from the cylindrical condensing lens than was utilized in older forms, thus increasing the intensity of the record on the film in the same way that a larger diaphragm opening in any camera increases the exposure without enlarging the image.

The large-diameter drum, used by Mr. Curtis, is a necessity for extremely high-speed work. Such a large drum has not been required heretofore for electrical phenomena, a compact daylight-loading one being used for the same length films. Such a film holder has been planned with a differential shutter which gives a small fraction of a revolution exposure and then a complete revolution without exposure, followed by another fraction of a revolution exposure, and so on, until the exposures cover the whole film. Thus, several high-speed records may be taken of some transient phenomena which are repeated several times with intervals between each transient longer than the duration of each transient. In the electrical industry such a film holder would be ideal for showing repeated short-circuit phenomena on oil circuit breakers, and switches. For mechanical measurements, such a film holder with differential shutter, might be used to give several high-speed records of the effect on a material of a terrific blow repeated at definite intervals until the material is shattered. The transient and the oscillograph lamp may be controlled by the shutter shaft, while the film rotates at a slightly different speed to get the intermittent exposures in the proper sequence. If the film speed is to be great and the time interval between exposures appreciably long, several revolutions of the film may occur before the lamp is lighted again in time to take another exposure when the shutter opens the next time, etc.

Schemes for recording several mechanical and electrical values with a single vibrator element have often saved much time and expense in testing. Before the development of the new portable oscillographs, the writer frequently recorded five distinct mechanical occurrences and times with one vibrator, leaving the two other vibrators for electrical measurements. The inductive kick from the actuating coil of an electrically driven tuning fork gave sharp kicks to the wave at the rate of 200 per second (or whatever rate was desired) while a potentiometer was used to record the displacement-time curve of the plunger of a quick-acting trip magnet. Contacts with resistances were arranged for showing when the main circuit breaker contacts parted, when the arcing tips parted, when the contact separation reached ½ in., and when the contacts were fully separated. The other vibrators showed the current and the voltage characteristics of the trip circuit.

The use of the double carbon pile for recording pressures, stresses, accelerations, etc., was found to be quite limited in its application, since it is affected by sideways shock. To avoid this error, electromagnetic schemes were resorted to, which were so planned that the converters were not affected by any disturbance except the particular values which were to be recorded.

The step-by-step methods for measuring displacements, including an accurately made commutator with one tooth to every ten degrees (except for the last which was omitted) were found to be altogether too crude for most vibration studies. Special apparatus, operating on the electromagnetic principle, was designed which made it possible to record torsional vibrations of less than one one-hundredth of a degree (0.01 deg.) and less than ten-millionth of an inch (0.000010 in.), at frequencies as high as 2200 cycles per second. Furthermore, the calibration of these devices was constant, and was unaffected by centrifugal force or high-speed rotation.

The writer feels certain that there is a greater field for the oscillograph for observing and recording mechanical and other initially non-electrical properties, than there ever has been in the electrical industry. The advent of the six-element oscillograph and the extremely portable single-element oscillograph described in the December, 1924 "*Electric Journal*" together with Mr. Curtis' article, should open the way for mechanical engineers to study their own problems as never before.

C. H. Sharp: The question of the source of light has been raised by Mr. Magalhaes, and that is an extremely pertinent question. I should like to ask whether an attempt has been made (and if so, whether it has been successful) to apply the little tungsten arc in vacuum, a lamp that is known in England as the Pointolite lamp, to this kind of work. That gives a very small source of light and I think one of very high intrinsic brightness.

Another thing that I wish to point out is this: that the oscillograph as it is at present constructed is essentially an ammeter. It utilizes the magnetic field produced by one turn, and that is all. Its sensitivity is limited by the fact that whatever field operates it is a field produced by a single turn in another field.

It would be an extremely useful thing if we could have an oscillograph which would set up a field from many turns, instead of only one. It would then become a high-resistance instrument, sensitive to extremely small currents, and, of course, requiring higher voltage to operate it. In other words, it would be a voltmeter rather than an ammeter.

We should not lose sight of the fact that the original oscillograph as proposed by Blondel a good many years ago was capable of doing this sort of thing. I refer to the oscillograph in which the moving element was like a Thomson galvanometer, in that it consisted of many little, soft iron needles on a quartz rod, suspended by a quartz fiber, in a magnetic field, and then actuated by another magnetic field at right angles, set up by coils which were in circuit with the current which was to be measured.

These coils evidently could either be of the small number of turns low-resistance type, making the instrument an ammeter, or of a large number of turns of the high-resistance type, making it a voltmeter. Thus, its theoretical applicability was considerably greater than the applicability of the present day oscillograph, which is made on the principle of the d'Arsonval galvanometer rather than the Thomson galvanometer.

I am quite aware of the fact that there are very serious difficulties with the original Blondel oscillograph, and on account of

those practical difficulties, that form of instrument was set aside in favor of the one which is now universally considered. But I want to point out that somebody in the light of present knowledge and of present developments might be able to develop an oscillograph of the multiple-turn type which would still further enlarge the field of this already very powerful instrument.

The cathode-ray oscillograph, of which a very interesting type with a hot cathode has recently come out, will do this thing, because it can use separate coils, and it is also capable of operating on the principle of electrostatic deviation. But, as we all know, this type of oscillograph suffers from certain other disadvantages which are of a great deal of importance in many applications. So that the cathode-ray oscillograph cannot be said to be in a position to displace the electromagnetic oscillograph, but rather to supplement it. As we know it is capable of portraying currents of extremely high frequencies such as are beyond the range of the electromagnetic oscillograph.

To repeat, one thing that we ought to have, if we can have it, is the electromagnetic oscillograph developed in such form that it will be sensitive to currents of very much smaller value than is the present one-turn oscillograph.

Edward Bennett: Dr. Sharp has stated that there is a need for an oscillograph of high current sensibility. It may be well to point out that if the oscillograph is to be used to obtain oscillograms of alternating currents or of rapidly varying currents its current sensibility may be increased a hundred fold or more by the use of a current transformer. Such a transformer is described in the TRANSACTIONS for 1914 in a paper entitled "A Milliampere Current Transformer." By the use of this transformer, extremely accurate oscillograms can be obtained of alternating currents having a r. m. s. value as low as 0.0002 ampere, provided this current is supplied under such conditions that a voltage drop of 4 volts across the current transformer is not objectionable. The limitations of the existing oscillographs as regards sensibility are best thought of and expressed in terms of the watt sensibility of the instruments. Thus, it requires a minimum watts expenditure of 0.2 milliwatts in the vibrator to obtain an oscillogram of reasonable amplitude.

With the advent of permalloy, it should be possible to construct current transformers to obtain oscillograms of currents as small as 20 microamperes.

C. H. Sharp: What about direct-current?

Mr. Bennett: If the current which is to be recorded is varying rapidly enough, that is, if it is not an extremely long-period phenomena the current transformer is satisfactory, although you have to make some interpretation then for the steady drift that occurs under those conditions.

L. T. Robinson: A very interesting point was raised by Dr. Sharp, with reference to the cathode-ray oscillograph, which certainly will do lots of things that nothing else will do but it sometimes fails to operate satisfactorily. In that respect, it differs from the other type of oscillograph, which is about twenty-five years ahead of it, perhaps, in commercial development.

With regard to the sensitivity of the oscillograph, it is seldom the case that Dr. Sharp is wrong, but I think in this instance he is. That is, I don't think that the earlier Blondel type is sensitive, when you think of the watt sensitivity. To be sure, it will go on a very small current, but in watts, I feel sure, that the other type is much more sensitive.

Professor Bennett's contribution about the current-transformer is all right, too, but it puts it into a less sensitive class rather than into a more sensitive class, because, however good the transformer is it must take some energy to run it.

The real way is to make use of the vacuum-tube amplifier. It is very sensitive, very effective, very easy to use, and at once you are in the microwatt class. That is, it consumes very little energy in relation to the quantities to be measured. With a properly designed amplifier it can even be made reasonably successful on direct-current.

F. G. Baum: I am encouraged to tell of the application of the oscillograph to a specific mechanical problem, because I think it will suggest the application to other problems.

A few years ago we started a water turbine under a 425-ft. head, 40,000 h. p., and when the load came on the turbine, a distinct vibration was set up in the penstock, the pipe line being about 1000 ft. long and 8 to 10 ft. in diameter. The vibration was so distinct that you could hear it several hundred feet away, and near the turbine it would break off the small pipes that were connected to the instruments. It was rather a disturbing thing to us and it occurred largely as the load came on. At light load, it occurred very little.

Mr. Roy Wilkins applied the oscillograph to this problem. I think you will find it described either in the Institute records or in the *Electrical World*, I am not certain which. He merely used a diaphragm taken from a phonograph, with a carbon element going to the oscillograph, and the vibration was found, I believe, to be about 80 cycles per second. Changes were made in the runner which changed the vibration to such an extent that the turbine was all right; it was perfectly safe as an operating problem although a slight vibration was still left.

However, it was decided that new runners should be designed and here is an application of the oscillograph to the design of a 45,000-h. p. runner of a water-wheel.

There are other applications for which we might use it. For example, on certain long spans where we pull up the wire tight, the wire at the tower is thrown into vibration. In one of our steel spans crossing the Bay of San Francisco, a span 4400 feet long, there was a decided vibration as the span approached the fixed support. That was corrected by adding weights, beginning with small weights away from the support and gradually increasing the weights as we approach the tower. But I think we could have made a better solution of the problem with the oscillograph.

I. M. Stein: The outstanding feature of an oscillograph is that it records what happens during very short intervals of time. Progress with these new mechanical and physical applications of the oscillograph will be more thorough and more rapid, if we can work with still shorter intervals, and this means a shorter period in the vibrating element. A short period is something which has to be built into the oscillograph. In other words, if the development of the oscillograph is along the line of putting into the oscillograph something which you can't put outside, leaving to vacuum-tube amplifiers the matter of getting proper sensitivity, we will get farther than by trying to get higher sensitivity inside of the instrument.

Direct-current amplification as mentioned by Dr. Sharp is very important. It would be a real service to humanity if one could improve the d-c. amplification methods; I have in mind particularly the need for a device to measure X-ray dosage in the treatment of cancerous growths. The problem involves the measurement of a minute direct current through an ionization chamber. It is only recently that d'Arsonval galvanometers have been developed to be sufficiently sensitive for this work. Such instruments are very satisfactory for investigators, but the X-ray physician needs a more rugged instrument with a good d-c. amplifier.

W. H. Pratt: One point that Dr. Sharp raised in connection with Mr. Curtis' paper (and it has been touched on also by Mr. Stein) is the sensitivity and the periods of operation. I think that Dr. Stein had in mind the Einthoven galvanometer when he made those remarks. Dr. Einthoven told me not long ago that in some of his recent instruments he was able to obtain a natural period of oscillation of the order of a million cycles per second; and the sensitivity to current is correspondingly great.

H. H. Moore: With reference to the method of measuring the speed of the film, I wish to call attention to the fact, that in

addition to the greater accuracy of this method over the use of a 60-cycle a-c. wave, it is also decidedly more convenient, and in the case of a three-element oscillograph it makes available an additional element thus increasing the usefulness 50 per cent, and obviating in many cases the use of an additional oscillograph.

Recently the Ballistic Section of the Naval Research Laboratory made an investigation of the hydraulic steering gear of the *U. S. S. West Virginia* and used extensively the oscillograph and the step-by-step method of recording. This work involved the measurement of hydraulic pressures of approximately 1000 lb. per sq. in. maximum at six principal points of the system; rudder angle, ship's heading, and power input to the steering motor, all relative to time. Each individual run required about 8 min. to complete. The pressure, rudder angle and power input intervals which were approximately equal required about 40 sec.

In connection with this work it was necessary to develop considerably new equipment for the oscillograph. A film holder to take 200 feet of film and give it a uniform rate of travel at about $^1/_2$ in. per second was developed. This compatarively slow film speed required a different timing mechanism and an apparatus was devised to give flashes of light each second. Incandescent lamps were used as the source of illumination. All of the apparatus functioned satisfactorily, and it is not believed that apparatus other than the oscillograph and the step-by-step method of recording are now available which would have given the desired results.

V. Karapetoff: In Fig. 11 curves are shown obtained by a graphical differentiation of an experimental curve. It may be of interest to call attention to my integraph, based on parallel-double tongs, which permits one to draw such derived curves directly, by simply following a given curve with a stylus. The instrument is described in the *Journal* of the Optical Society of America, 6:978, 1922.

G. W. Vinal (communicated after adjournment): Difficulties arising from the amount of current required to operate the oscillograph have been overcome in connection with a study of potential measurements and polarization at the Bureau of Standards, by the use of a resistance-coupled amplifier. The cell under examination was made a part of the potential applied to the grid of a vacuum tube. The oscillograph element was connected with the plate circuit of the second amplifying tube. With such an arrangement no current is required from the cell which is under investigation. By using a half cell, a variation in the potential of single electrodes may also be observed. A discussion of this method of using the oscillograph will appear in a forthcoming paper to be published by the Bureau of Standards.

A. Naeter (Communicated after adjournment): In the discussion following the presentation of the paper by Mr. Curtis it was stated that small transient currents might be stepped up by current transformers to make them sufficiently large for recording by means of an oscillograph. The writer desires to point out that in case the primary current contains transient terms the transformer itself introduces certain terms into the secondary current.

In a paper on "Transient and Permanent Phenomena in Electric Series Transformers" presented before the Royal Society of Canada in Ottawa on May 28, 1913, Andrew McNaughton determined from mathematical considerations and experimental data that in case of transients the secondary current is of one degree higher order than the primary current. Expressing this in physical terms, it means that the secondary transient current is distorted. In a bulletin on the "Characteristics and Limitations of the Series Transformer" issued by the University of Illinois Engineering Experiment Station, A. R. Anderson and H. R. Woodrow show as a result of their investigations that the series transformer, especially with an iron core is unreliable for recording transient or unsymmetrical currents. This bulletin agrees with McNaughton that transient currents are not reproduced exactly in the secondary of a current transformer.

H. L. Curtis: Mr. Craighead has asked concerning the type of comparator which was used in measuring the films. We have used a comparator in which a microscope is moved by a micrometer screw. The operation consists in setting the microscope on two adjacent events and reading the distance from the micrometer screw. With good quality films, it is possible to set the cross hair of a microscope on the center of a line with an accuracy of about 0.001 in. A discussion of the errors in such measurements is given in a paper referred to in Footnote 2 of this paper.

The question of film shrinkage is an important one. If the film shrinks uniformly, no error is introduced since the distance between timing lines shrinks to the same extent as the distance between the events measured. However, if the film shrinks unevenly, errors will be introduced. Some values of the shrinkage of films are given in "Notes of the Shrinkage of Photographic Films (*Journal* of the Optical Society of America and *Review of Scientific Instruments*, Vol. VII, No. 3, March, 1923) and a more complete discussion is given by Frank E. Ross, "Mensurational Characteristics of Photographic Film," *Astrophysical Journal*, pp. 181-191, April, 1924. This last paper was prepared at the Research Laboratories of the Eastmen Kodak Company and indicates that a very satisfactory film can be produced.

Mr. Craighead suggests that it would be desirable to have the timing lines reach the full width of the film. We have used such an arrangement but find that occasionally a timing line will occur at the same time as an event which is to be measured. This makes the accurate measurement of the event very difficult.

Mr. Magalhaes inquires concerning the relative speed of film that can be obtained with an arc lamp and with an incandescent lamp. With an arc lamp, we have successfully worked with a film speed of 100 ft. per sec. With incandescent lamps, we have made satisfactory records with a film speed of 10 ft. per sec. provided the lamp was used at over voltage during the time the film was exposed. The point-o-lite lamp, which is a tungsten arc in vacuo, gives about the same result as an incandescent lamp. Another source of light has been tried which is produced by heating, by means of an electric current, a tungsten wire in air until it vaporizes. The current is thrown onto the wire a few tenths of a second before the shutter is opened. This produces a very intense light but the resulting deposit of tungsten oxide is objectionable. Perhaps this could be avoided by using a carbon filament in place of the tungsten wire.

Much of the trouble with the arc lamp is due to the poor designs which are in common use. We have had very little difficulty with the hand-feed arc lamp here described. Satisfactory automatic arc lamps have been manufactured but they are not now on the market.

Mr. Legg spoke of using a short-focus cylindrical lens. This is, of course, desirable, and should be carried out as far as possible.

When an arc lamp is used the film speed could probably be considerably increased by using a fused-quartz optical system, together with a damping oil which is transparent to ultra-violet light. Such a system has been designed and partially constructed but has not been tested.

Temperature Errors in Induction Watthour Meters

An Analysis and the Development of a Temperature-Sensitive Magnetic Material Suitable for Compensation

BY I. F. KINNARD[1]
Associate, A. I. E. E.

and

H. T. FAUS[1]
Associate, A. I. E. E.

Synopsis.—*This paper is presented in two principal divisions, Part I and Part II. The first deals with the general problem of small errors due to temperature changes in watthour meters and describes methods of segregating the various components of these errors. It is shown that they may be divided into two principal groups, termed Class 1 and Class 2. Class 1 errors are operative at all power factors and are of the greater importance: Class 2 errors are important only at low power factors, and methods of eliminating these are pointed out. Both of these classes are further subdivided into their component parts.*

In Part II of the paper is described a method of compensating for Class 1 errors by means of magnetic shunts made of thermalloy. The term "Thermalloy" is applied to a series of copper-nickel-iron alloys having a large negative temperature coefficient of permeability and other unusual properties. These alloys are discussed in some detail, their manner of preparation and application being considered original.

In the appendix, a novel magnetic thermometer utilizing thermalloy is described.

* * * * *

Part I

Introduction

AN electromagnetic device, such as an induction watthour meter, the operation of which depends upon the exact magnitude and phase relation of the various fluxes, is more or less susceptible to changes due to variations in temperature. This is to be expected when it is considered that almost all of the properties of ordinary electrical and magnetic materials change to some extent with temperature and that in some of the essential materials in a watthour meter, such as copper and magnet steel, this change is very marked. It is true that this type of watthour meter is, to a large extent, inherently self-compensating and that the variation in speed of a well-designed meter, when a change in temperature occurs, has generally been considered too small to have any serious effect on accurate metering. In keeping with the constant tendency toward more precise measurement of power, however, it is expedient that this problem should be given careful consideration and steps taken to reduce the small effect of ambient temperature and self-heating.

There has been very little material published on the problem of temperature errors in induction meters, as far as the authors have been able to determine. Fawsett[2] has described a precision watthour meter in which he has used a manganin lag plate and a braking magnet mounted upon a bi-metal support which moved in and out in such a manner as to effect a temperature compensation. There has been at least one other meter designed utilizing the bi-metal principle in an endeavor to correct temperature errors by mounting the magnet adjustment-disk so that it is free to move closer to or farther from the magnet depending upon the ambient temperature. These schemes are dependent upon a mechanical motion about which there is always more or less uncertainty, and the magnitude of the compensation depends upon the position of the full load adjustment on the meters; so they are at best only approximations.

In order to arrive at a proper understanding of the nature of this problem, it will be well to review the causes of temperature errors in some detail.

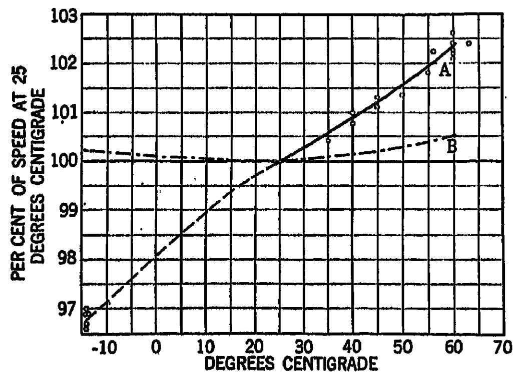

Fig. 1—Temperature-Speed Curves for Induction Watthour Meters
A—Power Factor = 1.0
B—Power Factor = 0.5

Analysis of Temperature Errors

It is generally known that induction-type watthour meters increase slightly in speed when a temperature rise occurs. Fig. 1 is typical of the relationship existing between percentage change in watthour meter speed and temperature for common types of meters at unity power factor and at 50 per cent power factor. It will be seen that a considerable difference in meter speed may be occasioned by a change from outside zero

1. Both of Engineering Department, West Lynn Works' General Electric Company.

2. New Precision Watthour Meter—*The Electrician*, March 7, 1924.

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 9-12, 1925 and at the Regional Meeting of Dist. No. 1, Swampscott, Mass., May 7-9, 1925.

weather to a heated room, which is of course an extreme condition of use. The effect of temperature at low power factors current lagging is much less than at unity, which indicates a greater tendency toward self-compensation under the former conditions. Different makes of watthour meters exhibit considerable difference in temperature characteristics, and some have a greater speed increase with rising temperature than that shown in Fig. 1; but in general they all follow the same laws.

In order to analyze the phenomena of temperature errors, we adopted the experimental method of selecting one possible variable and by holding it constant while the temperature was changed noting the result on the meter's performance.

There are two main classes into which the various factors governing changes due to thermal effects may be divided:

1. Factors governing the magnitude of either potential or current fluxes, or both, or the magnitude of the braking flux.

2. Factors governing the phase relation between potential and current fluxes.

Due to the fact that the torque is proportional to the sine of the angle between the useful potential and current fluxes, and that in a properly adjusted meter these are exactly at right angles for unity power factor, it follows that any small variations in flux phase relations are not important at high power factors. For example, a shifting of three degrees at 100 per cent power factor changes the torque only 0.14 per cent, while the same change in angle if the meter were operating at 50 per cent. power factor causes a change in torque of nearly 9 per cent. It might, therefore, be stated that errors under Class 1, are equally operative at all power factors and that those under Class 2, while negligible at unity power factor, are increasingly operative as the power factor decreases.

It has long been suspected that the control magnets were responsible for a large share of the observed temperature coefficient falling under Class 1. Several writers[3] have pointed out that permanent magnets have a decided temperature coefficient and that their strength decreases with an increase of temperature.

In order to ascertain to just what extent the magnet was responsible for the errors observed at unity power factor, it was necessary to devise some method whereby the braking torque could be held constant while the meter was raised to various temperatures. This was attempted in several ways, one of which was evidently quite successful as will be described below. Tests of this nature are inherently difficult and tedious, but great pains have been taken in obtaining the results herein described and it is believed that the information is reliable.

The first method tried for eliminating the uncertainty in the magnitude of the braking torque when the meter undergoes variations in temperature was the substitution, for the control magnet, of an air fan attached to an extended shaft and enclosed in a glass chamber. Various shapes and sizes of fans were tried without much success. The chief difficulty was in obtaining sufficient retarding torque, by this method, to work with any considerable driving torque or load on the meter; hence, friction played too prominent a part in the result.

It was then decided to endeavor to keep the braking flux constant by keeping the magnet at a constant temperature while the rest of the meter was heated. The meter was mounted in a glass case, which contained a resistance coil for heating and a fan for circulating the air and thus keeping the temperature uniform throughout. It was provided with a long shaft which extended through the top of the case and supported a manganin damping disk. The driving disk was also of manganin, so that any variation in speed of the meter when its temperature was raised should be due only to a change in driving torque, since the temperature of the magnet outside was kept constant as indicated by a thermometer held in close contact.

A difficulty with this arrangement was that the weight of the two disks and the long shaft was so great as to cause excessive friction. This, combined with the light driving torque due to the use of manganin disks, served to make the experiment extremely difficult, although for some time it was thought that we were obtaining quite satisfactory results. Sufficient data were obtained to indicate that the large part of the errors at unity power factor were to be found in the control magnets; but the test was finally abandoned in favor of the one next described.

The method that we found to be most successful for holding the braking flux constant was by the use of a soft iron magnet having the same shape as the standard type I-14, with which we were working. Magnetizing windings, having sufficient turns to provide the required braking flux by the use of a very small magnetizing current, were placed around each half of this magnet. In order to measure accurately just how much braking flux was cutting the disk, an exploring coil wound in the general form of the figure 8 and shaped to conform to the outline of the meter disk was wound on a celluloid form and placed in close proximity to the bottom of the disk. Substantially, all of the braking flux that cut the disk was linked with this exploring coil. By connecting the latter to a ballistic galvanometer and reversing the primary current in the electromagnet, a means of measuring the total flux ballistically was provided. In order to get the required accuracy of one-tenth of one per cent which we desired in this experimental work, a null method of measurement was adopted rather than a deflection method. This consisted essentially of simultaneously reversing the currents in the primary of a standard mutual inductance and in the magnetizing coils on the magnets. The respect-

3. The Effects of Changes of Temperature on Permanent Magnets—*Am. Jour. Sci.*, Vol. XV, No. 87, March, 1903.

ive impulses in the secondaries were passed differentially through a ballistic galvanometer, and when the point of balance was obtained the value of the current in the mutual inductance was the measure of the total effective flux of the control magnets.

A diagram of connections is shown in Fig. 2. The reversing switches S_1 and S_2 were connected together

mechanically so that they could both be reversed at the same instant. The procedure in making the test was to adjust the current in the braking electromagnet by means of the rheostat R_2 until the meter ran at the desired speed. The flux was then measured by adjusting the current in the primary of the mutual inductance until the galvanometer gave no deflection when both switches were reversed. The value of the flux passing through the disk and exploring coil could be readily calculated from well-known magnetic formulas such as are used for ordinary ballistic testing and need not be given here. After the meter speed at room temperature had been measured, the temperature of the meter under test was raised to the desired value, the braking flux was adjusted to its original strength, and the speed was again determined by comparison with a standard test meter which was kept at room temperature.

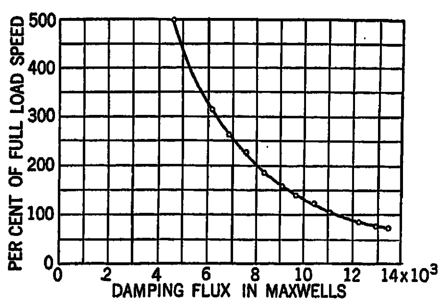

FIG. 3—RELATION OF BRAKING EFFORT TO TOTAL FLUX IN MAGNETS

Meter run under constant load conditions and braking flux varied.

This test was reasonably satisfactory and gave results which were quickly checked to within one-tenth of one per cent. One great advantage which it possessed over all others tried was that the meters under test need not be changed in any other respect; and, therefore, the results obtained were directly applicable to a standard induction watthour meter. This apparatus was first useful to determine the relationship existing between braking or retarding effort and total flux in a magnet. Fig. 3 shows one of the curves obtained on a meter running under full load conditions at unity power factor, the braking flux being varied in such a manner that the speed changed from approximately 75 to 500 per cent of full-load speed.

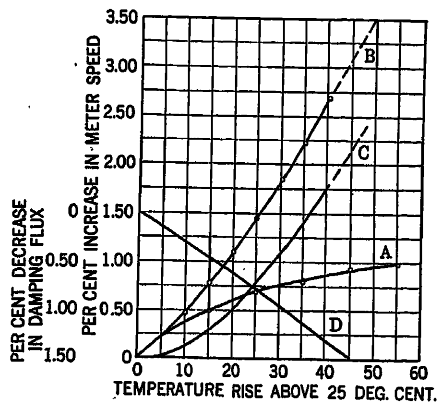

FIG. 4—SEGREGATION OF TEMPERATURE ERRORS IN INDUCTION WATTHOUR METER AT UNITY POWER FACTOR

A—Change in Speed with Constant Braking Flux
B—Change in Speed with Standard Control Magnet
C—Change in Speed Due to Standard Control Magnet
D—Variation in Braking Flux of Standard Control Magnet

If plotted on double logarithmic paper, the speed will be seen to vary inversely as the 1.8 power of the flux. Theoretically this should be a squared relation, and experimental results fit quite closely with this value when it is considered that the data were taken over a very large range of speed and that it is probable the value of friction changed to some extent, as well as other factors not taken into consideration in the theoretical value.

Meter speeds were next measured, at various temperatures, and constant braking torque at unity power factor and 50 per cent power factor both at full load and light load. Part of these tests were made with the lag plate completely removed from the meter, thus determining just what effect this had on the temperature coefficient. Complete curves were taken in each case, and sufficient points were obtained and check tests made to minimize observational or accidental errors.

The results of tests at 100 per cent power factor are shown by Curve A in Fig. 4. It will be seen that the

meter speed still increases with increase in temperature. This must be due to an actual increase of driving flux cutting the disk, as it cannot be explained by a change in phase relation of the flux as noted previously. It is evident that the most plausible reason for this increase

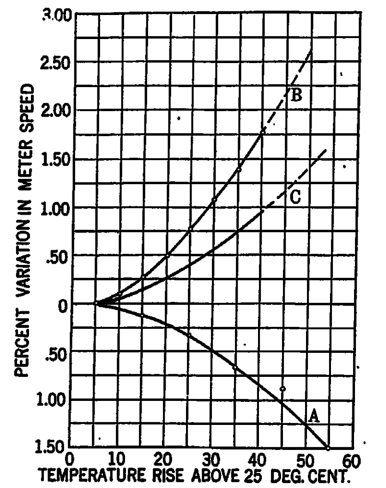

FIG. 5—SEGREGATION OF TEMPERATURE ERRORS IN INDUCTION WATTHOUR METER AT 50 PER CENT POWER FACTOR

A—Change in Speed with Constant Braking Flux
B—Change in Speed Due to Standard Control Magnet
C—Change in Speed with Standard Control Magnet

in driving torque is that the permeability of the silicon steel laminations in the driving elements changes sufficiently with temperature to cause this effect. Changes in iron loss also have a small influence on the magnitude of the induced voltage or flux, as will be

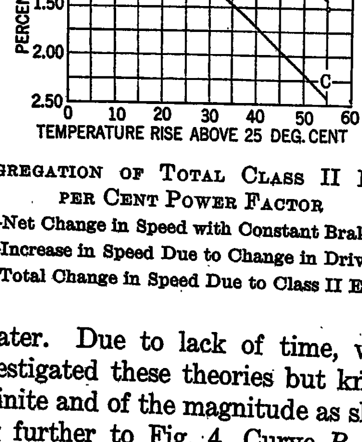

FIG. 6—SEGREGATION OF TOTAL CLASS II ERRORS AT 50 PER CENT POWER FACTOR

A—Net Change in Speed with Constant Braking Flux
B—Increase in Speed Due to Change in Driving Torque
C—Total Change in Speed Due to Class II Errors

explained later. Due to lack of time, we have not further investigated these theories but know that the effect is definite and of the magnitude as shown.

Referring further to Fig. 4, Curve *B* represents a temperature-speed curve taken with the retarding torque supplied by a standard control magnet. The difference between these two curves is represented by Curve *C* and is the effect of the change in flux of the control magnet on the meter speed. Curve *C*, then, is the actual change due to the temperature coefficient of one particular magnet; and, although we have reason to believe that magnets vary somewhat in regard to the magnitude of this effect, this curve is fairly representative. The diagonal Curve *D* in Fig. 4 represents the actual change in total flux of the magnet corresponding to this change in meter speed as obtained from the flux-speed curve shown in Fig. 3. This shows a nearly linear relation and indicates that the temperature coefficient of the magnet is approximately 0.0003 per degree centigrade.

Tests were also made at unity power factor with the lag plate removed from the meter, and it was found that there was a small difference both in shape and in magnitude of Curve *A*. It was not of sufficient magnitude, however, to be considered of much importance, and we

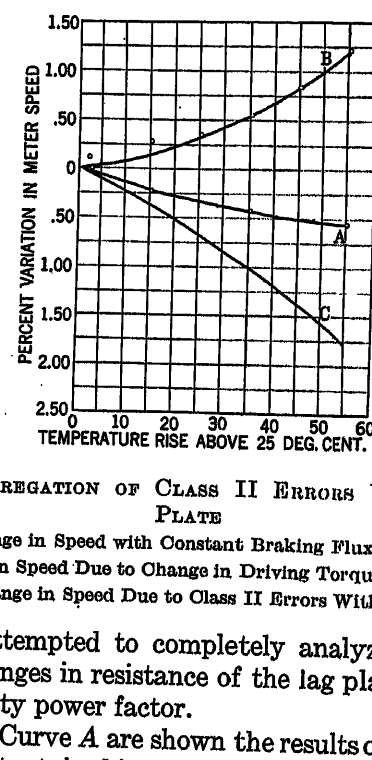

FIG. 7—SEGREGATION OF CLASS II ERRORS WITHOUT LAG PLATE

A—Net Change in Speed with Constant Braking Flux
B—Increase in Speed Due to Change in Driving Torque
C—Total Change in Speed Due to Class II Errors Without Lag Plate

have not attempted to completely analyze the small effect of changes in resistance of the lag plate on meter speed at unity power factor.

In Fig. 5, Curve *A* are shown the results of tests made with a constant braking flux at 50 per cent power factor. In this case, the meter slows down with increasing temperature and this effect is undoubtedly due to the shifting of phase relations noted under Class 2 errors less the increased driving torque, as shown in Fig. 4, Curve *A*. By adding to the former curve, the change in speed due to the permanent magnet Fig. 4 Curve *C*, we arrive at Curve *B*, Fig. 5, which is the usual increase in speed noted with a standard meter at 50 per cent power factor.

Considering Fig. 6, Curve *A* is the same as shown in Fig. 5 and is the net negative error observed at 50 per cent power factor with braking flux held constant. If we now substract from this the error observed at 100 per

cent power factor under the same conditions, which is constantly present in the opposite direction, we arrive at Curve C, the total change in driving torque due to a shift in phase angle with temperature. It will be noted that this is nearly a straight line, and the reason for it will be described later.

The lag plate was then removed and the 50 per cent power factor test repeated. The results are plotted in

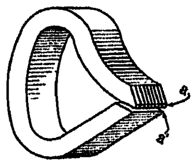

Fig. 8—Standard Type of Single Watthour Meter Magnet

Fig. 7, Curve A. By subtracting from this the results of a similar test at unity power factor, we obtain the total change due to shifting of phase angle, as shown by Curve C. By comparing these results with Fig. 6, it will be seen that the lag plate has a very decided part in the meter's temperature coefficient at low power factors.

In order to check these results, some direct tests (which it is hoped will be described in more detail in a later paper) were made on permanent magnets; and, in so far as horseshoe magnets of the general types found in Fig. 8 are concerned, it has been conclusively shown that the relation between strength and temperature is such as is illustrated by the curve in Fig. 9. In a properly treated magnet, there is a definite strength corresponding to a given temperature, and heating and cooling curves are substantially the same for temperatures under 100 deg. cent. providing the magnet is held at any one temperature for a sufficient length of time to reach equilibrium.

It has been suggested by some of our colleagues that the jaws of the magnet at aa', Fig. 8, might open slightly with a temperature rise, thus causing an increase in the length of air-gap and a consequent diminution of flux. Thorough investigation has been made of this effect and it has been found negligible in relation to the others; for although a very slight effect of this nature does exist, it amounts only to a small percentage of the total observable increase in meter speed with temperature. A very extended investigation of this phase of the problem was completed nearly two years ago by the author, and the method adopted for detecting changes in the gap with temperature was to insert a skeleton meter with magnet attached in an oil bath suitably controlled with heating and cooling coils. Any change in the gap was amplified by means of a scissors-arm arrangement and the motion was accurately measured with a cathetometer. In order to get the effect of changes in the length of gap on the meter speed, the magnets were forced apart by means of a special clamp and the actual change in gap measured with an optical device which reflected a beam of light on a scale at a distance. The principal conclusions derived from this work were as follows:

1. All magnets tested showed a definite tendency to open their gaps under temperature, so that the length of air gap was increased by amounts varying from 0.1 to 0.35 per cent for a 60 degree (Centigrade) rise. This expansion is undoubtedly due to the relieving of internal strains and is partly dependent on the exact heat treatment to which the magnets have been previously subjected.

2. The meter speed was affected by amounts ranging from 0.08 to 0.26 per cent by changes in the dimensions of the air gap due to 60 degrees (centigrade) rise in temperature. The maximum change noted accounts for less than 7 per cent of the total temperature error in the meter, and on the average the increase in the length of the air gap might be expected to account for approximately 5 per cent of this error.

As a result of this work, the factors causing temperature errors may be further subdivided as follows:

Class 1:

1. Internal changes in permanent magnet steel.
2. Change in length of air-gap of magnets.
3. Change in permeability of magnetic circuits of the potential and current elements.
4. Small change in magnitude of potential flux, due to shifting in phase of the magnetizing current (see vector diagram in Fig. 10).

Class 2:

1. Change in resistance of potential windings.
2. Change in iron losses in potential element.
3. Change in resistance of lag plate.

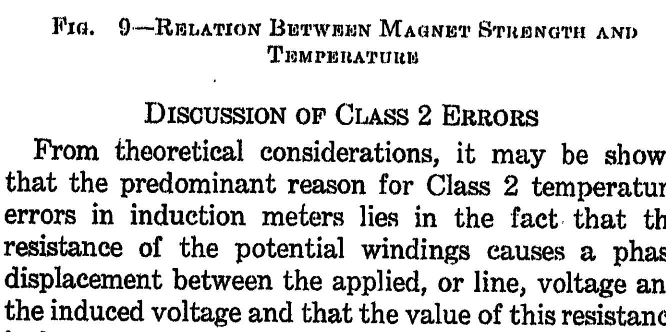

Fig. 9—Relation Between Magnet Strength and Temperature

Discussion of Class 2 Errors

From theoretical considerations, it may be shown that the predominant reason for Class 2 temperature errors in induction meters lies in the fact that the resistance of the potential windings causes a phase displacement between the applied, or line, voltage and the induced voltage and that the value of this resistance is dependent upon temperature.

Without reviewing the general theory, we may state that the torque is proportional to the product of the current and potential fluxes and the sine of the angle

between them. We have already shown (page 12) that the lag plate accounts for about 30 per cent of the Class 2 temperature errors by virtue of its change in resistance; hence we shall now leave it out of the discussion. Since the power used to drive the disk is only about 0.1 per cent of the loss in the potential element, when discussing vector relations between the main fluxes and potential drops this small induced current may be entirely neglected.

Considering the potential element, then, we may represent it by the simple equivalent circuit as shown in Fig. 10A; the line voltage V is balanced by the induced voltage E_1 and the $I_o\, r_1$ drop in the windings. The exciting current I_o may be divided into the usual

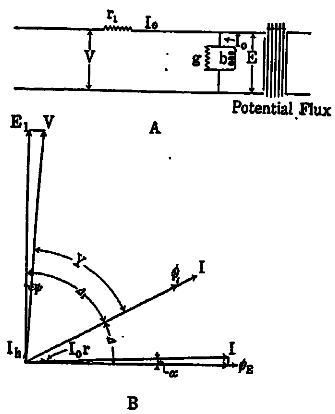

FIG. 10

A. Equivalent Circuit Diagram of Potential Element of Watthour Meter, Secondary Circuit Neglected.

B. Vector Diagram of Watthour Meter Omitting Secondary (Lag Plate and Disk) Currents

V = Line voltage = 110
r_1 = Resistance of potential windings = 63 ohms
E_1 = Induced voltage in potential windings = 109.8 volts
I_0 = Exciting current = 0.0982 ampere
I_h = Power component of $I_0 = gE_1$ = 0.00437 ampere
I_m = Magnetizing component of $I_0 = jbE_1$ = 0.0981 ampere
α = Hysteretic angle = 2.55 deg.
I = Line current
ϕE = Flux in potential element
ϕI = Flux in current element
Cosine λ = Line power factor = 0.50
ψ = Angle of lag

components $E\,g$ and $E_1\,jb$ representing the power and magnetizing portions respectively. If we now draw the vector diagram for this circuit as shown in Fig. 10B, using the actual measured values of the various constants of an induction watthour meter, the relative importance of iron losses and ohmic resistance as they affect the phase relations is seen at a glance. The torque T may be expressed by the following equation as noted above:

$$T \propto \phi_E\, \phi_I \sin \Delta;$$

or, since $\phi_E \propto E_1$ and $\phi_I \propto I$,

$$T \propto E_1 I \cos \Delta_1.$$

Now $\Delta_1 = \lambda + \psi$, where $\cos \lambda$ is the line power factor and ψ is the angle between the line voltage and the induced voltage. Therefore, to get a change in torque due to change in angle ψ, either r_1 or I_0 must change.

It is evident that the angle ψ is approximately directly proportional to the resistance r_1, and, therefore, at low line power factors any change in r_1 means an appreciable change in torque.

If, however, the iron losses are eliminated entirely, thus bringing I_0 in phase and equal to I_m, the magnitude of $I_0\, r_1$ remains practically unchanged with no resulting change in torque. This is not strictly true, because the theory of the meter assumes E_1 to be proportional to V and a shifting of the angle of the vector $I_0\, r_1$ with varying iron losses will result in a small variation in this proportionality. This variation affects Class 1 errors slightly and may be grouped with them.

From the above discussion, it will be seen that if the resistance r_1 be either held constant or reduced to a negligible value, the principal cause of Class 2 temperature errors will be removed. In precision meters it is preferable to reduce the ohmic resistance by enlarging the winding space available in the potential element.

As a matter of interest, we have been able to compensate exactly for change in resistance with temperature by embedding in the potential windings a carbon filament sealed in a glass tube. The negative temperature coefficient of the carbon serves to keep the total resistance of the circuit constant over quite wide ranges. From other considerations, however, this method has its limitations.

In order to check the above analysis experimentally, an induction meter was tested without a lag plate at 50 per cent power factor. By starting with an additional resistance inserted in the potential circuit, it was possible to keep the total resistance constant as the meter was heated to 60 deg. cent. by gradually cutting out the former. It was found that the meter then had substantially the same characteristic speed-temperature curve as that shown in Fig. 1, thus indicating that change in resistance was entirely responsible for Class 2 errors.

Discussion of Class I Errors

These errors are operative at all power factors and are the most important to be considered. They arise from causes that, in general, cannot be removed and hence must be compensated for. In the great majority of cases, single phase meters are operated at power factors above 90 per cent; and, hence, if Class 1 errors can be eliminated, a substantial advance in the art of accurate metering has been effected.

In the case of two-element ployphase meters, one of the elements is frequently operating at a quite low power factor; and Class 2 errors are usually more prominent. In spite of this, Class 1 errors are still of greater importance and it is just as necessary that they be eliminated.

A very satisfactory method of accomplishing this has been worked out and will be described in Part II.

Part II

Thermalloy, a Temperature-Sensitive Magnetic Material

We have recently succeeded in developing a series of magnetic copper-nickel-iron alloys having low points of magnetic transformation combined with a linear temperature-permeability relation. The particular series of alloys that have been found satisfactory for our purposes have been given the distinguishing name of "Thermalloy" and a letter is used to designate the

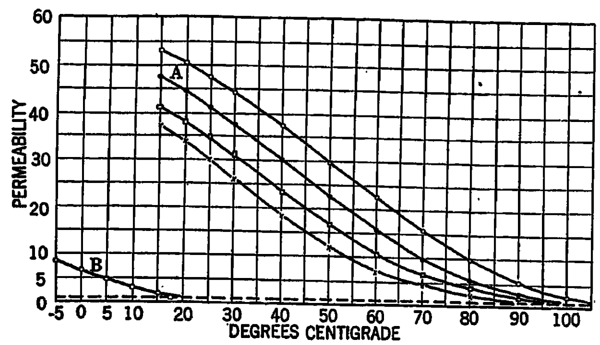

Fig. 11—Temperature-Permeability Curves for Five Samples of Thermalloy $H = 15$

exact composition in each case. At present chief use is made of two particular alloys belonging to this group which are designated as thermalloy *A* and thermalloy *B*. In Fig. 11 is shown a family of curves representing the relationship existing between permeability and temperature for samples of this material in a constant field of 15 gausses.

In order to test these alloys for uniformity, a simple device is made use of as illustrated in Fig. 12. A

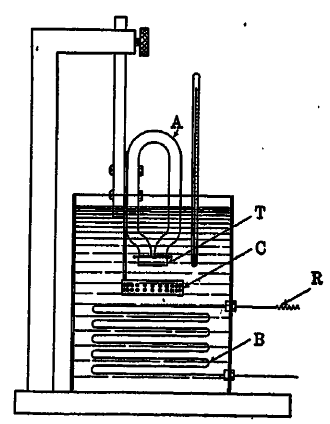

Fig. 12—Device for Control Tests on Thermalloy

standard test piece, *T*, weighing five grams is suspended by a permanent magnet, *A*, in a water bath which can be gradually heated by the small heater *B*. When the test piece has reached the temperature at which the magnet can no longer retain it due to the fact that it has become practically non-magnetic, it falls into the retaining basket, *C*. The temperature of the bath is read by a thermometer and this gives a value that is proportional to the point of magnetic transformation of the material under test. Although this reading is somewhat below the true transformation point, when the test piece falls from the magnet its permeability is very low indeed and for most purposes can be considered non-magnetic at that particular temperature, which we shall term its release point.

In obtaining release points we usually make use of a sample 5/32 inch in thickness, and it has been found from experiment that there is practically no difference in results if samples varying from 1/16 in. to 3/16 in. are used. This simple test, therefore, gives a very ready means of comparing different melts of the same material and also of obtaining the relationship existing between apparent point of transformation and percentage composition of the alloy.

By referring to the premeability-temperature curves in Fig. 11 it will be noted that the permeability rapidly decreases at a nearly constant rate until it approaches that of air when its rate of decrease diminishes. These curves were taken on cast rings of thermalloy, which were carefully machined to size. They were wound with 100 turns secondary and about 500

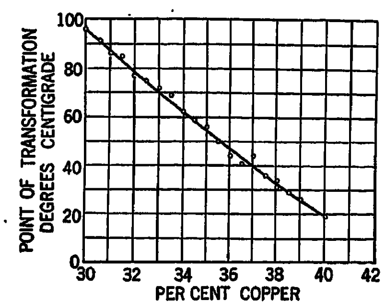

Fig. 13—Curve Showing Relation Between, Copper Content and Apparent Point of Magnetic Transformation of Thermalloy

turns primary so that a minimum heating would result from the magnetizing current. An ordinary ballistic test was employed, but the samples were placed in a tank of oil the temperature of which could be suitably controlled. Base metal thermo-couples were utilized to obtain the exact temperature of each sample, the hot junction of the couple being inserted beneath the insulation on the ring. It might be noted at this time that the so-called "release point" as measured by our testing device agrees very well with the temperature at which these curves appear to reach the permeability of air. For example, Curve *A* is taken on a material that has a release point varying from 92 to 98 deg. cent., whereas the curve indicates approximately 100 deg. cent.

Fig. 13 shows release points plotted against per cent copper, and it is interesting to note that the relationship is practically linear. Small irregularities in the case of some of the samples are probably due to slight variations in the pouring temperatures and cooling rates. The samples were melted in an Ajax high frequency induction furnace, poured, and allowed to cool in sand moulds. Alloys of this nature vary mark-

edly in magnetic properties with composition and heat treatment,[4] hence conditions must be carefully controlled in order to produce uniform results. Gans and Fonseca[5] have published an interesting article showing how the point of transformation from a ferro-magnetic to para-magnetic state in pure copper-nickel alloys varies with the composition. The values of transformation points obtained by them check those shown in Fig. 13 very closely, although they worked

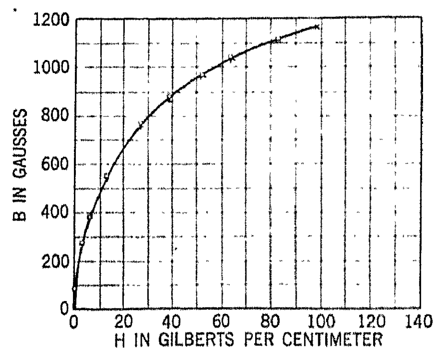

FIG. 14—HYSTERESIS LOOP FOR THERMALLOY A
Temperature = 29.5 deg. cent.

with pure nickel. This close agreement is probably largely accidental, however, because methods of test differ widely and they do not specify heat treatment which is very important. These investigators found a linear relation which checks our results, but so far as we have been able to learn no one has investigated the character of permeability-temperature curves below the transformation point for these alloys.

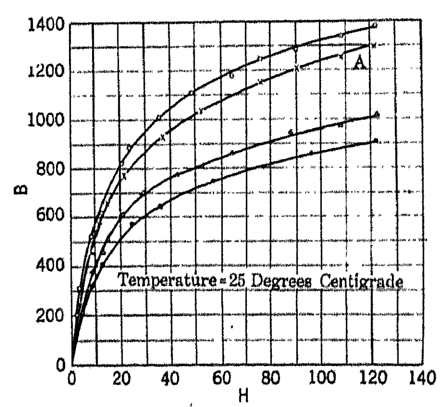

FIG. 15—NORMAL INDUCTION CURVES FOR FOUR SAMPLES OF THERMALLOY
Temperature = 25 deg. cent.

Thermalloy *A* contains approximately:
Cu 30.0 per cent
Ni 66.5 per cent
Fe 2.2 per cent
Impurities 1.3 per cent

One effect of adding iron to the alloy is to raise the point of magnetic transformation. The addition of 2.3 per cent of iron to an alloy of 70 per cent pure nickel and 30 per cent electrolytic copper raised the release point about 45 deg. cent. Since most commercial nickels contain some iron we simply add sufficient additional to bring the total percentage up to the desired value. Among other advantages it is possible to obtain the required results at a much lower cost in this manner.

Heat treatment of thermalloy has important effects on its magnetic properties. Grade *A*, for instance, gives an average reading of 95 deg. cent. as its release point in our test when cooled slowly in a sand mould; if it is cast in graphite moulds it is practically non-magnetic at 20 deg. cent. The same metal when cast in a mould of zerconium silicate released at 60 deg. cent. The castings in both of these cases were one-half inch square and seven inches in length. In the case of the bar having the 60 deg. release point heating for two hours at 700 deg. cent. and cooling in air raised this point to 98 deg. A sample having a release point of 95 degrees was heated to 900 deg. and quenched in cold water. This treatment lowered its release point to

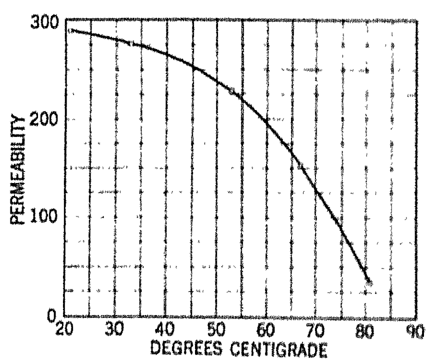

FIG. 16—TEMPERATURE-PERMEABILITY CURVE FOR MONEL METAL

75 deg. It will be seen, therefore, that in order to obtain uniformity in results it is necessary to carefully control the conditions under which the alloys are made.

The heating and cooling premeability-temperature curves are practically identical for thermalloy, providing it is held at any one temperature for a sufficient length of time to reach equilibrium. This is on account of the extremely small hysteresis loss in this material. In Fig. 14 are shown the points obtained on a hysteresis loop taken at a maximum magnetizing force of 100 *H*, which serves to bring it well past the knee of the normal induction curve. Within the limits of accuracy of the apparatus used in obtaining these data very little loss can be detected. Another unusual characteristic is that the retentivity is only about 8 per cent of the maximum induction so that with an air gap in the magnetic circuit the remanence should be inappreciable.

Of course, the permeability of these alloys is quite

4. Nickel and its Alloys—*Bureau of Standards Circular*, No. 100.
5. Die Magnetischen Eigenschaften von Nickel-Kupfer Legierungen—*Ann. Physik*, 61, p.742.

low as indicated by the normal induction curves in Fig. 15. For certain applications, however, high permeability is not essential or even desirable as is the case with the one herein described. The specific resistance of thermalloy A is about 49 michroms per centimeter cube:

The chemical composition of thermalloy A is similar to that of monel metal but by referring to Fig. 16 it will be seen that the characteristic permeability-temperature curve is very much different. The permeability of monel falls off very rapidly as the point of transformation is approached, as is the case with iron and other ferro-magnetic materials. It is believed that this sudden decrease in permeability on approaching the point of magnetic transformation is a characteristic of nickel-copper alloys in which the two metals form a homogeneous mixture.

The Heusler alloys[6] are similar from a metallurgical point of view to the alloys just discussed since both are solid solutions with copper as the solvent. Also the Heusler alloys have low points of magnetic transformation and increasing the copper content lowers this critical point. In general, they are more difficult to work with, both in regard to casting and machining, than the copper-nickel series.

From the foregoing it will be seen that we now have available an almost perfect means of compensating for variations in watthour meter speed with temperature.

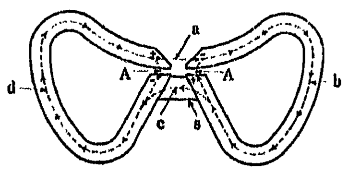

FIG. 17—SCHEMATIC DIAGRAM OF MAGNET COMPENSATION WITH THERMALLOY

Fig. 17 shows a magnetic shunt made of thermalloy inserted between the control magnets, of a watthour meter. In this arrangement two single magnets are paired together and the polarity is such that there is a small amount of flux circulating around the path a, b, c, d. We may think of this part of the flux as being shunted from the main path across the gaps and it is increased by the insertion of the small bridge, S, of thermalloy, which may be termed a magnetic shunt. With an increase of temperature the total flux of a magnet decreases as has previously been described, whereas in order to effect a compensation for Class 1 errors it is necessary that the total damping flux actually increase somewhat. In the device shown in Fig. 17, this condition does exist because as the temperature rises, the permeability of the magnetic shunt decreases linearly and a larger percentage of the total flux crosses the air gaps, $A.A.$ By selecting a shunt of the correct dimensions this effect will exactly compensate for the overall temperature error of the meter.

An average speed-temperature curve for a watthour meter has been shown in Fig. 1. It will be seen that the rate of decrease of meter speed with temperature increases rather rapidly just below room temperature, whereas the rate of increase in permeability of thermalloy A below room temperature has a tendency to decrease. This would result in under-compensation at low temperatures, and in order to overcome this difficulty we have made use of a compound magnetic shunt; that is, we insert a piece of thermalloy B in parallel with the first. This has a release point of 15 deg. cent. and hence is non-magnetic at ordinary room temperatures. As the temperature falls, however, it serves to correct the under compensation as above noted due to its increasing permeability, thus giving results that are correct at very low temperatures. The cross sections of these two shunts are so adjusted that the meter runs at correct speed at −14 deg., +25 deg. and 55 deg. cent., and the compensation holds good over considerably larger ranges.

In order to determine whether uniform compensation could be effected by this means, hundreds of magnets were built up and tested on stock meters, and Table I shows the results obtained on a typical group of 20 magnets. The maximum error due to temperature at unity power factor was 0.4 per cent for a 30 deg. cent. rise. The chief reason exact compensation cannot be effected on a large scale is that individual magnets vary somewhat in temperature coefficient, but the variation is small and for practical purposes can be neglected. Table II shows the results of similar tests on a group of uncompensated magnets. It will be noted that variations occur between magnets of the same order as is present in Table I.

Conclusions

Temperature errors in induction watthour meters can be divided into two general classes,—1. Those affecting the magnitude of the driving flux or braking flux, 2. Those affecting the phase relation between the line voltage and induced voltage in the potential element.

The permanent magnets used for braking are responsible for the greater portion of the errors under Class 1, and this being due to a natural characteristic of magnet steel cannot be eliminated.

Ordinarily, Class 2 errors are not of great importance, but they can be reduced by proper design of the potential element. They are caused almost entirely by changes in resistance of the potential windings and lag plate.

Class 1 errors may be neutralized by a single compensation, consisting of a device whereby a small portion of the flux is shunted through a special alloy—(thermalloy)—the permeability of which is very sensitive to temperature.

Induction watthour meters compensated with thermalloy magnetic shunts, even without any further modifications, are practically independent of temperature changes over very wide ranges providing the power factor is reasonably high. By suitable modifications, the compensation may be made independent of power factor.

The application of compensated magnets to meters on a production basis gives a reasonable degree of uniformity in results, and very rarely will errors as high as 0.013 per cent per deg. cent. rise be encountered.

This method of compensation has the distinct advantage of being independent of any necessary adjustment of the meter, and is extremely simple and positive in its action.

By preparing certain copper-nickel-iron alloys in the form of castings suitably heat treated, a linear relationship is obtained between permeability and temperature. By controlling the copper content the point of transformation of these alloys may be made to occur at almost any desired temperature below that of pure nickel.

The hysteresis loss of thermalloy is extremely low; hence the heating and cooling curves in a constant field are practically identical, although there is a small time lag before the metal reaches equilibrium at any one temperature.

It is believed that some of the characteristics of these alloys, such as perfectly reversible straight line permeability-temperature relationship, combined with negligible hysteresis, has escaped previous notice and that they are an important contribution to engineering materials.

It is probable that the linear temperature-permeability relationship of thermalloy is due to the non-homogeneous manner in which the copper is held in solution, which gives the effect of the summation of a large number of alloys, each having a different transformation point.

In addition to temperature compensation, thermalloy may be used for a variety of purposes one of which is a direct reading low temperature thermometer as described in the appendix.

Appendix

Description of Magnetic Thermometer Utilizing Thermalloy

The approximately linear temperature-permeability relation of thermalloy may be utilized in the construction of magnetic temperature indicators. An instrument of this type is shown in Fig. 18. In this figure, *A -A.* is a vane made of thermalloy and *B -B.* is a vane made of iron or of some other magnetic material having a low temperature-permeability coefficient. It is evident that the armature will take up a position in which the sum of the magnetic moments acting on *A.-A.* is equal and opposite to the sum of the magnetic moments acting on *B -B.* This position will vary with a variation in temperature as the moments on *A -A.* vary with its change in permeability. The upper limit of the scale is reached when the temperature is equal to the magnetic transformation temperature of the thermalloy. The lower limit is not sharply defined, as this would require either that the thermalloy reach a value of permeability compared with which that of the iron would be neglibible, or that the temperature-permeability coefficient of the thermalloy would have

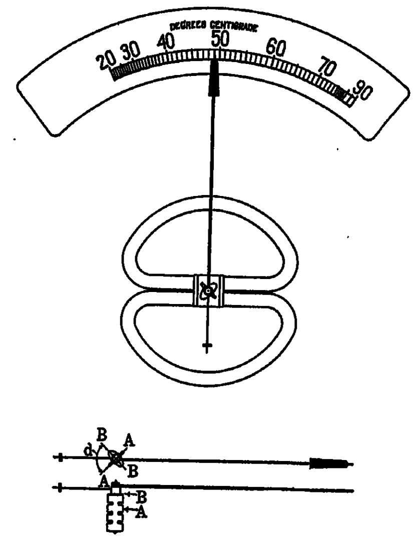

Fig. 18—Diagram of Magnetic Thermometer

to become equal to that of the iron. However, with the instrument shown in Fig. 18 the congested region extends over only a small part of the scale.

It is also possible to construct magnetic thermometers using a thermalloy vane or an iron vane in a magnetic field acting against the torque of a hairspring. In the case of the iron vane instrument, variation of torque with temperature is obtained by means of a thermalloy shunt in parallel with the air-gap in which the iron vane is placed.

Discussion

H. B. Brooks: The paper by Kinnard and Faus is important and valuable, not only for its definite data and clear reasoning, but also because it is a tangible indication of the interest which is being taken in the question of the accuracy of metering. This interest reveals itself in many ways; for example, in the increasing attention which is being given to the ratio and phase-angle performance of instrument transformers. Among reasons for this interest may be mentioned the greater attention which must be given to plant operation, because of higher costs of fuel and other essential supplies; the growing tendency toward interconnection, with the consequent need of accurately measuring interchanged energy; and the necessity for accurate electrical measurements in acceptance tests of turbo-generator units, where an error of a fraction of one per cent may mean an error of thousands of dollars in penalty or bonus. Such tests must necessarily extend over a period of hours, and the load cannot be kept as constant as might be done with small machines in the laboratory. It is only natural, therefore, that those having to make such tests should turn to the watthour meter as a means of measuring the energy and hence the electrical power output. However, from information which has come to us, it appears that such use of watthour meters does not give results as consistent as can be had by the use of indicating wattmeters read at sufficiently frequent intervals. Nevertheless, the large amount of labor required for the latter procedure makes it desirable to bring up the performance of the watthour meter, if possible, to such a stage that it will be good enough for plant acceptance tests. The work done by Kinnard and Faus is an important step in this direction, and I hope they will continue their analysis of sources of meter errors and means for overcoming them.

There is an astonishing lack of accurate information on temperature errors in watthour meters. Published papers exist, but they either relate to meters of obsolete types, or lack necessary data. For example, one paper on temperature errors of American watthour meters leaves it to be inferred that the meters were of the alternating-current type, and while giving many curves of performance, fail to state the power factor of the loads. Text books also are often at fault; for example, an English book published in 1923 states that "In an induction meter both the operating and the braking torques are developed by the medium of eddy currents, often in the self-same disk, so that temperature effects cancel out completely." Similar inaccurate and superficial statements may be found in some other reputable treatises on meters.

Taking up the paper in detail, I would first inquire why a watthour meter was used as a standard by which to determine the performance of the meter under examination. Even though this standard meter was kept at room temperature, it seems probable that errors resulting from self heating and consequent temperature inequalities within the standard meter might affect the observed results undesirably, and that a wattmeter would have been preferable.

Referring to the tests at unity power factor with the lag plate removed, I would suggest that by replacing the lag plate with a lag *coil* of similar form, closed through an adjustable external rheostat, the effect of change of resistance could be readily determined.

A comparison of Fig. 6, Curve *C*, with Fig. 7, Curve *C*, shows that the high temperature coefficient of the copper lag plate is responsible for a fair share of the Class 2 error in this particular type of meter, and suggests the use of some material of lower temperature coefficient.

It is gratifying to have a definite answer, such as the authors give us, in regard to the idea that the length of the gap of meter magnets varies with temperature. The value given for the temperature coefficient of the gap flux presumably refers to the kind of steel in regular use at this time. Fitch and Huber, at the Bureau of Standards, found values ranging from -0.0001 to -0.0003 per deg. cent., with a mean value of -0.0002. At the time this work was done (1913) tungsten steel was used, as far as we were aware.

I think the authors are to be congratulated on their neat and simple solution of the matter of Class 1 errors, especially in view of the peculiar form of Curve *A*, Fig. 1, which they take care of by using two bridge pieces of different grades of thermalloy in parallel.

The statement that Class 2 errors are more prominent in two-element polyphase meters is evidently made with the idea that such meters usually measure loads of power factors less than unity, for on the usual assumption of a balanced three-phase load a polyphase meter working under a given phase-angle error (alike in the two elements) measures the total load on it with exactly the same error as would occur in measuring the load with an otherwise identical single-phase meter with the same phase-angle error. In other words, with balanced loads we do not need to reason differently concerning polyphase meters and single-phase meters as regards either Class 1 or Class 2 errors.

The next step is evidently to get rid of Class 2 errors, and if possible in a manner as simple and elegant as the one given in the paper for Class 1 errors. I wish to mention a method which has occurred to me recently, which has apparently been shown to be sound in principle by a simple experiment. According to Schmiedel, the flux Φ_I from the current electromagnet lags behind the current I (see Fig. 10B) by a small angle, which we may call γ, and which for simplicity the authors of the paper have not considered; the effect of this angle is that the lag plate must be adjusted to lag the voltage flux Φ_E by an angle δ which is not equal to ψ but to $\psi + \gamma$, at standard temperature. When the temperature increases, ψ increases while δ decreases, so that the compensation is no longer correct. In this lies the entire reason for Class 2 errors. I propose that we put a lag coil on the current electromagnet, thus lagging its flux Φ_I by an additional angle which may be called β. Hence at standard temperature we must now adjust δ to be equal to $\psi + \gamma + \beta$, in order that the meter may be correctly lagged. Let us give the lag coil on the current electromagnet a high temperature coefficient, for example by closing it through a resistor of very pure iron wire, and also give the lag coil on the voltage electromagnet a suitably low temperature coefficient. We may thus make the small angle β decrease with temperature at a sufficiently rapid rate to compensate for the increase in ψ and the decrease in δ; in other words, to maintain the relation

$$\delta = \psi + \gamma + \beta$$

at all temperatures, and thus eliminate Class 2 errors. It is obvious that β must also compensate for any change of γ, concerning which at present no numerical data seem to be available. It is of interest to note that the iron-wire resistor for the current lag coil may be embedded, wholly or in part, in the voltage winding, in order to respond to changes in temperature of the latter, just as the authors of the paper did with their carbon filament.

In making this suggestion, I realize that we cannot lose sight of the variables other than temperature to which a meter is

exposed, such as variations of voltage, frequency, and wave form, and if my proposal for eliminating Class 2 errors should lead to an unavoidable increase in the errors from these causes, another and unobjectionable solution must be found. The suggestion is offered for what it is worth, in the hope that it may assist in the eventual solution of the problem of temperature compensation of watthour meters.

J. R. Craighead: With respect to Mr. Kinnard's paper, there is only one point I should like to call attention to. Under Conclusions, he has a conclusion referring to driving torque and damping torque as being only one side of the thing which may cause the watthour meter to go wrong. It seems to me that if the driving torque and the damping torque, in the broad sense, are both correct, you have a correct watthour meter. In other words, errors in driving torque or damping torque constitute the whole error. I would suggest that he use the word "flux" perhaps instead of "torque" in that place as expressing more accurately what he means.

F. B. Magalhaes: I wish to place on record a statement which is not intended to be complimentary on a personal basis to the authors but which would be made quite impersonally to any one presenting the same development. Progress in any field can be considered as going forward by more or less slow steps, and after a step forward has been taken there is a consequent search or analysis made on that step, to develop all of the possibilities that may be obtained from the single step forward.

The authors of this paper in using the methods which they have described have introduced a new means for correcting certain errors that have to the present time been considered more or less accepted or inherent in the design of a watthour meter. Without any doubt, this step forward will therefore be followed by a considerable amount of lateral or parallel research to develop all the possibilities that the step forward may offer. On this basis, it should be recorded that the idea of using a small piece of alloy near the jaws of the magnet as an automatic means for correcting the temperature errors that have heretofore had to be accepted, is distinctly to be commended as an important step forward.

One specific question I would like to ask is in reference to the permanence of the alloys which they have used. They have outlined in some detail the necessity of watching carefully the mixture of the alloy and their heat treatment. It leaves, therefore, a question in the reader's mind, I believe, as to the ultimate permanency of the alloy. The results that have been obtained can be seen on the curves. However, the permanent value of the results that have been obtained will be based largely on the permanence of the correction that has been made. If the alloy is not a stable alloy and may change with the passing of time or under temperature conditions that may be encountered in the field, it will detract very greatly from the value of the results obtained. It would be interesting to know, therefore, what results the authors may have to establish this point of permanence.

Joseph Slepian: There are just a few consequences of the phenomenon that Messrs. Kinnard and Faus use that I think will be interesting.

Some time ago there was a patent issued to Thomas A. Edison disclosing the rather ambitious project of making a heat engine using this very phenomenon. Edison proposed to allow a large mass of iron to be pulled into a magnetic field, there to be heated until it became non-magnetic, and then to be released, thus getting work at the expense of heat energy.

The fact that it is possible to get work out of this phenomenon at the expense of heat makes it possible to apply the principles of thermodynamics and get relations connecting the properties of these materials.

One need only apply the first and second laws of thermodynamics. It will necessarily follow that a piece of magnetic material having a temperature coefficient must change its temperature as it moves from a weak field into a strong field. That is, its specific heat must change. I believe it will have to rise in temperature as it moves into a strong field and fall in temperature as it moves into a weak field.

I would like to ask Messrs. Kinnard and Faus just what are the special merits of the alloys which they have chosen. There are, of course, many alloys that have transition points at temperatures in the ordinary range. Some of them have been known for a long time. Those of most interest were the Heusler alloys which contain no elements which are ordinarily magnetic, and the question occurs to me as to whether these other materials are wholly unusable, or whether it is simply some point of refinement that causes one to use these particular alloys rather than the others that are known.

W. H. Pratt: The method of correcting for Class 1 errors is peculiarly direct and effective. It corrects the errors where they occur and when they occur. I mean by this that the thermalloy shunt is in such intimate contact with the controlling magnets that it partakes uniformly of the temperature changes of the latter, and on account of the absence of hysteresis renders the correction particularly effective.

The course suggested for minimizing Class 2 errors is also directly aimed at securing excellent results, for by the reduction of the resistance of the potential coils not only is the desired result obtained, but it is a change that is in the right direction to improve still further the behavior of the meter in regard to frequency and wave-form errors.

I think this last remark has a bearing on some points that Mr. Brooks raised in his discussion. The arrangement that he proposed for compensating for phase displacement is such as to expose the windings to the rather extreme changes of temperature which comes from the current coils. The coils which he suggested would be naturally exposed to these rather extreme changes, and it would not accomplish that further refinement of the meter that is accomplished by a reduction in resistance.

C. M. Jansky (by letter): This paper is of considerable scientific and practical importance as it is the best analysis of the influence of temperature that I have seen. There is no mention made, however, of the study of this problem that was made at the University of Wisconsin several years ago by Mr. B. E. Miller. The results of his investigations of the effect of temperature on the registration of watthour meters at 10, 50, 100 and 150 per cent loads were published in the September 18, 1915 issue of the *Electrical World.* Mr. Miller's results show that the error is not the same with increasing as with decreasing temperatures. The per cent of registration when plotted against temperature gave a decided "hysteretic" loop. Messrs. Kinnard and Faus do not refer to this paper, but if they have seen it I would be pleased to have their explanation of this difference in the accuracy with increasing and decreasing temperatures.

I. F. Kinnard: In Dr. Brooks' discussion, he asked why we made use of a watthour meter rather than a wattmeter in obtaining our readings. We believe a watthour meter may be advantageously used as a standard, in order to study the effects of varying temperatures on another watthour meter if care is taken to insure that the standard watthour meter is kept at a constant ambient temperature, and if, before readings are made, it is allowed to run a sufficient length of time to reach its maximum self-heating value. Very accurate results are obtainable, with a minimum of trouble due to other possible variations such as frequency.

In connection with the point raised in regard to studying the effects of changes in temperature of the lag plate by the use of a lag coil with an external resistance, this can undoubtedly be done and should give interesting information, although for our particular purposes we did not consider it necessary. We do not feel that the lag plate causes temperature errors of sufficient magnitude to call for the use of brass or manganin as the situa-

tion now stands. It has been pointed out, however, in the paper that for certain applications Class 2 errors can and should be eliminated, or at least reduced by modifications of the potential element. When this is done the copper lag plate will undoubtedly be dispensed with.

It is true, as pointed out by Dr. Brooks, that the same reasoning applies to polyphase meters as discussed for single-phase. Class 2 errors are, however, of more importance in the polyphase meter due to the fact that the line power factor is frequently quite low. This can be fairly satisfactorily taken care of by using but one compensated and one uncompensated magnet on a two-element meter. As I previously stated (and it has been brought out in the discussion), the better way is to eliminate Class 2 errors by reducing resistance of the potential winding.

Mr. Magalhaes raises the question of the permanency of thermalloy used as a magnetic shunt. I wish to say that we have had magnets compensated in this manner under observation for over a year and a half and no aging effects of any magnitude have been observed.

We might also bring to your attention the fact that copper-nickel alloys have been continuously used for a large number of years in connection with resistance materials, Monel metal and other applications, and it is known to be a stable combination.

Mr. Craighead points out a statement in the first part of the conclusions that might be open to some question, and I believe his point is well taken. I meant to refer to the driving flux in classifying the errors that do not depend upon power factor.

Dr. Slepian points out a very interesting fact, that there are other alloys such as the Heusler alloys, which probably have some characteristics similar to those we have described for the copper-nickel series. As a matter of fact, we have mentioned in the paper that the Heusler alloys have a possible application in this connection, although we believe the copper-nickel series can be better controlled, has a somewhat higher permeability, and is easier to machine, outside of the fact that it is of lower cost.

Prof. Jansky asked whether or not there is a hysteresis lag in the heating and cooling curves of a watthour meter. We have not observed any such effect, in the large number of tests made with these meters, although there is a distinct time lag. That is, if a watthour meter is held at any one temperature for a sufficient length of time to reach equilibrium, its cooling curve will be identical with its heating curve.

C. H. Ingalls: For the past twelve years, the Meter Division of the Boston Edison Company has corrected for the temperature errors of its portable test meters through thermometers permanently installed in the meters. A recent occurrence illustrates how the accuracy of an uncompensated meter may be affected by certain abnormal temperature conditions.

Two testers were working in the same locality, one of whom went to work directly from home, the other starting from the office. The former kept his test meter in his automobile over night, while the latter's meter was stored in a warm place. This resulted in a difference in temperature of 20 deg. cent. between the two meters at the start of the day's work, corresponding to a difference in the corrections to be applied to the test meters of nearly two per cent. Subsequent tests proved that the thermometers and the applied corrections were correct. It is particularly gratifying that such a simple and positive means of correction for temperature errors can be applied to test meters. The correction of temperature errors at low power factors is not quite as important as the correction at unity power factor, because, with comparatively few exceptions, watthour meters are tested on the system only at unity power factor.

A. E. Knowlton: It might be well to mention that reference to the temperature errors of watthour meters in this paper gives no occasion to the multitude of users of electric service to be disturbed about the situation. I think it is fairly safe to say that they are having that service metered to them with a degree of accuracy not matched by any other commodity service, whether sold by the pound, by the cubic foot or by count. We are dealing here with the minutiae and any layman who chances to read papers of this kind has no reason to be disturbed by our activities in improving electric metering.

I. F. Kinnard: The point brought out by Mr. Ingalls serves to illustrate how a simple and reliable temperature compensation, such as described in this paper, will aid in obtaining precision results in the calibration of watthour meters. As he has indicated, it was hitherto necessary to be sure that test meters were not at abnormally high or low temperatures before using them, in order to obtain the best results. The automatic compensating shunt, however, insures a constant performance over very wide temperature ranges and makes it entirely unnecessary to use thermometers.

As Mr. Knowlton has intimated, the fact that a distinct refinement has been made in the art of watthour-meter manufacture should not in the least shake our confidence in existing meters. If the paper be read carefully it will be seen that errors or variations due to temperature are inherently small in this class of apparatus. It is, however, a distinct advantage to be able to state that temperature will in no way affect the results obtained irrespective of any extreme conditions of use, and it is to that end we are working.

Storage Battery Electrolytes*

BY G. W. VINAL† and G. N. SCHRAMM†
Member, A. I. E. E. Non-member

Synopsis.—Experiments have been in progress at the Bureau of Standards to determine quantitatively the effect produced by a wide variety of impurities on the rate of sulphation of storage battery plates. The method for making the determinations involves measuring the changing weight of the plates suspended in the solution. The various impurities are classified according as they affect the negative plates, the positive plates or both. A discussion is given also of certain combinations of impurities. Sodium and magnesium sulphates which are sometimes added to the electrolyte to "improve" the behavior of the battery are without effect on the rate of sulphation. It is important that some generally recognized specifications for storage battery electrolytes should be established.

Introduction

The satisfactory operation of a storage battery is in a large measure dependent upon the physical and chemical properties of the electrolyte which it contains. Within recent years storage batteries have come to be used under widely varying conditions of service, and millions of them annually pass into the hands of people who have no technical knowledge of their construction or adequate information with regard to the care which they should receive. Some of them are used at extremely low temperatures in airplanes and signal service while others are subjected to abnormally high temperatures in the tropics. Considering the diversity of the service which they have to perform, it is increasingly important that the physical and chemical properties of the electrolyte should receive more extended study.

For a number of months experiments have been in progress at the Bureau of Standards to determine quantitatively the effect produced by various impurities on the rate of sulphation of storage battery plates. The method which involves a determination of the weight of the plates while suspended in solution has been described in a previous publication.[1]

The results of experiments on a few of the impurities have been previously published in the JOURNAL of the American Institute of Electrical Engineers.[2]

TABLE I
ACCURACY OF MEASUREMENTS ON NEGATIVE PLATES
(Average of 14 experiments, pure electrolytes, 1.250 sp. gr. 25 deg. cent.)

Time (hours)	Average Gain in Weight (grams)	Probable Error of Average Value (grams)	Probable Error of Single Observation (grams)
50	0.69	0.03	0.15
100	1.44	0.06	0.24
200	2.68	0.09	0.33
300	3.87	0.13	0.41
400	5.03	0.16	0.50
500	6.08	0.21	0.60

In the present paper the results of experiments covering a wide range of impurities are given. The tables that follow give the quantitative relation between the amount of the various impurities which were added to the pure electrolyte 1.250 specific gravity, and the effects produced as judged by the change in weight of the plates.

Accuracy of Measurements

In the course of the experiments a number of determinations have been made of the rate of sulphation of storage battery plates in pure electrolytes having a specific gravity of 1.250 at 25 deg. cent. These may be considered as control experiments by which the effects produced by the impurities are to be judged. One control experiment was made with each group of five measurements. An analysis of these permits the computation of the probable error of the average value and the probable error of a single observation.

It is important to establish the range of the probable error in these computations. There are a number of impurities which produce little or no effect, and any definite statement that they do or do not produce an effect must be based upon a comparison with the normal values for plates in pure solutions to within the limits of the probable error.

Table I, for negative plates, and Table II, for positive plates, give the average gain in weight in pure electrolyte for these plates together with the probable error. In classifying the impurities according to the effects produced, the average value of the control experiments is given for comparison, except in Table VII where the measurements all belong to one group. For these, the value of the control experiment of this group is given.

Impurities Affecting the Negative Plates Only

The impurities which affect the negative plates only (Table III) may be divided into two classes:

a. Impurities which are deposited quickly in the metallic state upon the negative plates and produce appreciable gassing. These include platinum, copper and silver. A closed circuit exists between the underlying lead of the plate and the impurity which is deposited upon it. Lead sulphate is formed in proportion to the quantity of electricity flowing and the plate

gains in weight. Hydrogen is liberated at the surface of the impurity. The local action produced by these impurities proceeds at a fairly rapid rate until the ultimate capacity of the plate is exhausted. A considerable part of silver and copper, which was deposited on the plates as a spongy or tree-like mass, subsequently fell off so that the gain in weight of the plates represents chiefly lead sulphate. These impurities cannot be eliminated by changing the electrolyte in the battery, but their effect may in some cases be mitigated as Gillette[3] has shown. The results which are given in Table III show that platinum is one of the most deleterious of impurities. Extremely small amounts are sufficient to produce rapid sulphation of the plates. Copper produces less effect. These results have been abstracted from the previous paper by Vinal and Altrup, and in the case of copper a correction has been made for a misplaced decimal point in the former publication.

TABLE II
ACCURACY OF MEASUREMENTS ON POSITIVE PLATES
(Average of 17 experiments, pure electrolytes, 1.250 sp. gr., 25 deg. cent.)

Time (hours)	Average Gain in Weight (grams)	Probable Error of Average Value (grams)	Probable Error of Single Observation (grams)

b. The second class of these impurities includes those chemical compounds which are reduced more slowly at the negative plates and result in little, if any, perceptible liberation of hydrogen. In some cases these impurities can be eliminated from a battery by replacing the electrolyte. For some of these, a quantitative comparison may be made between the calculated and observed changes in weight of the plate.

Bismuth presents an interesting example of the reduction produced at the negative plates accompanied by the deposit of the bismuth itself as a brown powder on the plate. Bismuth trioxide reacts with sulphuric acid to form bismuth sulphate and this, in turn, is reduced at the negative plate to bismuth with the formation of an equivalent amount of lead sulphate. For the 12.5 grams of bismuth trioxide, which were added to the solution, 24.4 grams of lead sulphate should be formed, and to this must be added the weight of the bismuth, 11.2 grams, deposited on the two plates in the solution making 35.6 grams as the calculated increase in weight of the plates. The amount actually observed was 33.6 grams. No appreciable effect was produced by the bismuth on the positive plates. The local action produced by the bismuth which is deposited in the pores of the negative plates is relatively slow, but the diffusion of the electrolyte into the plates is doubtless impeded with a consequent loss in the available capacity.

Antimony and arsenic, like bismuth, affect the negative plates, but are without apparent action at the positive plates. Antimony in particular produces a rapid discharge of the negative plates. The reactions of antimony and arsenic are probably analogous to those of bismuth, as the reduced material becomes visible after a short time. There is, in addition, a marked accelerating effect in the case of antimony, since the sulphation of the negative plates as measured by the increase in weight is much greater than would be calculated for the equivalent reduction of the antimony sulphate. This effect is less in the case of arsenic. The presence of either antimony or arsenic in the electrolyte is also detrimental because of the possible formation of stibine or arsine in the presence of hydrogen. These poisonous gases, escaping from the cells, become a serious hazard to those using the battery.

Nitrates which were added to the solution as nitric acid were reduced at the negative plate and produced a marked increase in the rate of sulphation. Even so small a quantity as 0.001 per cent produced a measurable result. Small quantities of nitrates probably do little permanent damage as they are gradually eliminated from the cell as oxides of nitrogen or reduced to ammonia. Nitrates were without effect in our experiments on pasted positive plates, but their use as corrosive agent in forming planté plates from sheet lead is, of course, well understood.

TABLE IV

Impurities Affecting both Positive and Negative Plates

In the previous paper,[4] details of the reactions of iron and manganese have been given. Iron is perhaps the most common impurity in storage battery electrolytes. It is oxidized at the positive plate and reduced at the negative plate without depositing on either *ad infinitum.* Since it stays in solution it can be eliminated by changing the electrolyte. Manganese is more detrimental to the positive plates than to the negatives. Its reactions are complicated and will not be repeated here.

Chlorine is a detrimental impurity for both the positive and negative plates, although in small quantities its effects are more pronounced on the positives. Chlorine is liberated at least in part from the cell, but others have stated that a portion of it is oxidized to perchloric acid and this remains in the electrolyte. The addition of sodium chloride to the electrolyte was tried because of the reactions which occur when sea-water may accidentally find its way into storage batteries used on shipboard.

Impurities Affecting Positive Plates Only

Impurities of this class are organic compounds. In our experiments with acetic acid, the effects produced were smaller than were anticipated, and several additional portions of acetic acid were added to the same jar at intervals without much effect as shown in the table.

Following the experiments with acetic acid a small group of separators which had not been previously used in batteries were extracted with sulphuric acid (1.250 specific gravity), and this solution was tried on both positive and negative plates. No appreciable effect on the changing weight of the negative plates was observed. However, the effect on the positive plates was striking. Separators which had been previously treated preparatory to their use in storage batteries produced smaller effects than similar separators which had not been so treated. These results led us to try dextrose, sucrose, invert sugar, and starch which produced effects of about the same amount. Tannic acid, however, produced only a very small effect as shown in the table. These results show that the separators have important effects which warrant further investigation.

Local Action Produced by Combinations of Impurities

Table VI shows the effects produced on negative plates by combinations of impurities which, taken singly, produced less effect than when present in combination.

Kugel[5] showed that the action of such combination as tungsten and copper exceeded materially the effects of either of these materials singly. The extraordinary effect of adding a small percentage of copper to a solution containing a small percentage of tungsten is shown graphically in Fig. 1.

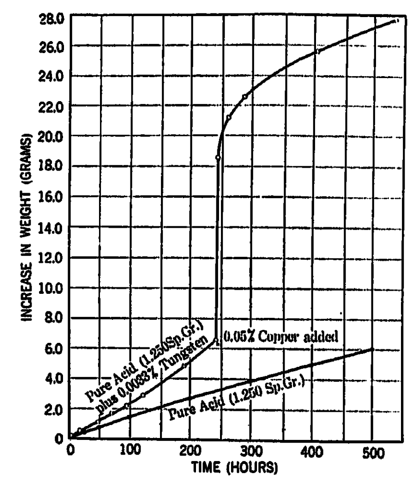

Fig. 1—Effect of a Combination of Copper and Tungsten on Negative Plates

In addition to the experiments on tungsten and copper, combinations of copper with other impurities such as mercury, molybdenum, zinc, arsenic, and antimony were tried. In all of these cases it was found that the rate of sulphation of the negative plates was greatly accelerated. These results are significant in showing that it is important to limit the percentage of copper which may be present in the electrolyte to the smallest reasonable figure.

In explanation of this effect, Kugel has suggested that the polarization on the copper is decreased by the presence of tungsten. Scarpa[6] has advanced a similar explanation that the presence of tungsten lowers the overvoltage necessary for the evolution of hydrogen

on the surface of the copper. For this reason the local currents flowing between the copper and the underlying lead of the plate are greatly increased. This appears the most probable explanation and our results show that in addition to tungsten, which is an unusual impurity to find in storage battery electrolytes, there are a number of others much more likely to be present which may produce the same effects.

TABLE V

LOCAL ACTION PRODUCED BY IMPURITIES AFFECTING ONLY THE POSITIVE PLATES

(Results are expressed as the gain in weight of a single plate at intervals from 50 to 500 hours).

Impurity	Percentage Impurity	Time in Hours					
		50	100	200	300	400	500
None	(Control experiments)	0.34	0.51	0.66	0.86	1.05	1.15

Separator extracts (untreated)	..	8.9	13.5	18.6	21.1	..	..
Dextrose	1.0	23.2	26.3	27.2	..	..	..
Sucrose	1.0	23.6	26.7	27.6	..	..	..
Invert Sugar	2.0	23.6	26.4	26.8	..	..	..
Starch	0.5	11.5	20.3	25.1	..	..	..
Tannic Acid	0.10	0.6	1.1	1.9	2.6	..	..

In the course of our experiments combinations of tungsten with arsenic, antimony, and several other impurities were tried, but the tungsten produced no unusual effect except when in combination with copper.

Impurities Producing Little or No Effect

In the course of our experiments a number of impurities were tried which produced little or no effect on either the positive or negative plates. These included sodium, calcium, magnesium, aluminum, zinc, cadmium and mercury.

At various times sodium and magnesium sulphates have been suggested as an addition to sulphuric acid of the ordinary electrolyte to decrease the sulphation of the plates. Table 7 gives in detail the results which were obtained when these materials were added to 1.250 specific gravity electrolyte, and it will be seen that the agreement between the solutions containing these materials and the control experiment is within the limits of experimental error for both positive and negative plates. These results indicate that these substances are without effect on the rate of sulphation in concentrations up to 5 per cent, and no benefit is to be derived by adding them to ordinary solutions. Others have claimed that the presence of sodium sulphate and similar substances is harmful, resulting in the disintegration of the negative plates.

TABLE VI

LOCAL ACTION PRODUCED BY COMBINATIONS OF IMPURITIES AFFECTING THE NEGATIVE PLATES

(Each experiment was started with the first named impurity and then copper was added at the time shown)

Combination	Material Added	Percentage Impurity	Time of Adding Cu (hours)	Time in Hours					
				50	100	200	300	400	500
None (Control experiments)				0.69	1.44	2.68	3.87	5.03	6.08

Suggested Specifications for Sulphuric Acid

Specifications for battery acid have been issued by many different agencies and a comparison of them shows wide divergence in the impurities which are listed and the maximum amounts which may be considered permissible. If suitable specifications for sulphuric acid for use in batteries can be formulated and receive general recognition, it is likely that they will find use also in other industries. The amount of concentrated sulphuric acid used per year for batteries in this country is probably in excess of 30,000,000 pounds.

If the amount of impurities allowed by the specifications is made too small, serious difficulty may be encountered in finding acid sufficiently pure to meet them. On the other hand the specifications must limit the impurities to amounts that are within the range for satisfactory battery operation.

Specifications are usually drawn to apply to the concentrated acid. If pure water is used to dilute this to the proper concentration for battery use the percentage of the impurity will be proportionately reduced. It is desirable that water of a high degree of purity be used, and no general statement as to the permissible use of natural water can be made for the reason that its purity varies from place to place and from one time of the year to another.

The following Table VIII, on the purity of sulphuric acid and solutions for battery use, has been taken from a recent book on storage batteries.[7] It is believed that this table is consistent with the results of this investigation and represents acid that can be readily procured. It may be desirable, however, to limit the amount of copper to a smaller percentage in view of the large local action which it produces when present together with certain other impurities shown in Table VI.

TABLE VIII
PURITY OF SULPHURIC ACID AND SOLUTIONS FOR BATTERY USE

	Concentrated Acid	Unused Electrolyte	Used Electrolyte
Specific gravity 60°F	1.835	1.280	1.280
Per cent H_2SO_4	93.19%	36.8%	36.8%
Color	Colorless	Colorless	Colorless
Suspended matter	None	None	Lead compounds only
Platinum	None	None	None
Arsenic and antimony	Traces	Traces	Traces
Manganese	Trace	Trace	Trace
Iron	0.010%	0.004%	0.015%
Copper	0.005%	0.002%	0.005%
Nitrates and nitrites	Traces	Traces	Traces
Chlorides calculated as Cl	Trace	Trace	Trace
Organic matter	Trace	Trace	Trace
Sulphurous acid	Trace	Trace	None

The term "trace" is often used, but ill-defined. In general this term in these specifications should be regarded as meaning less than 0.001 per cent. Any standard specification of this character should include also a statement of the tests to be employed.

Our experiments have shown that there are other impurities, in addition to those included in Table VIII, which produce effects in the storage battery. However, they are rarely present in sulphuric acid. It does not seem necessary to name them all, as a statement can be added calling attention to the fact that other impurities are absent.

The limits for impurities given in Table 8 are presented for discussion, and it is hoped that they may serve as a basis for specifications that will receive general recognition.

7. Storage Batteries, by Vinal, page 120 (1924).

Discussion

J. L. Woodbridge: Mr. Vinal has given us the results of a new method of studying the subject of local action in the storage-battery cell. As he states, in his paper, considerable work has been done on this problem by other methods, one of them being the direct measurement of the capacity of the cell at different times, and another being an indirect method, by measuring the evolution of gases that are given off from the plates.

Each of these methods has certain disadvantages, and probably the true picture can best be obtained by a combination of all three. The direct measurement of the capacity of the cell is subject to error and can be made only at the beginning and the end of the standing test and not at any intermediate points. Furthermore, the capacity of the cell is a very variable quantity influenced by many factors, and it is very difficult to insure that an observed change of capacity is due to the particular factor that you are studying. The measurement of gas evolution is also subject to serious handicap in getting the exact results desired. This new method, therefore, is bound to throw considerable light on the problem.

There are several factors which affect the local action in a cell; for example, the temperature of the cell, the density of the electrolyte, and the history and physical condition of the plates themselves. Mr. Vinal's work has thus far been confined, as represented in his paper, to measurement at constant temperature and at one particular density of the electrolyte. We hope, therefore, that he will be in position to continue this work and to take into account these other factors.

There is another factor which would also have a very marked effect on the local action, and that is the presence or absence of electrolytic action. Mr. Vinal's work has been done so far on the cells standing on open circuit. If current is passed through the cell, a very different set of data will undoubtedly be obtained. For example, the effects of forming agents in the electrolyte will be very different when current is passing through the plates from what they are when the cell is standing on open circuit. Also, the results of the presence of metallic impurities will be varied by the effect of electric current in depositing these impurities on the negative plate.

There is one point in Mr. Vinal's paper in connection with which I would like to ask for a little additional information. For example, in Table III, and I think in other tables, two columns are given, one showing the material added, the other showing the percentage of the impurity used. It isn't entirely clear as to whether this percentage refers to the material in the form in which it is shown in the first column or whether it refers to one element. For example, copper sulphate is given in the first column, and it is not quite clear whether the percentage of copper is intended, or the percentage of the sulphate. The same might apply to nitric acid—I presume the percentage refers to the total percentage of nitric acid.

It is to be hoped that this investigation may be carried further because the problem is a large one and the amount of useful investigation that can be done is almost unlimited.

R. L. Young: Though, not a chemist, I have found the paper interesting, in that it discloses the reasons for some commonly accepted battery practises and points the way toward safe operation.

Impurities: It is of interest to note, for example, that iron, one of the most frequent and active impurities, is not deposited on the battery plates but stays in solution, so a change in electrolyte should reasonably eliminate it from the cell. I assume it would also be necessary to replace wood separators and wash the plates.

The tests showing that certain elements are very active in the presence of copper but are practically harmless otherwise, emphasize the importance of keeping brass or copper terminals and connections free from corrosion, I would enter a plea for the more general adoption by the manufacturers of terminals made exclusively of lead alloy, or where conductivity demands copper, a more complete protection of the copper portions.

Among the harmless impurities it is very fortunate that we find sodium. The foaming action of baking-soda solution during neutralization, and its non-corrosive nature, make it ideal for general use and particularly for washing down bus-bars and connections, also when necessary, walls and ceilings of battery rooms. Apparently little harm would result if small quantities of solution should accidentally drip into the cells and it might be satisfactory to leave bus-bars unwashed by clear water if it is not intended to repaint them at the time. I should like the sanction of the authorities to follow this practise.

Gases: I find a reference to the possible liberation of poisonous gas, stibine or arsine, when antimony or arsenic impurities are present in the electrolyte. A company, with whose practises I am familiar, has some thousands of batteries in operation, some of them having 50 or more cells of large capacities similar to those used in central-station standby service. Practically all of these batteries use antimony-lead alloy grids on both positive and negative plates and it may be expected that antimony gets into the electrolyte. We have never observed any indication of poison or other harmful effects on attendants and I would question whether this danger is not more theoretical than real. Is not the ordinary ventilation provided for reasonable comfort and to prevent the formation of explosive mixtures, sufficient to reduce the antimony hazard to a negligible amount?

Specifications: Efforts toward the establishment of recognized standard specifications for electrolyte are commendable, as they will probably tend toward the development of better quality, larger supply and possibly reduced cost. They may have to be somewhat flexible, or perhaps a series of specifications will be necessary, as I understand that the amount of any one impurity permissible may be affected by the percentages of others present. This at least is more or less the case with water for battery use and I would like to see specifications on this as well. Perhaps radio fans would be interested in knowing that New York City water is usually safe, whereas the very excellent artesian well water furnished in many suburban towns is not recommended for batteries.

In Table VIII, I would suggest that two columns be added to cover values for 1.210 electrolyte, this being the standard for many batteries in stationary service.

G. M. Howard: I would like to say a word with regard to the question of antimony and arsenic in the electrolyte.

To a man who has worked with storage batteries for years, it is rather startling to read a statement like this: "These poisonous gases escaping from the cells become a serious hazard to those using the battery."

Mr. Young has touched on that from the commercial and practical end. I think all users of batteries will agree with him that there have been no cases of poisoning. Certainly we have never heard of any.

As Mr. Vinal has said, the use of antimony in the grid is almost universal. Practically all lead storage batteries today contain antimony, and that means that there is nearly always a trace in the electrolyte. Certainly there is likely to be.

We have made careful tests in our laboratories when antimony was known to be present in the electrolyte, and we have never been able to detect any in the gas. On the other hand, arsenic, if present in the electrolytic may give off arsine, but, of course, arsenic is only an accidental impurity, and is never present in sufficient quantity to constitute a hazard. The point I want to emphasize is that the normal constituent, antimony, does not form stibine.

G. W. Vinal: I would like to discuss first the point which was raised by both Mr. Young and Mr. Howard regarding the possible formation of stibine.

The statement in the paper about antimony and arsenic relates primarily to these materials in solution. It should not be construed as meaning that the use of antimony in the grids is detrimental to the battery, nor liable to be a source of danger. A careful analysis of the electrolytes taken from fifteen batteries of six different makes showed that only very small traces of antimony were present in the solution. In all cases the amount observed was less than one part in 100,000. This clearly shows that under the ordinary operating conditions the antimony used in making grids does not pass into the solution. In rare instances, however, appreciable amounts of antimony have been found in the solutions, and it is to guard against such cases that it seems well to include antimony and arsenic in the proposed specification. Manufacturers of batteries endeavor to use materials which are free from arsenic and which might give rise to the liberation of arsine. Authentic cases of the liberation of stibine appear to be lacking, although we know from chemical reasoning that the conditions do make the formation possible, at least theoretically.

In answer to Mr. Young's question as to whether the ventilation in a battery room is sufficient to take care of such gases, I think the answer is quite clearly "yes."

As to the effect of sodium in the electrolyte, our experiments show that it did not affect the rate of sulphation appreciably.

A word of caution is perhaps desirable and Mr. Woodbridge has very well pointed out the fact that several methods of experimentation are desirable to reach final conclusions. I had some correspondence, with reference to sodium, with engineers of the Prest-O-Lite Company before coming to this meeting. They are of the opinion that traces of sodium may produce deleterious effects when batteries are continuously charged and discharged. That is somewhat contradictory to results which we have obtained, and yet I think that it is a point which may very well be investigated further.

As to the matter of using natural water, I know that water in New York City is commonly used in large batteries. I think New York City is blessed. It has a very fine water supply. I have been very careful, however, not to make any definite statement about the use of natural water, because natural water varies so much from place to place, and while it may be perfectly all right to use it in one location it may be unwise to do so in another. The Bureau of Standards has often been quoted as saying that the use of natural water is permissible. As a matter of fact, we have not issued any such statement.

I believe that nitrates in small amounts, such as are considered here, gradually tend to eliminate themselves from the batteries, some passing off as gas and some being reduced to ammonia.

I want to mention again Mr. Woodbridge's comments about the combination of methods. Of course, the work which we have done gives an indication of the local action which is produced within the cells, but it is quite desirable that these results should be supported, by measurements made on the batteries under normal operating conditions. We have made a few measurements on weighing the plates, with the passage of current both charging and discharging, but that work has not progressed very far. How far we shall be able to go we cannot say at the present time, but there is a very wide field of work.

One more point about the percentage of impurities,—particularly in the case of copper: the percentage which is given in the table is the percentage of copper. The impurity was added in the form of copper sulphate, but allowance was made for the SO_4 radical and for the water of crystallization.

The Theory of Probability
and Some Applications to Engineering Problems

BY E. C. MOLINA[1]
Member, A. I. E. E.

Synopsis.—The purpose of this paper is to encourage a wider recognition by engineers of a body of principles which in its mathematical form is a powerful instrument for the solution of practical problems. Some subjects in which the theory of probability has been used are recalled, the fundamental principles are stated and applied to three problems chosen from the field of telephone engineering.

* * * * *

"THE subject to which I now invite attention has high claims to consideration on account of the subtle problems which it involves, its important practical applications and the eminence of those who have cultivated it." (Todhunter: History of the Mathematical Theory of Probability, 1865).

You are all familiar with the importance of the theory of probability in its applications to life assurance, biology, radioactivity and other branches of pure and applied science. In telephony the theory has been utilized for over a quarter of a century. This is not surprising. The calls to be handled during a busy hour fall at random with reference to a given instant. Hence, a knowledge of total and average loads does not suffice for determining the quantities of equipment required for rendering efficient and economical service. The mathematical theory of probability enables one to evaluate the frequencies of different deviations from known average conditions. With this information the solution of trunking problems becomes precise, the quantities of equipment required for existing systems is determined and as changes in the art occur the merits of proposed systems can be weighed, thereby assuring that the public's demands for service be met satisfactorily.

The theory of probability is of immediate aid in the planning of inspection programs which must be carried out in order that apparatus may leave the manufacturer in fit condition to perform its functions. The interpretation of empirical data is facilitated and often the application of the theory to hypothetical conditions makes unnecessary the carrying out of costly statistical investigations.

The application of the theory of probability to engineering problems is a subject of so much importance that it is believed the engineering societies could well afford to give more consideration to it than has been given in the past. While there have been one or two instances of Institute papers discussing probability matters, such, for instance, as "A Method of Determining Resultant Input from Individual Duty Cycles and of Determining Temperature Rating" by Mr. Bassett Jones, in general the Institute papers have paid little attention to this matter. It is the purpose of this paper to present the fundamentals of the theory of probability in a form which it is hoped will appeal particularly to practical engineers, and to discuss specifically the application of these fundamental principles to a number of practical problems.

The fundamental principles of our subject, first formulated in a comprehensive manner by Laplace in his classic "Théorie Analytique des Probabilités" may be stated as follows:

First Principle. The probability that an event may happen in a specified manner is the ratio of the number of ways it can happen as specified to the total number of ways in which it can happen. For example, the probability that an ordinary six-face die will, when cast up in the air, give a number greater than 4 is 2/6 since there are only two faces marked with numbers greater than 4; whereas, the total possible number of ways in which the die can turn up is obviously 6.

This first principle is really nothing more or less than a definition of probability. It is implicitly assumed that all the possible cases are equally likely or probable. This implicit assumption has been severely criticised by some philosophers. Moreover, Poincaré, Bertrand and others have claimed that a logically satisfactory definition is impossible. However, this statement should not be disturbing any more than being reminded that there is no precise answer to the question "what is matter?"—should disturb a group of chemists.

Second Principle or Theorem of Total Probability. When a complex event can be reduced to a group of *mutually exclusive* simple events, the probability for the complex event is the *sum* of the probabilities corresponding to each simple event. Or thus—the probability of the happening of any one of several events, no two of which can concur, is the *sum* of their separate probabilities. As an example, suppose that one of our men has plans to return from Chicago next summer either by the Pennsylvania R. R., the New York Central R. R. or else by boat through the Great Lakes. If p_1, p_2, p_3, are the probabilities for these three routes respectively, the probability that he returns by rail is

$$p = p_1 + p_2$$

1. American Telephone and Telegraph Company, New York, N. Y.

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 9-12, 1926.

Third Principle. If there be given any number of *independent* events, the probability that they will all happen is the *product* of their respective probabilities. Suppose we have in front of us, three bags filled with red, white and blue balls. If 7 per cent of the balls in bag No. 1 are white, 19 per cent of those in bag No. 2 are white and 40 per cent of those in bag No. 3 are white and we draw one ball from each of the bags, then $P = (7/100)\,(19/100)\,(40/100)$ is the compound probability that all three of the drawn balls will be white.

Fourth Principle. The probability of the concurrence of two *dependent* events is the product of the probability of the first times the probability that when that has happened, the second will follow.

Fifth Principle. This fifth principle may be considered as a corollary to the fourth. Suppose we know the *a priori* probability in favor of an event which *has* happened and that we also know the *a priori* probability for a compound event consisting of the event which has occurred followed by another event which has not yet occurred. Then the probability that the second event *will* occur is equal to the *a priori* compound probability divided by the *a priori* probability of the event which has occurred. Example—Bids are open for the construction of a city subway. Let P be the compound probability that a certain construction company bids *and* submits satisfactory plans. Let p_1 be the probability that said company bids. Then, if the company *has* made a bid, the probability that the plans submitted will be satisfactory is $p_2 = P/p_1$.

We now come to a principle which is of fundamental importance for most if not all fields of engineering. The so-called "Theory of Sampling," which is of immediate interest to every engineer, seems to be inextricably tied up with this principle in spite of efforts made to separate them.

The five principles given above relate to the theory of *a priori* probability. The next principle has reference to *a posteriori* probability or probability of *causes.* The essential difference between *a priori* and *a posteriori* probability may be indicated as follows: Consider a bag containing 1000 balls some of which are white. We are dealing with the *a priori* probability when, *knowing the ratio of white to total balls* we put the question, what is the probability that 100 drawings will give 7 whites? It is assumed that a drawn ball is replaced in the bag before the next ball is drawn. We are dealing with *a posteriori* probability when, *knowing that* 100 *drawings did give* 7 *whites* we put the question, what is the probability that the ratio of white to total balls has a specified value, (say 11/1000 for instance)?

As before, we will follow closely in the footsteps of Laplace. His classic generalization of Bayes' theorem laid the corner stone for the edifice erected by mathematicians and statisticians since the publication of the *Théorie Analytique.* Two preliminary definitions will help us to understand Laplace.

Consider again the bag containing 1000 balls from which 100 drawings gave 7 whites. Note that the unknown ratio of white to total balls is a *hypothesis* or *cause* leading to the observed result. We may consider any one of 999 possible hypotheses:

1—ratio is		p_1	=	1/1000
2—	"	" p_2	=	2/1000
3—	"	" p_3	=	3/1000
K—	"	" p_k	=	K/1000
997—	"	" p_{997}	=	997/1000
998—	"	" p_{998}	=	998/1000
999—	"	" p_{999}	=	999/1000

The *a posteriori* theory assumes that there is a known probability for the *Kth* hypothesis before the results of the drawings are disclosed. Call this the *existence probability for the Kth hypothesis.* If the *Kth hypothesis* exists there is a definite probability that it will give the observed result. Call this the *productive probability for the Kth hypothesis.*

Sixth Principle. The *a posteriori* probability in favor of a specified cause is a fraction whose numerator is the product of the existence and productive probabilities of that specific cause while the denominator is the sum of like products for all the causes.

Seventh Principle. If two events are governed by the same set of mutually exclusive causes and one event *has* happened, the probability that the second event *will* happen is equal to the sum of all the products obtained by multiplying the *a posteriori* probability of each cause (as determined from the observed event) by the probability that the cause, if acting, will produce the second event.

Applications. "The applications of the principles which we have just expounded to the various questions of probability requires methods whose investigation has given birth to several methods of analysis and especially to the theory of combinations and to the calculus of finite differences."[2]

As a telephone engineer the author need not apologize for being more familiar with the application of the theory of probability to telephone problems than to problems relating to other fields of engineering. In what follows, it is not intended to discuss at length any major telephone problem. Such a discussion would be worthy of at least as much space as has been allotted to this paper. Moreover, the inherent interest of a major problem would distract attention from the probability principles made use of in its solution.

As an immediate application of the first principle or definition of probability consider the following problem:

n calls fall at random in an interval of time A. As the calls fall they are automatically counted by a meter. This meter, however, cannot function properly if the time interval between two consecutive calls is less than a small interval a.

2. Laplace Théorie Analytique.

What is the probability that a correct count of the n calls will be obtained? In other words, what is the probability that no two consecutive calls will be separated by a distance less than a?

The mathematical analysis contained in the appendix to this paper gives

$$P = [1 - (n - 1)\ (a/A)\ ]^n$$

The curves of Fig. 1 show the numerical values of the probability P for various values of n for the two

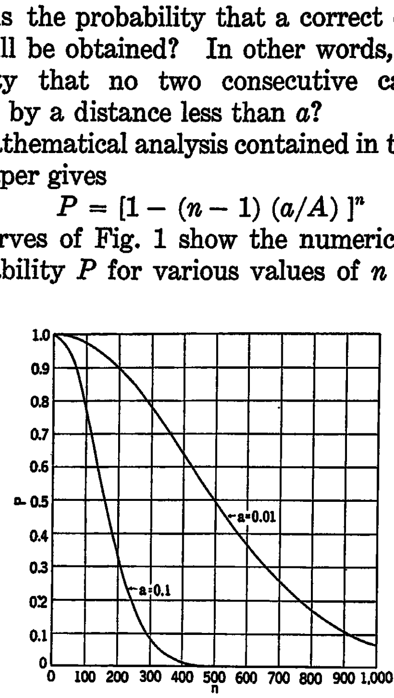

FIG. 1

cases $a = 0.1$ sec. and $a = 0.01$ sec. The large interval A is assumed to be one hour.

For an illustration of the applicability of the second and third principles consider the following telephone trunking problem.

Referring to Fig. 2 consider a group of 269 subscribers, each equipped with a 20-point line switch. The line switches have common access to a group of 20-trunk lines. When a subscriber removes his receiver

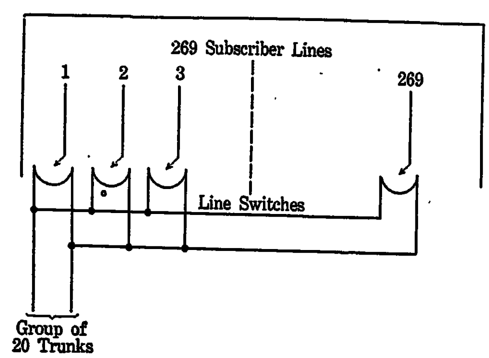

FIG. 2

from the hook, his line switch revolves and connects him to an idle trunk, if one exists.

What is the probability that when a particular subscriber, X, calls he fails to obtain a trunk at once?

It will first be shown that this trunking problem transforms into a simple dice-throwing problem. The answer to the dice problem is then obtained at once by recourse to the *binomial* expansion which was used so effectively by Mr. Bassett Jones in the solution of his problem. To facilitate the transformation, let us make some simplifying assumptions.

A—During the period of time under consideration, the busy hour of the day, each subscriber's line makes one call which is as likely to fall at any one instant as at any other instant during the period.

B—If a call, when initiated, obtains a trunk immediately, it retains possession of that trunk for exactly two minutes. In other words, a constant holding time of two minutes' duration will be assumed.

C—If a trunk is not obtained immediately, the calling subscriber waits for two minutes and then withdraws his call. If, while waiting, a trunk becomes idle, he takes it and converses for the interval of time remaining before his two minutes are up.

Referring to Fig. 3, let point P represent the unknown instant within the hour at which X calls. Consider the two minutes immediately preceding the instant P. Evidently, by assumption C, calls falling outside of this particular two-minute interval cannot prevent X from obtaining a trunk.

If, however, at least 20 of the remaining 268 subscribers initiate their calls within the particular two minutes under consideration, there will be no trunk line immediately available for X. This follows from assumptions B and C.

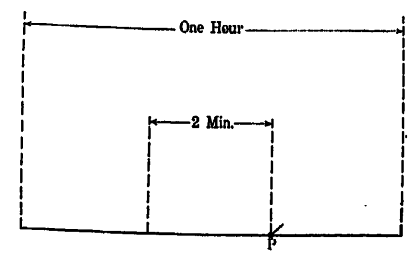

FIG. 3

Consider some one of these 268 other subscribers, for example Y. The probability that Y calls in the two minutes under consideration is, by assumption A, the ratio of 2 minutes to 60 minutes, or 1/30, which is exactly the same as the probability that he would throw an ace if he were to make a single throw with a 30-face die. Likewise, the probability that still another subscriber calls in the two minutes under consideration is exactly the same as the probability that this other subscriber should throw the ace in a single throw with a 30-face die.

It is evident then, that the probability that X fails to get a trunk immediately is the same as the probability of throwing at least 20 aces if 268 throws are made with a 30-face die. To facilitate the determination of this probability and the solution of similar problems, probability tables of the type shown in Table I have been computed. In the table, the average number of times an event may be expected is represented by a. The probability that the event occurs at least a greater number of times $c = a + d$ is represented by P. In the problem under consideration, the average

number of aces expected is $8.96 = \frac{268}{30}$ Likewise in the present problem $c = 20$. Turning to the table, we find that corresponding to $c = 20$ and $a = 8.96$, the value of the probability P is 0.001. In the particular telephone problem under consideration this means that once in a thousand times when X calls, at least 20 of the other subscribers will have called in the two minutes immediately preceding, and therefore X fails to get a trunk immediately. In other words, we may consider that on the average, one in every thousand calls is delayed.

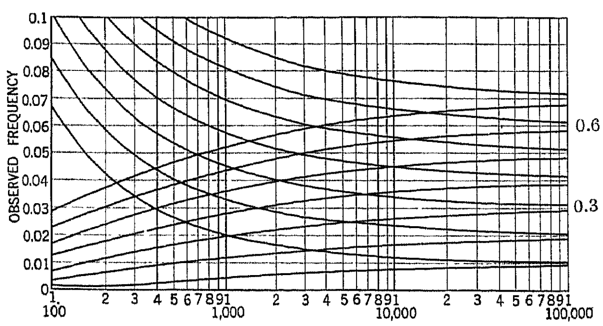

Fig. 4—Curves Showing Probable Range of True Frequency Vs. Number of Observations for Observed Frequencies of 0.01, 0.02, 0.03, 0.04, 0.05, 0.06, 0 07. Weight = 0.98

Finally, as an application of that most far-reaching but much debated sixth principle, consider this telephone traffic problem:

A group of 50,000 calls originated in an exchange area. An unknown number of them were delayed more than 10 seconds. Observations were made on 300 of the calls and of these 9, or 3 per cent, were delayed more than 10 seconds. With this information is it a safe bet that the unknown percentage for the entire 50,000 calls is below 5? Or better yet, are we justified in betting 99 in 100 that the unknown percentage for the 50,000 calls is below 5? Or again, may we bet 8 in 10 that the unknown percentage is between 0.5 and 5? It is taken for granted that the observer is justified in believing that the calls under consideration fulfill the conditions of random sampling such as that each call is independent of every other call, or that an appreciable number of the calls is not due to the occurrence of some unusual event,—the Wall Street explosion, for example.

Obviously the telephone problem is analogous to the problem of the bag containing an unknown ratio of white balls. The corresponding elements in the two problems may be tabulated as follows:

1st. 1000 balls in bag vs. 50,000 calls originated.

2nd. 100 balls drawn vs. 300 calls observed.

3rd. 7 white balls drawn vs. 9 calls delayed more than 10 seconds (*i. e.*, defective with reference to a particular characteristic).

4th. To the 999 possible, hypotheses with reference to the unknown per cent of white balls correspond 49,999 possible hypotheses with reference to the unknown per cent of calls delayed more than 10 seconds.

The problems differ in that a ball drawn from the bag is returned before another drawing is made, whereas an observed call is comparable to a ball being drawn and not returned. However, with the numbers involved this discrepancy may be ignored.

The attached curves, Fig. 4 show graphically the conclusions to be drawn from the mathematical analysis. A glance at the right-hand end of the curves will show that they are associated in pairs. The upper curve of a pair slopes downward from left to right while its mate slopes upward.

Consider the pair of curves marked 0.03. For the abscissa 300, they give as ordinates the values 0.0625 and 0.014. The interpretation of these figures is as follows: if 300 observations gave 3 per cent of calls delayed then we may bet

1st. 99 in 100 that the unknown percentage of calls delayed is not greater than 6.25.

2nd. 99 in 100 that it is not less than 1.4 per cent.

3rd. 98 in 100 that it lies between 1.4 per cent. and 6.25 per cent.

Likewise, considering the curves marked 0.06 if 1000 observations gave 6 per cent of calls delayed, then we may bet

1st. 99 in 100 that the unknown percentage of calls delayed is not greater than 8.05.

2nd. 99 in 100 that it is not less than 4.4 per cent.

3rd. 98 in 100 that it lies between 4.4 per cent and 8.05 per cent.

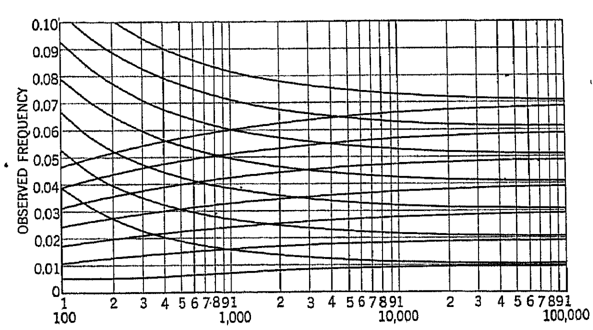

Fig. 5—Curves Showing Probable Range of True Frequency Vs. Number of Observations for Observed Frequencies of 0.01, 0.02, 0 03, 0.04, 0.05, 0.06, 0.07. Weight = 0.08

It is obvious from the shape of the curves that a few hundred observations do not give more than a vague idea as to the unknown per cent of calls delayed. On the other hand, the gain in accuracy obtained by making more than 10,000 observations would hardly justify the expense involved. The number of observations which safety requires in any particular problem must be determined by the conditions of the problem itself. If we are willing to take a chance of 9 in 10 or 8 in 10 instead of 99 in 100 or 98 in 100, respectively, the curves of Fig. 5 will give us an idea of the range

within which the unknown percentage of defectives lies.

Appendix

Counting Meter Problem

n calls fall at random in an interval of time A. As the calls fall, they are automatically counted by a meter. This meter, however, cannot function properly if the time interval between any two consecutive calls is less than a small interval a.

What is the probability that a correct count of the n calls will be made?

Consider the two diagrams of Fig. 6. The lower diagram indicates any one of the many different number of ways in which the calls may fall. Evidently this number is the same as the number of different sets of values which we can give to the set of variables $y_1, y_2, y_3 \ldots y_n$, so that each variable is equal or greater than zero, but their sum not greater than A. Using the language of the integral calculus, the number of possible sets of values for $y_1, y_2 \ldots y_n$ is

$$\int_0 \int_0 \int_0 \ldots \int_0 dy_1\, dy_2\, dy_3 \ldots dy_n$$

where the upper limits of the integrals must be such as to satisfy the condition

$$O < \Sigma y < A$$

On the other hand, the upper diagram indicates any

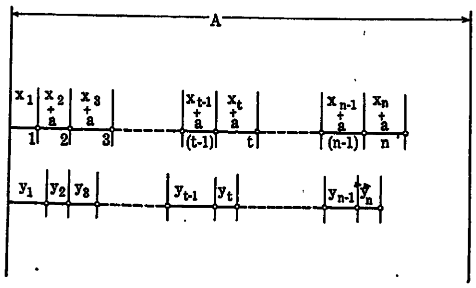

Fig. 6

distribution of the calls consistent with the condition that the distance between consecutive calls is not less than a. Note, that since there are n calls, there are $(n-1)$ intervals, each of which must not be less than a.

The number of distributions satisfying the desired condition is evidently the same as the number of sets of values which can be given to the set of variables $x_1, x_2, \ldots x_n$ so that each variable is equal or greater than zero, but their sum is not greater than $A - (n - 1)\,a$. The number of possible sets is given by the multiple integral

$$\int_0 \int_0 \int_0 \ldots \int_0 dx_1\, dx_2\, dx_3 \ldots dx_n$$

where the upper limits of the integrals must be such as to satisfy the condition.

$$O < \Sigma X < [A - (n - 1)\,a]$$

Therefore, the desired probability is

$$P = \frac{\text{(favorable cases)}}{\text{(total possible cases)}}$$

$$= \frac{\int_0 \int_0 \int_0 \ldots \int_0 dx_1\, dx_2\, dx_3 \ldots dx_n}{\int_0 \int_0 \int_0 \ldots \int_0 dy_1\, dy_2\, dy_3 \ldots dy_n}$$

Transform the integrals by the substitutions

$$y = A\,t, \quad x = [A - (n - 1)\,a]\,s$$
$$dy = A\,dt,\ dx = [A - (n - 1)\,a]\,ds$$

Then

$$P = \frac{[A - (n-1)\,a]^n \int_0 \int_0 \int_0 \ldots \int_0 ds_1\, ds_2\, ds_3 \ldots ds_n}{A^n \int_0 \int_0 \int_0 \ldots \int_0 dt_1\, dt_2\, dt_3 \ldots dt_n}$$

The conditions to be satisfied by the limits of integration in both numerator and denominator are now both the same, that is,

$$O < \Sigma t < 1, \quad O < \Sigma s < 1$$

The integrals, therefore, cancel out, saving us the trouble of evaluating them, and we obtain

$$P = \left[\frac{A - (n - 1)\,a}{A}\right]^n = [1 - (n - 1)\,(a/A)\,]^n$$

TABLE I

AVERAGES (a) CORRESPONDING TO DEVIATION (d) PLUS AVERAGE (a) TO BE EXPECTED WITH DIFFERENT PROBABILITIES

Deviation Plus Average, $c = a + d$	P: 0.001	0.002	0.004	0.006	0.008	0.010	Deviation Plus Average, $c = a + d$
	Average = a

Sampling Problem. As stated in the body of the paper, when the total number of calls under consideration is large as compared with the number of calls observed, the problem is essentially identical with the problem of drawing balls from a bag, the ball taken at each drawing being returned before the next drawing is made.

Assume, then, that n drawings from a bag containing an unknown ratio of white to total balls resulted in c white drawings and $(n - c)$ not white. In other words, assume that the observed frequency of white balls was (c/n). Considering the unknown ratio as a cause, let $W(x)$ be the *a priori* existence probability for the value x. The productive probability for the

value x, that is, the probability of obtaining c white and $n - c$ not white balls if the unknown ratio were x, is

$$\binom{n}{c} x^c (1-x)^{n-c}$$

where $\binom{n}{c}$ is a symbol for the combinations of n things c at a time.

By the sixth principle the *a posteriori* probability in favor of the unknown ratio having the value x is

$$P(x) = \frac{W(x)\binom{n}{c} x^c (1-x)^{n-c}}{\sum\limits_{x=0}^{1} W(x)\binom{n}{c} x^c (1-x)^{n-c}} = \frac{W(x)\, x^c (1-x)^{n-c}}{\sum\limits_{x=0}^{1} W(x)\, x^c (1-x)^{n-c}}$$

Therefore, the *a posteriori* probability that the ratio x does not exceed the value p_1 is

$$P(x > p_1) = \frac{\sum\limits_{x=0}^{p_1} W(x)\, x^c (1-x)^{n-c}}{\sum\limits_{x=0}^{1} W(x)\, x^c (1-x)^{n-c}}$$

When the total number of balls in the bag is large so that the difference between any two consecutive possible values for x is small, we may substitute integrals for the summations; giving

$$P = \frac{\int_0^{p_1} W(x)\, x^c (1-x)^{n-c} dx}{\int_0^1 W(x)\, x^c (1-x)^{n-c} dx} \qquad (1)$$

Assume first that $W(x)$ is a constant b for $o < x < g$, where $g > p_1$. Then

$$P = \frac{\int_0^{p_1} x^c (1-x)^{n-c} dx}{\int_0^{g} x^c (1-x)^{n-c} dx + \int_g^1 \frac{W(x)}{b} x^c (1-x)^{n-c} dx}. \qquad (2)$$

Now assume that

$$\int_g^1 \frac{W(x)}{b} x^c (1-x)^{n-c} dx,$$

is negligible compared with

$$\int_0^g x^c (1-x)^{n-c} dx,$$

and also assume that g, c and $(n-c)$ are such that approximately

$$\int_0^g x^c (1-x)^{n-c} dx = \int_0^1 x^c (1-x)^{n-c} dx$$

Then, finally,

$$P = \frac{\int_0^{p_1} x^c (1-x)^{n-c} dx}{\int_0^1 x^c (1-x)^{n-c} dx} = \frac{(n+1)!}{c!\,(n-c)!}\int_0^{p_1} x^c (1-x)^{n-c} dx, \qquad (3)$$

This well-known formula might have been obtained by assuming *a b* initio that $W(x)$ is independent of x. Particularly should it be noted that this independence is not identical with the assumptions made above. In the applications which are here contemplated the values p_1, c and n are such that g need be but a small fraction of the range 0 to 1.

In the "Theorie Analytique" Laplace transforms (3) so that it can be evaluated in terms of the Laplace-Bernoulli integral

$$\frac{2}{\sqrt{\pi}}\int_0^k e^{-t^2} dt$$

where k is a function of p_1, c and n. This transformation is most valuable when p_1 is in the neighborhood o ½. For small values of p_1 the transformation which converts the binomial expansion to Poisson's exponential binomial limit is more appropriate and gives, writing $(n p_1) = a_1$,

$$P = \frac{1}{c!}\int_0^{a_1} y^c e^{-y} dy = P(c+1, a_1) \qquad (4)$$

Discussion

B. Jones: In the introduction to his paper Mr. Molina draws attention to the apparently little recognized value of the Calculus of Probabilities in engineering studies. Permit me to draw your attention to the extraordinary importance this calculus has acquired in modern mathematical physics as a means of developing the necessarily statistical expressions for the so-called laws of nature.

Since the time of Laplace the calculus of probabilities has been the foundation of Astronomical research. It is the basis of the kinetic theory of gases. Maxwell shared with Gibbs the work of developing dynamics as a statistical science. As Reiche puts it "Planck has turned the problem of radiation into a problem of probabilities." Eddington points out that Einstein's grand summary is to the effect that "the present state of the world is that which is statistically the most probable." Thus, a branch of mathematical science born in a gambling dive, is found capable of dealing with the most varied classes of more or less random phenomena which, from craps to atomic structure, make up the detail of this world. It assumes nothing as fixed given or absolute, and, in so far, the formulas of probabilities are very descriptive of the world's behavior. Perhaps our's *is* the most probable world.[1]

Mr. Molina has given us an outline of a few important theorems in the probability calculus. I wish to present the outline of a further very elementary and very useful method of dealing with the probable character of a sample drawn from a mixture when the probable frequencies of the several components of the mixture are known, and when we are interested in the failure of the sample to be thoroughly representative of the mixture. The method has wide engineering application extending from the sampling of crushings, screenings, and concrete mixtures, to the determination of probable duty cycles as a means of selecting apparatus having suitable characteristics. It may also be used to determine the demand factor imposed on hydraulic and electrical distributing systems serving a number of devices operating intermittently, or subjected to varying demands.[2]

Let the total number of elements composing the mixture be P, of which one element has the frequency a, a second element has the frequency b, a third element has the frequency c, and so on. That is, $P = a + b + c + \ldots\ldots$

Let n be the number of different kinds of elements in the mixture, irrespective of the number of elements of each kind.

Let a sample having a total of N elements be drawn.

1. The Most Probable World, Jones, *Tech. Engineering News*, Vol. IV, No. 9, March, 1924.

2. The application of the method to the determination of water supply and waste in buildings is given in a Bureau of Standards *Bulletin*.

Then the probability that any one of these elements is an a, is a/P; that it is a b is b/P; that it is a c, is c/P; etc.

The probability that any one of these elements is not an a, is $1 - a/P$; that is it not a b, is $1 - b/P$; that it is not a c, is $1 - c/P$; etc.

The probability that none of the N elements drawn is an a is $(1 - a/P)^N$; and, so on, for the other kinds. Therefore the average probability that any element in the sample *will not* be any one of the n kinds is

$$1/n \left\{ (1 - a/P)^N + (1 - b/P)^N + \dots \right\} \quad (1)$$

This is also the probability that the sample will not be representative of the mixture.

The probability that the sample will be representative of the mixture is

$$1 - \left[\frac{1}{n} \left\{ (1 - a/P)^N + (1 - b/P)^N + \dots \right\} \right] \quad (2)$$

Therefore the probable number of kinds of elements contained in any sample of N elements is given by

$$S = n\left(1 - \left[\frac{1}{n} \left\{ (1 - a/P)^N + (1 - b/P)^N + \dots \right\} \right]\right) \quad (3)$$

Should the sample be so constrained that any one element, say the p^{th} is certainly present, the corresponding term $(1 - p/P)^N$ is to be omitted from (1), giving, in place of (3),

$$S_{(n-1)} = (n-1)\left(1 - \left[\frac{1}{n-1} \left\{ (1 - a/P)^N + (1 - b/P)^N + \dots \right\} \right]\right) \quad (4)$$

as the probable number of different kinds of elements *other than* p contained in the sample.

Should it happen that all the elements are equally distributed in the original mixture, so that $a = b = c = \dots = P/n$ where, as before, $P = a + b + c + \dots$, and n is the number of kinds of elements in the mixture, then (3) reduces to

$$S = n \left\{ 1 - (1 - 1/n)^N \right\}, \quad (5)$$

a well-known form that may be used in many cases where a b, c, etc., are not materially different from one another.

As a case, let it be required to find the probable number of stops that will be made by an elevator car containing N passengers drawn from a crowd of P people composed of a people bound for the first floor above the bottom terminal stop, b people bound for the second floor, c people bound for the third floor, ... , and x people bound for the top or nth floor.

Since, barring accidents, the top terminal or nth floor is a certain stop, the term $(1 - x/P)^N$ is to be omitted from (1) and the probable number of intermediate stops is given by (4). The total number of stops, including the top terminal, is $S_{n-1} + 1 = S$.

If H be the travel between the bottom terminal and the top terminal, the average distance covered between start and stop is H/S. From this, and the time-velocity characteristics of the equipment, the probable average duty cycle of the hoisting equipment can be determined, which, when converted to equivalent r. m. s. input, gives the equivalent continuous output.

If a number of such equipments are operating simultaneously, the probability method given in my paper on "A Method of Determining Resultant Input from Individual Duty Cycles", TRANS. A. I. E. E., 1922, p. 457, may be used to determine the equivalent continuous rating of the feeders to the hoisting-engine group. In spite of the fact that this paper has been characterized as "school-boy mathematics," the method has been in successful use for a number of years and has resulted in considerable savings in cost of installation, and particularly so in just such cases to which it has been said the method is inapplicable.

The most probable time distribution of load on generating plants has been determined by this method and given to manufacturers as a basis for the submission of apparatus suited both in type and rating to meet such probable actual conditions and not suited to wholly non-existent conditions resulting from purely empirical guesses. In recent cases we have found that the resulting temperature rise of the apparatus in service is extraordinarily close to the expected rise, indicating that the actual r. m. s. value of the load is fairly close to the calculated r. m. s. value, and that the owner has paid for machines neither too small nor too large. I have many records of cases where generating capacity and rated motor output, both determined on a wholly empirical basis, are considerably in excess of the actual demand—in some cases this excess is 50 per cent and more. Feeder sizes often run 100 per cent above the actual necessary rating.

In closing I wish to draw attention to the fact that the method of probabilities does not start from any pre-conceived mathematical notions from which, by purely logical processes and almost mechanical dexterity in the manipulation of mathematical symbols in accordance with fixed rules, an answer is turned out willy-nilly. On the other hand, the method of probabilities is one of continuous cut and try based on no evidence other than the given data. It is no substitute for thought, but rather requires very clear reasoning at all stages of the process. Every step must be carefully visualized. This is its extraordinary advantage as a mental training. It has somewhat the same pedagogical value as the study of legal procedures. The correctness of the results obtained are wholly dependent on the common sense used in its application.

A. G. Chapman: Applications of the theory of probability have long been useful to telephone engineers in studying the problem of limiting cross-talk between telephone circuits to tolerable amounts. In considering cross-talk, two paralleling telephone circuits may be conveniently divided into a succession of short finite elements. The two circuits will be coupled in each element. The coupling is usually due to electric and magnetic induction, although in the case of a phantom circuit and its side circuits, resistance coupling may be of some importance. The speech power at a terminal of the disturbed circuit depends upon the resultant effect of all these couplings and upon the power impressed upon the disturbing circuit. In a well-designed telephone plant the couplings are due to small deviations from perfect construction rather than to dissymetries in design. It is impossible, therefore, to predict accurately the cross-talk between any two well designed and maintained telephone circuits. Estimates may be made, however, of the most probable cross-talk between two circuits and the chance of exceeding the most probable value by various percentages. In case there are a number of circuit combinations having the same probability of a given value of cross-talk, it is useful to estimate the average cross-talk and also a value of cross-talk which there is but a small chance of exceeding.

Such estimates are very useful in studying the importance of deviations from perfect construction in loading coils, in sections of telephone cable and in any apparatus occurring repeatedly in a long telephone circuit. Estimates of probable cross-talk are also essential in studying the design of loading systems and systems of arranging repeaters in telephone circuits as well as in considering the matter of permissible deviations from the theoretical values in the spacing of wires and transposition poles of open-wire lines.

The computations of probable values of cross-talk must, of course, be coordinated with an extensive program of testing to serve as a check on the necessary approximations in the computations and as an indication that the circuits have been installed in the proper manner.

As a formal mathematical problem, applications of the theory of probability to computations of cross-talk offer considerable difficulty and the solutions are necessarily approximate. The problem involves determining the probable resultant of a large

number of deviations, that is, the successive couplings between the elements of the telephone circuits. The law followed by the individual deviations must be approximately determined from experimental data. It is usually satisfactory to assume the normal law of error for the individual deviations but the law of combination of the various deviations is usually complex. Two adjacent deviations of the same magnitudes may not add or subtract algebraically since the resultant cross-talk currents of any particular frequency may be out of phase due to a difference in the nature of the two couplings. In long telephone circuits, the attenuation of the speech waves and the finite speed of propagation with its resultant retarding of phase must be taken into consideration, and also the large number of frequencies of which a speech wave may be assumed to be composed. As a result of the propagation phenomena, two similar but non-adjacent deviations will produce cross-talk currents at a circuit terminal differing in phase and magnitude, depending upon the distance between them and the frequency. In addition, the separation between two telephone circuits may not be uniform. For example, in a telephone cable, two circuits may be adjacent for a short distance, say 500 ft., and then occupy a large number of non-adjacent positions before coming together again. In spite of all these complexities, however, it has been found practicable to obtain approximate solutions of probability cross-talk problems which have been very useful in engineering the telephone plant.

R. S. Hoyt: Mr. Molina has chosen his principle illustrative examples from the extenisve field of traffic and trunking problems.

I believe that the Institute will be interested at this time in an outline of applications of probability theory to certain problems in two other fields of telephone engineering—namely, in telephone transmission engineering, and in radio engineering.

Of the three problems which I propose now to outline, the first two arose in the applications of two-way telephone repeaters to long telephone lines or cables, and the third relates to the use of selective circuits for reducing "static" interference in radio reception.

By way of preface to the first two problems it may be recalled from the theory of repeaters that the practicable amplification obtainable from a two-way repeater is limited by impedance unbalance between the two lines involved, or between the two lines and their balancing networks. The theory of probability finds here a natural field of application because the impedance unbalance mentioned arises mainly, or at least to a considerable extent, from numerous random internal irregularities in the structure of the lines, as will appear more fully in the following outlines of the two problems themselves.

The first problem relates to periodically loaded lines or cables. These contain numerous small random irregularities consisting in slight inequalities in the inductances and spacings of the loading coils. The individual departures are effectively unknown; but their arithmetic averages are known from coil manufacturing data and line construction data, and the probability laws to which they conform are known or else can be reasonably assumed. For such a loaded line, when already constructed, the problem is to calculate the probability that the line has an impedance departure less than a specified value. On the other hand, in the designing of such a loaded line, the probability problem is to predetermine the allowable average coil-inductance departures and spacing departures to meet the requirement consisting in a specified probability that the impedance departure will not exceed a specified value. Such problems arose as long ago as the construction of the first transcontinental telephone line.

The second problem relates to continuously loaded cables. Such a cable may comprise numerous short sections which are slightly unequal in their linear constants, owing to manufacturing variations. If these sections are connected in a random sequence the probability problems are analogous to those outlined in the preceding example. On the other hand, from a study of the measured constants of the individual sections it is possible to determine the best sequence of the sections to minimize the resultant impedance departure of the final cable. However, the securing of this optimum sequence involves additional expense besides delay. To decide whether these are justified, probability may be invoked in order to determine the probable impedance departure that would result if the sections were connected in a mere random sequence. Such a problem arose several years ago in the design and construction of the submarine cable between Key West and Havana.

The two problems just outlined illustrate the fact that in a physical system so extensive as the Bell System there exists many classes of numerous physical elements such that the elements in any one class, while all nominally alike, actually differ from each other by small random amounts in a statistical manner. Usually it is impracticable to know the numerous departures individually, and, even if they were known, it would usually be impracticable to compute their resultant effects of direct summation. But from the mere knowledge of a statistical index (such as the arithmetic average, for instance) and the statistical or probability law to which the departures conform, the probable departure of the system can often be calculated with relatively little labor.

The third problem, which is quite different from the two preceding, arises in radio transmission, and relates to the possibilities and limitations of selective circuits when employed for reducing "static" interference. Owing to the unknown, irregular, and random character of this type of interference, the problem is essentially a statistical and probability problem leading to an expression of results in terms of mean values. Such a treatment has yielded general deductions having practical significance, notwithstanding the meagerness of knowledge regarding the character and the frequency-distribution of static. Reference may be made to a paper by John R. Carson entitled "Selective Circuits and Static Interference" which was presented to the June meeting of this Institute in Chicago. (TRANS. A. I. E. E., 1924, page 789).

Design of Non-Distorting Power Amplifiers

BY E. W. KELLOGG[1]

Associate, A. I. E E.

Synopsis.—The paper deals with the problem of obtaining the maximum output possible from a given amplifier tube, while keeping the distortion down to a negligible amount. A tube can be rated for this purpose in terms of the watts output obtainable, when a sine wave voltage of as great an amplitude as can be advantageously utilized, is applied to the grid. This maximum sine wave output is very much less than the rating of the same tube for oscillator purposes. Starting with a set of static characteristics for a given tube, the dynamic characteristic for any resistance load is readily plotted, and the power output and distortion can be read from the dynamic characteristic. A simple rule has been given by Mr. W. J. Brown for determining the best conditions of load resistance and grid bias for a given plate supply voltage. The best load resistance is shown to be twice the internal plate resistance of the tube. If the supply voltage exceeds a certain value, the application of the rules just mentioned would lead to excessive heating of the anode, and therefore a different procedure is followed, calling for greater grid bias and higher load resistance. There is an advantage in using low impedance tubes. The balanced or push-pull circuit, while reducing distortion, will not make up for failure to operate the tubes under proper conditions, nor will it greatly increase the permissible output per tube. The dynamic characteristic for a reactive load is not readily plotted, but for design purposes it is sufficient to determine the best operating conditions for a resistance load, and then make the impedance of the reactive load high enough to keep the plate current variations within the same limits as for the resistance load. An important application of the principles outlined here, is the design of radio telephone transmitters where serious distortion results from overworking the modulator tubes. For moderately deep modulation there should be from two to four modulating tubes for each oscillator tube. Certain details of design are discussed in the closing paragraphs.

Problem Encountered in Power Amplifiers

In the design of an amplifier whose function is to bring voice or radio signals from bare audibility to comfortable head-phone intensity, the problem of distortion due to curvature of the tube characteristics is hardly a factor, or at least presents no difficulties. The principal concern of the designer is to obtain a large ratio of amplification per stage, and to avoid serious inequalities in the amplification for different frequencies within the required range. When we design an amplifier to operate a loud speaker or to modulate a radio transmitting set the problem takes on an entirely different aspect. A sensitive loud speaker in a small room needs something like a hundred times as much power as a pair of head phones, and here we encounter serious distortion if we attempt to use small tubes or low plate voltage, especially if we push the intensity above a very moderate value. We have reached the power limit of the last tube. By raising the plate voltage and increasing the negative bias on the grid we can raise the power limit and get louder speech or music of good quality, provided we do not exceed the limit of allowable plate voltage, or plate watts and provided there is ample emission from the filament. If we need still more power, we must go to a larger tube, or use several tubes in multiple. Amplifiers the design of which is concerned chiefly with the amount of power obtainable from the final stage, are of the class which we are here designating as "power amplifiers."

Sine Wave Ratings

The relative power obtainable from various vacuum tubes may be estimated in terms of their power outputs of sine-wave alternating current, a sine-wave alternating voltage being impressed on the grid in each case. The magnitude of the grid voltage required is usually of secondary consideration, since it represents no power consumption and is a small factor in determining the total size and cost of the amplifier.

Comparison with Oscillator Ratings

Power tubes as sold are usually given a rating in watts. This rating represents the high frequency output when the tube is used as an oscillator. The power available from the same tube with the same plate voltage is much less when distortionless amplification is required, for the reason that in the amplifier, operation

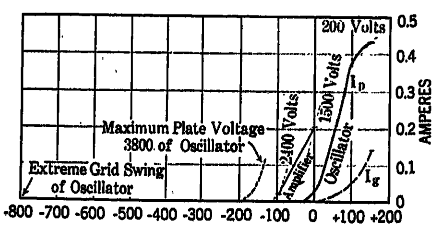

Fig. 1—Comparison of Working Range of Oscillator and Amplifier

must be confined to a portion of the characteristic which is straight, or substantially so, while the oscillator has no such limitation. Thus we find that a tube rated at 250 watts output as an oscillator can supply only about 22 watts of sine-wave output as a straight-line amplifier at the same average plate voltage. Fig. 1 shows the relative working range on a small scale. It will be noticed that the amplifier range is shown as limited to negative-grid voltages. If the grid is allowed to become sufficiently positive (with respect to the negative end of the filament) to take an appreciable electron current, it imposes an irregular load on the preceding

1. Research Laboratory, General Electric Co., Schenectady, N. Y.

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 9-12, 1925.

tube which causes wave form distortion. In other words, it is necessary not only that the plate-current vs. grid-voltage characteristic be a straight line but the grid current vs. grid voltage characteristic must be straight over the working range as well, and the only straight part of any considerable length is where the grid current is zero.

Necessary Measurements

The first concern in the design of a power amplifier is the choice of the tube for the power stage, and the determination of operating conditions. This involves a study of the straight line ratings of the tubes under consideration. Except for certain precautions mentioned in a later paragraph we may safely ignore the effects of electrode capacities in an audio frequency amplifier. We can then calculate the performance of a tube from its "static characteristics," or the voltage-current relations obtained point by point by means of meters. The characteristics required are a set of curves showing the plate current as a function of grid voltage, each curve corresponding to a designated plate voltage. Fig. 2 shows the static characteristics for a certain tube having an oscillator rating of 250 watts. The series of plate voltages chosen should preferably be at uniform intervals, and sufficiently near each other to give ten or more curves, ranging from about one-fourth to double the average voltage at which the plate is to be worked. The curves for high voltage need not be carried to high-current values. Some of the points will have to be taken by closing the switch and taking the readings before the plate has had time to become excessively heated.

Dynamic Characteristic

The simplest circuit to analyze is that shown in Fig. 3, in which the alternating current output of the tube

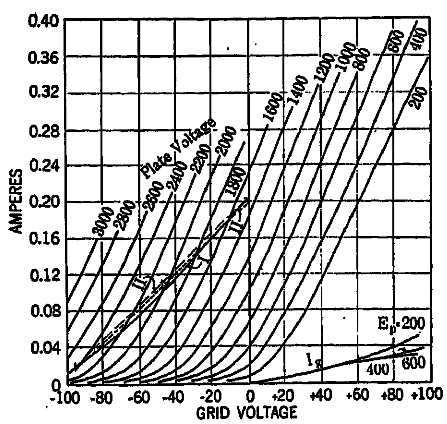

Fig. 2—Static and Dynamic Characteristics of Three Electrode Tube

is used up in the resistance through which the direct current is fed to the plate. While this does not appear to represent the conditions of a practical circuit, we shall find that the conclusions reached in this case are applicable to the commonly employed circuits shown in Fig. 9. and 10. The only essential difference is that in the latter circuits the average plate voltage is practically the same as the supplied voltage.

For the present, considering that the circuit is as shown in Fig. 3, let us find from Fig. 2 the operating characteristic or "dynamic characteristic" for some assumed value of external resistance R, and supply

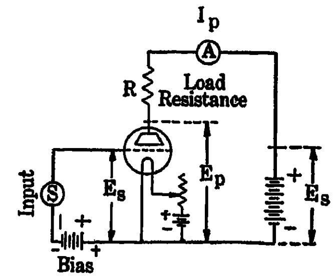

Fig. 3—Simple Circuit for Determining Rating of Amplifier Tubes

voltage E_s; for example, $R = 5000$ ohms and $E_s = 2500$. If the grid voltage is given such a value that the plate current is 0.1 ampere, the voltage at the plate will be $2500 - 0.1 \times 5000 = 2000$. Similarly, 2200 volts at the plate corresponds to

$$\frac{E_s - E^p}{R} = \frac{2500 - 2200}{5000} = 0.06 \text{ amperes,}$$

2400 volts corresponds to 0.02 amperes and 1800 volts to

$$\frac{700}{5000} = 0.140 \text{ amperes.}$$

Points are plotted for these values of current on the corresponding voltage curves, and a curve through the points as shown in Fig. 2, is the dynamic characteristic for the conditions assumed. It will be noticed that while the dynamic characteristic or working curve is straighter than the curves for constant plate voltage, it begins to bend decidedly at low current values, where the other curves turn most sharply. Thus, to keep the wave form distortion within proper limits, the minimum current must not fall below a certain value. In the present case we will take 0.02 amperes as the minimum current. This corresponds to 2400 volts on the plate and − 96 volts on the grid. The other end of the working range is zero grid volts, which, from the curve, is seen to correspond to 1500 volts at the plate and 0.2 amperes. A current varying from 0.02 to 0.2 ampere is equivalent to a direct current of 0.11 amperes, with a superimposed alternating current of 0.09 ampere maximum or $\frac{0.09}{\sqrt{2}}$ ampere effective value. Similarly the voltage varying from 1500 to 2400 is equivalent to a direct voltage of $\frac{1500 + 2400}{2} = 1950$, and an alternat-

ing voltage of $\frac{2400 - 1500}{2} = 450$ volts maximum or $450\sqrt{2}$ volts effective. And the a-c. power consumed in the resistance R is $\frac{0.09}{\sqrt{2}}$ by $\frac{450}{\sqrt{2}} = \frac{0.09 \times 450}{2}$ $= 20.25$ watts. The calculation of power may be abbreviated to

$$\frac{(E_{max} - E_{min})(I_{max} - I_{min})}{8}$$

$$= \frac{(2400 - 1500)\,(0.2 - 0.02)}{8} = 20.25$$

Estimate of Distortion

In calculating the power, no allowance has been made for possible errors introduced by the fact that the characteristic is not truly a straight line. Fig. 4, Curve I, shows the current wave resulting from impressing a sine wave voltage on the grid, varying from 0 to − 96 volts, or in other words, biasing the grid − 48 volts and swinging its potential 48 sine ωt. volts. If we draw a straight line II, on Fig. 2, falling as much below Curve

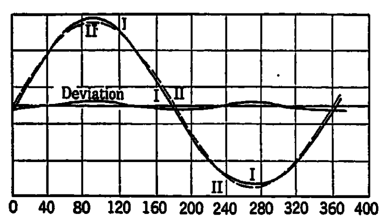

Fig. 4—Output Current Wave Compared with True Sine Wave

I at the ends as it is above it at the middle, and draw the corresponding wave form on Fig. 4, we have a true sine wave II. The difference between the two curves is almost totally a double frequency component with an amplitude 0.056 of the fundamental. Thus Curve II is the fundamental component in Curve I, and its amplitude is 0.09 amperes, or just what was assumed in calculating the power. In general, where the curvature is all in one direction as is true in nearly all cases in the present problem, the wave-form distortion consists principally in the production of even harmonics, and if only even harmonics are present, the difference between the maximum and minimum current is twice the amplitude of the fundamental. In addition to the 20.25 watts of fundamental-frequency power supplied by the tube to the resistance R, there is a small amount, 0.0006 watts, of higher frequencies.

If the working characteristic, Curve I, Fig. 2, has a practically uniform rate of change of slope, or, in other words, if it can be represented by a piece of a parabola, the only harmonic produced is the second or double frequency, and its amplitude is given by the amount by which the Curve I falls below the straight line II, at the center and rises above it at the ends. For simplicity, it seems desirable to compare curvatures on the basis of the maximum deviation of the working curve from a straight line, and since a very close approximation to the actual curve can usually be made by a section of parabola, this deviation may be expressed as the percentage of second harmonic produced, taking the amplitude of the fundamental wave as 100 per cent. In Fig. 2, Curve I is 0.005 amperes below Curve II at the center, and the same amount above it at the ends, so that the second harmonic has an amplitude of 0.005 amperes, as against 0.09 amperes for the fundamental. The ratio is $\frac{0.005}{0.09} = 0.056$ or 5.6 per cent. If the straight line were drawn between the ends of Curve I, it would be 0.01 amperes above Curve I at the middle, and the ratio of this to the total current range is $\frac{0.01}{0.18}$ or again 5.6 per cent. It is unnecessary to draw the straight line. The ratio of second harmonic to the fundamental is

$$\frac{\frac{1}{2}\,(I_{max} + I_{min}) - I_0}{I_{max} - I_{min}} = \frac{0.11 - 0.10}{0.18} = 0.056$$

in which I_0 is the plate current corresponding to the mean-grid voltage, which is $-\frac{0 + 96}{2} = 48$ volts in this case.

It is sometimes more convenient to find the deviation of the curve from the straight line connecting its ends, by a horizontal instead of a vertical measurement at the middle. This horizontal deviation (expressed in grid volts) divided by the total grid swing should give the same result as the vertical deviation divided by the total current swing, provided the curve is parallel to the straight line at the middle. In this case the middle value for plate current is 0.11 amperes which, on Curve I, corresponds to − 43 volts grid, and the relative magnitude of the second harmonic by the grid voltage measurement is $\frac{48 - 43}{96} = 0.052$. The discrepancy is within the limits of accuracy in reading the curves.

If the wave form distortion just calculated is considered more than allowable, it may be reduced by shortening the range, especially by raising the minimum plate current. For example, if the grid voltage varies only between zero and − 88 volts the other conditions remaining the same, we shall have

E_g	E_p	I_p	
0	1500	0.2	I_{max}
− 88	2350	0.03	I_{min}
− 40	1925	0.115	$\frac{1}{2}\,(I_{max} + I_{min})$
− 44	1962	0.1075	

Power $= \frac{1}{8}(850 \times 0.17) = 18$ watts

Second harmonic ratio $= \frac{0.0075}{0.17} = 0.044$ by current values, or

$\frac{4}{88} = 0.0455$ by grid voltages.

Effect of Higher Load Resistance

Let us next try a higher resistance load, 10,000 ohms, raising the supply voltage to 2800, so that with 0.08

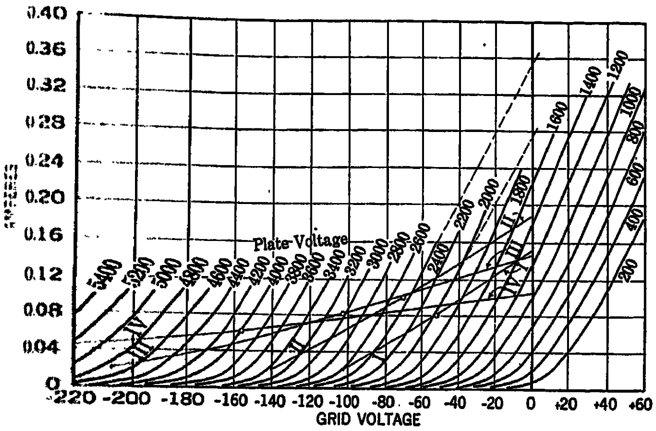

Fig. 5—Dynamic Characteristics with Various Values of Load Resistance

ampere flowing, the plate voltage will be 2000. This gives a point on Curve I of Fig. 5, where the characteristics of the same tube have been redrawn. A change of 200 volts at the plate corresponds to a current difference of $\frac{200}{10,000} = 0.02$ amperes. Starting with the 2000 volt and 0.08 ampere point we may plot the new dynamic characteristic by marking a series of points on the successive voltage curves, each point differing from the preceding one by 0.02 amperes. Again taking 0.02 amperes as the minimum plate current, we find we can swing the grid between zero and − 105 volts, giving

E_g	E_p	I_p	
0	1280	0.152	I_{max}
− 105	2600	0.02	I_{min}
− 49	1940	0.086	$\frac{1}{2}(I_{max} + I_{min})$
− 52.5	1980	0.082	I_o (for mean E_g)

Total current range 0.132 amperes
Total voltage range 1320 volts.
Power $\frac{1}{8}(.132 \times 1320) = 21.8$ watts

Second harmonic ratio $\frac{0.086 - 0.082}{0.132} = 0.03$ by current values

$\frac{52.5 - 49}{105} = 0.033$ by grid voltage

The above figures are comparable with those taken from Curve I Fig. 2, on the basis of substantially the same plate voltage when the grid is at its mean potential. Two results of going to a higher load resistance should be noted; there is more power output, and, for the same value of minimum plate current, the wave form distortion is less. The internal resistance of the tube is about 5000 ohms, and that more power should be delivered to a 10,000-ohm load than to a 5000-ohm load may seem at first surprising to those who are accustomed to think in terms of impedance fit. With a fixed grid swing the 5000-ohm load would receive the greater power, but with the high impedance load, the grid may be swung farther before distortion becomes serious. The common practise of applying a voltage to the grid (from an oscillator, microphone and amplifier, or radio receiving set)—and then varying the load impedance by trying various transformer ratios and selecting the tap which gives the loudest response,—is misleading. A tap which gives weaker response than the maximum may, when the input is readjusted, enable the amplifier to put out more power without distortion.

Best Conditions When Voltage is Limited

Mr. W. J. Brown[1] has given a simple rule for selecting the best load impedance and working range for the case where the mean voltage on the plate is limited to a certain value, and also a proof that the maximum power will be received by a load resistance equal to twice the internal resistance of the tube. In Fig. 6, $F D$ is the minimum value of plate current, below which the curvature becomes excessive; $A B$ is the plate current curve for a constant plate voltage equal to the mean plate voltage assumed in the problem, and $E C$ is the working curve. The constant voltage, curve $G C$, corresponds

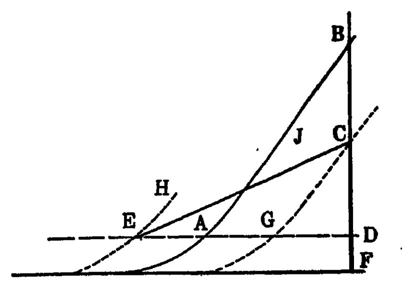

Fig. 6—Diagram Illustrating Method of Determining Best Operating Conditions

to the minimum voltage, and $E H$ to the maximum. The voltage amplitude is $r (B C)$ where r is the internal tube resistance, and the root-mean-square alternating voltage is $\frac{1}{\sqrt{2}} r (B C)$. The measurement $C D$ is equal to twice the current amplitudes, or the root-mean-square alternating current is $\frac{1}{2\sqrt{2}} (C D)$. The pro-

1. Discussion, Symposium on Loud Speakers, *Proceedings of London Physical Society*, Vol. 36, Part 3. April 1, 1924.

duct of the r. m. s. voltage and current, or the power, is equal to $\frac{1}{\sqrt{2}} r\,(B\,C) \frac{1}{2\sqrt{2}} (C\,D) = \frac{r}{4} (B\,C)\,(C\,D)$

Since the measurement $B\,D$ is fixed, the product $(B\,C)\,(C\,D)$ is a maximum when $B\,C = C\,D$ or C is located half way between D and B. The value of the external resistance is equal to $\frac{\text{voltage amplitude}}{\text{current amplitude}}$

$= \frac{r\,(B\,C)}{\frac{1}{2}(C\,D)} = 2\,r$ when $B\,C = C\,D$. The location of the point C and the value of the load resistance determine the working characteristic $E\,C$, and its intersection with $A\,B$ determines the proper value of grid bias.

In the foregoing it is assumed that r is constant, but since this is not the case the result is only an approximation. For larger currents r is less than for small currents, and the value of r in the relation,—voltage amplitude $= r\,(B\,C)$, changes with the location of C. With r a function of the position of C, the condition for maximum product $r\,(B\,C) \times (C\,D)$ is no longer that $B\,C$ shall equal $C\,D$. The shape of the characteristics above the level of the point C can have no bearing on the operation. It would appear logical to use a value of r corresponding to currents between $F\,D$ and $F\,C$ and to locate the point B as if the same value of r held for the higher currents. This means simply to draw the upper part of the line $A\,B$ straight, maintaining a slope equal to that in the working range $A\,J$. This point is brought out not because the error in the method described by Mr. Brown would, in general, be serious, but because in many cases the upper parts of the curves $A\,B$ are more difficult to obtain experimentally or data to plot them may be lacking. As in many other problems involving maxima, precision is not required here, the output remaining nearly the same through a wide range in load resistance.

Limitation Set by Anode Loss

We have so far considered the case where the mean plate voltage is limited, for example by the available supply, but where no other limitation is imposed. If the supply voltage can be raised sufficiently to enable the tube to put out all the power of which it is capable the limit of output may be set either by the power which can safely be dissipated from the plate, or by a combination of plate dissipation and insulation. For voltages below a certain value the rule illustrated in Fig. 6 is applicable. Applying this rule, the output goes up very fast with increase of voltage, and the average power supplied to the plate also increases rapidly. For example, Curve I of Fig. 5 is for a mean-plate voltage of 2000 and gives 21.8 watts output and 162 watts, plate loss. Curve II is for 2400 volts and gives 40.8 watts output and 250 watts plate loss. This is the maximum plate loss which we may safely allow for the tube in question. Up to this point the mean plate current has been increasing with increase of voltage. For higher voltages the current must be limited to

$$\frac{\text{Permissible plate loss}}{\text{Mean plate voltage}}.$$

The mean plate voltage and plate current determine the grid bias. Since the grid voltage may swing to zero in the positive direction, the extreme negative swing will be twice the bias. The minimum value of plate current and the extreme negative grid potential fix the lower end of the working characteristic and the maximum plate voltage. Thus we have the voltage amplitude and the current amplitude, from which we find the load resistance and the power output. Referring again to Fig. 5, if the mean plate voltage is 3000, the mean current is limited to $\frac{250 \text{ watts}}{3000 \text{ volts}} = 0.0833$ amperes. On the 3000 volt curve we find that the grid bias corresponding to 0.0833 amperes is $-$ 103 volts. The grid may then swing between zero and $-$ 206 volts. The plate voltage corresponding to 0.02 amperes, assumed minimum current, and $-$ 206 grid volts is 4700. Then the voltage amplitude is $4700 - 3000 = 1700$, the current amplitude $0.0833 - 0.02 = 0.0633$, the load resistance $\frac{1700}{0.0633} = 26{,}800$ and the power output $\frac{1700 \times 0.0633}{2} = 54$ watts. With the load resistance known the working curve may be drawn. If its intersection with the zero grid volts axis shows that the current and voltage swing during this half cycle is greater than during the other, there will be a correction to the power calculation. In this case the maximum current is 0.148 amperes and the minimum voltage is 1250. The revised power calculation is then $\frac{(4700 - 1250)\,(0.148 - 0.02)}{8} = 55$. If the curvature is small as in this case it is hardly necessary to draw the curve, the first calculation being sufficiently close.

If experimental characteristics at the extreme high voltages are not available, substantially the same result may be obtained if the curvature is slight, by locating the upper end of the working characteristic, which will be on the zero grid volts line, and with a plate current value as much above the average, as the minimum is below. If there is considerable curvature it is better to follow the first method, drawing in additional constant voltage curves by extrapolation if necessary. Fortunately for the ease of extrapolation the constant voltage characteristics are substantially alike in shape, and each is displaced horizontally from the next by the voltage interval divided by the amplification constant of the tube.

That the method just described will give the greatest possible power output for the voltage and mean plate current assumed, may be seen from the following. In swinging the grid from zero to twice the bias, we are using the largest grid swing allowable, increasing the bias without raising the plate voltage would give only a small increase in grid range, but a large reduction in current amplitude. Any lower load resistance would cause the lower end of the working curve to fall below the permitted minimum plate current, and therefore give distortion. Any higher load resistance with the same grid swing would decrease output, because we are already using a resistance much higher than the internal resistance of the tube, and it is a general principle that with a given grid swing, the more nearly the load resistance can be made to approach the tube resistance the greater will be the tube output.

The following table shows how the output of the tube with characteristics given in Fig. 5, varies with the voltage of the plate supply. The voltage E_0 given in the first column is the plate voltage when the grid is at its bias potential, and I_0 is the corresponding plate current.

Plate Volts E_0	Plate Amperes I_0	Grid Bias	Plate Loss	Output			Load Resist	Second Harmonic Ratio
				Amperes Max. A. C.	Volts Max. A. C.	Watts		
1980	0.082	−52.5	162	0.066	660	21.8	10,000	0.03
2460	0.10	− 71	246	0.085	960	40.7	11,250	0.03
3000	0.0833	−103	250	0.064	1725	55	26,800	0.0052
4000	0.0625	−157	250	0.0425	2970	63	70,000	
5000	0.05	−210	250	0.03	4120	62	137,000	

Since the tube is not designed to withstand more than approximately 2500 volts, the maximum output which can be realized is 41 watts. The purpose of carrying the calculations to higher voltages is merely to illustrate the method of determining load impedance and output when plate loss rather than plate voltage is the limiting factor, and to bring out certain relations. In the above table the minimum current has been taken throughout as 0.02 amperes, although in view of the fact that distortion is less with the high resistance loads, the lower limit of current might properly have been reduced. Had this been done the maximum output would have occurred at a still higher voltage. If we permitted the minimum current to go to zero it would have appeared that the output increased indefinitely with increase of voltage. This is because the voltage also cannot go to zero. The power output of the tube is $\frac{1}{2}(I_0 - I_{min})(E_0 - E_{min})$ which becomes $\frac{1}{2} I_0 (E_0 - E_{min}) = \frac{1}{2} I_0 E_0 - \frac{1}{2} I_0 E_{min}$ if I_{min} is zero. As the voltage is increased, the supplied watts $E_0 I_0$ being maintained constant, I_0 becomes less and also E_{min}, so that the output approaches $\frac{1}{2} I_0 E_0$.

Limiting Value of Output

If the tube impedance is lowered by using coarser grid mesh or closer electrode spacings, E_0 can be lowered and a greater output obtained. If we imagine a tube of such low impedance that the voltage could go to zero, as well as the current, the output would be $\frac{1}{2} E_0 I_0$, or one-half the permissible plate loss; and if the latter is kept constant, the output would be independent of the voltage chosen. In practical cases, it appears in general that, for a given value of plate loss, the lower the tube impedance and the higher the supplied voltage, the greater will be the output, and for most efficient use, a power amplifier tube should be worked at the highest voltage compatible with good life.

Output Subtracts from Plate Loss

The average power $E_0 I_0$, supplied to a straight line amplifier tube, is the same whether an alternating voltage is impressed on the grid, or the grid potential remains stationary at the bias value. When the tube is operating into a resistance load, the plate loss is reduced by the amount of the useful output. However, this does not make it permissible to make $E_0 I_0$ greater than the allowable plate loss, for amplifiers do not operate with any fixed grid swing; and even if an amplifier should be used for constant tone production the alternating voltage might go off at any time. Nor should it be inferred that in all amplifiers the plate loss will go down when an alternating voltage is applied to the grid. If there is much curvature or the swing is excessive, the average current will generally increase, and if the load is of low resistance there will be little power absorbed in the load to offset the increase in the supplied watts. Under such conditions the plate loss may increase when alternating voltage is applied to the grid.

Permissible Distortion

In comparing various tubes for a given purpose or in assigning power ratings to tubes, it would be logical to set a limiting value of distortion. For scientific or measurement work the distortion permitted would depend on the nature of the work. On the other hand for the reproduction of speech or music it does not seem possible to assign any general rule as to how much distortion should be permitted, nor to give any simple criterion for setting a limit. There is good reason to believe that the response of the ear is not linear, or, in other words, that harmonics are produced in the ear

itself[2]. This being the case, the ear would not be critical toward the production of overtones in the amplifiers. On the other hand, if the working characteristic is fairly straight over a certain range and then turns quite sharply, an impairment of quality is quickly noticed if the grid swing exceeds that which corresponds to the straight part of the characteristic. It would appear that much greater deviation from a straight line can be allowed if the curvature is practically uniform, than if the characteristic turns abruptly. While it does not seem possible to set a limit to distortion, applicable to all tubes, the practical limit in a particular case does not seem difficult to decide upon. For example, in the case of the tube whose characteristics are shown in Fig. 5; if we assume E_0 to be 2500 volts and the plate loss not to exceed 250 watts, we can assign various values to the minimum current and find the maximum power obtainable for each case. A low minimum current means a considerable curvature allowed, but permits more power to be obtained. Fig. 7 shows the power output and the distortion as functions of I_{min}. It will be noticed that below about 0.02 amperes, the gain in output is slow and the increase in distortion is rapid. Analysis of a number of practical tubes indicates that it is rarely necessary to permit more than about 5 per cent distortion in order to realize about all the useful output of which the tube is capable.

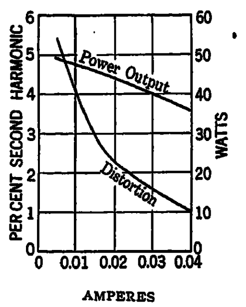

FIG. 7—RELATION BETWEEN DISTORTION AND MINIMUM CURRENT

PUSH-PULL CIRCUIT

In this connection, the question naturally arises whether the working range can be increased by use of a "push-pull" circuit, like that shown in Fig. 8. Such a connection balances out the even harmonics if the tube characteristics are alike, and is, therefore, a possible means of reducing distortion. The gain in output per tube, however, is small. Referring to Fig. 5, Curve II, we see that, for the range shown the curvature is very slight, but we cannot extend the curve on the lower end without its turning horizontal, nor on the upper end without driving the grid positive. Trying to drive the grid positive causes a distortion of the grid voltage wave which has the same effect on the plate current as if the grid voltage wave were not affected, but the working characteristic turned toward the horizontal to the right of the zero-grid-voltage point. A working characteristic which bends toward the horizontal at both ends, or in other words, has a reversed curvature, causes odd harmonics in the output current wave, and the balanced, or push-pull circuit, does not neutralize odd harmonics. While the push-pull circuit does not make it permissible to increase the working range of the tubes appreciably, there are cases in which it is advantageous. For some scientific work, it is important to reduce all distortion to the minimum, and if the tubes are worked over a very moderate range so that only the double frequency harmonics are produced, the balanced circuit can be made to practically eliminate the distortion. It possesses a practical advantage in that the direct currents in both halves of the output transformer winding, balance each other magnetically, thus reducing the tendency to saturate the core, and making a lighter, smaller design of transformer possible. As against these advantages, the push-pull circuit calls for an interstage transformer which introduces some distortion.

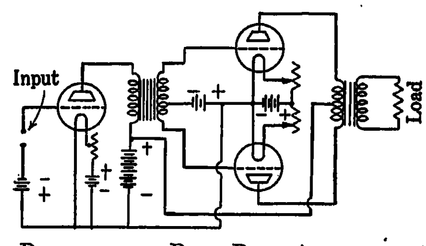

FIG. 8—BALANCED OR PUSH-PULL AMPLIFIER CIRCUIT

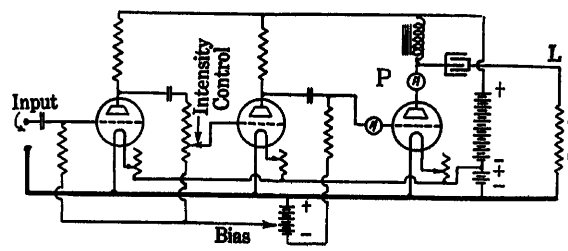

FIG. 9—RESISTANCE CAPACITY COUPLED AMPLIFIER WITH CHOKE COIL-CONDENSER FEED TO LOAD

LOAD CIRCUITS

Figs. 9 and 10 show connections frequently used for the output of power amplifiers. In Fig. 9, the choke coil must have a high reactance compared with the tube and load resistance, and the stopping condenser must have a low reactance compared with the load resistance, for all frequencies in the working range. Otherwise, distortion will result, the low frequency

2. "Sensation of Tone" by H. L. F. Helmholtz (Edition of 1877), Chapter VII. Quantitative measurements supporting this theory are given by R. L. Wegel and C. E. Lane, *Physical Rev.*, Feb. 1923. "Auditory Masking of One Pure Tone by Another."

currents being partially suppressed either by excessive reactance in the condenser, or too much leakage through the choke. With a properly designed circuit, we may think of the choke as maintaining a constant direct current equal to the average plate current, I_0, while the condenser offers a practically constant counter-electromotive force equal to the average plate voltage E_0. Now, suppose that the plate current changes momentarily to $I_0 - i$. Since the current through the choke remains constant, the difference or i amperes must flow through the load. The potential at L then becomes $+ i R$ which, added to the strain E_0 on the condenser, brings the potential at P to $E_0 + i R$. Similarly, when the plate current is $I_0 + i$ the load current is reversed, the potential at L is $- i R$ and at P is $E_0 - i R$. It will be recognized that from the standpoint of the tube, this condition duplicates that illustrated in Fig. 3, the only difference being

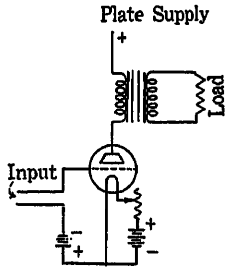

FIG. 10—TRANSFORMER COUPLED LOAD

that in Fig. 3, the supply voltage would have to be $E_0 + I_0 R$ in order to maintain the average voltage E_0 at the plate. The conditions met in the transformer connection of Fig. 10 are similar. An ideal transformer with a resistance R connected to its secondary terminals introduces into the primary circuit, an effective resistance for alternating currents equal to R multiplied by the square of the ratio of primary to secondary turns, but for direct current, it introduces only the ohmic resistance of the primary winding. The practical transformer, if properly designed to avoid distortion, gives a close approximation to the relations just stated. The magnetizing current must be small compared with the with the load current at the lowest frequencies with which we are concerned, and the series reactance due to leakage flux must be small compared with the load impedance for the highest frequencies considered.

REACTIVE LOADS

We have so far considered only pure resistance loads. The dynamic characteristic for a tube with a reactive load is not readily plotted, but its general form can be shown and the conditions for avoiding distortion as found for the case of resistance load are applicable to the reactive load. If there is reactance in the load, the dynamic characteristic becomes elliptical in form; a true ellipse if the constant voltage curves are straight over the range between maximum and minimum current, and a distorted ellipse if there is appreciable curvature within this range. It is generally possible to adjust the load impedance to any desired value, either by means of a transformer, or by changing the number of turns in the windings of the instrument which constitutes the load. Such changes do not materially alter the power factor. In fitting a reactive load to the amplifier tube, the procedure recommended is first to determine for the case of a resistance load, the load resistance, plate voltage, grid bias, and grid swing for maximum output; then using the same plate voltage and grid swing, make the load impedance such that the maximum and minimum values of plate current will be the same as in the case of the resistance load. This means making the vector sum of load impedance and tube plate resistance the same for the two cases[3]. If these conditions are complied with, the principal sources of distortion are avoided, namely, swinging the grid positive, and working with too low minimum currents.

Since load impedances are functions of frequency and audio frequency amplifiers must operate properly for a wide range of frequencies, the question arises at what frequency should the load impedance have the value which has been determined as suitable? The only safe rule is to make the calculation for the frequency at which the load impedance is lowest. Exception might be made in case currents of the frequency in question were known to be of low intensity compared with those of other frequencies. For example, most telephone receivers and loud speakers have lowest impedance at low frequency. A case might arise in which it was known that the low frequency components in the currents to be amplified were weak as compared with those of higher frequency. It would then be permissible to determine the load impedance at a higher frequency. But such a situation is difficult to imagine. When pains are taken to build a distortionless amplifier, it is only reasonable to assume that the remainder of the system would be designed with a view to minimizing distortion, and since the greater part of the energy in both voice and most music, is carried by the lower tones, the amplifier would be called on to handle the largest amplitudes at low frequency.

MODULATION OF RADIO TRANSMITTERS

Fig. 11 shows the modulator and oscillator tubes of a radio telephone transmitter. There are many possible arrangements of the oscillating circuits, but the means

3. The alternating current in the plate circuit is equal to

$$\frac{\text{(alternating grid voltage) (amplification constant of tube)}}{\text{(vector sum of load impedance and tube resistance)}}$$

For derivation of this relation see "The Thermionic Vacuum Tube" by H. J. Van der Bijl, pages 157 and 177. See also pages 175 and 176 for discussion of form of dynamic characteristic with reactive load.

for varying the intensity of the oscillations or "modulating" them is, in most cases, like that shown in Fig. 11. The large inductance, L_1, keeps the total current constant, while the function of the small inductance, L_2, prevents absorption of radio frequency power by the modulator tube. When the grid of the modulator tube swings toward positive the plate takes more current, leaving less current available for the oscillator, and the voltage drops, causing a reduction in the amplitude of the oscillations. Similarly, when the grid of the modulator swings negative, the voltage rises and the oscillation amplitude increases.

If the voltage supplied to an oscillator is varied and the current read and plotted, the relation in general is found to be represented by a straight line over the range for which the oscillations are stable. Therefore, the oscillator is equivalent to a resistance load on the modulator tube. If the time of discharge of the grid condenser is appreciable compared with an audio cycle,

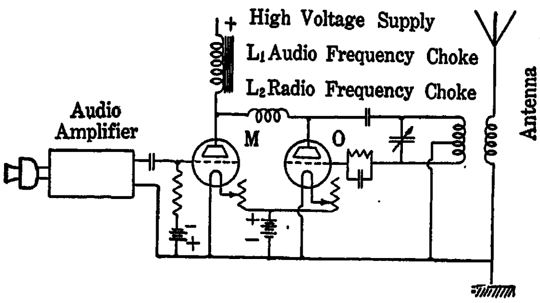

FIG. 11—RADIO TELEPHONE TRANSMITTER SHOWING METHOD OF MODULATION

a reactive component is introduced and the effective resistance of the oscillator will be less for high than for low frequencies, but with properly proportioned grid leak and condenser, the oscillator is practically a pure resistance. From the standpoint of the modulator tube the circuit then becomes equivalent to that shown in Fig. 9, with the blocking condenser omitted and the current through the choke increased by the amount of the average direct current taken by the oscillator.

The type of oscillator and supply voltage having been chosen, the design of the modulating system involves first the determination of the effective resistance of the oscillator. This may be found by varying the voltage and measuring the change in supplied current corresponding to a given change in voltage. The effective resistance depends, among other things, upon the grid leak, antenna resistance, antenna coupling, and filament current; and if any of these factors are changed, a new measurement of resistance will be necessary.

The modulator tube or tubes must work at the same mean-plate voltage as the oscillator. The load resistance can be controlled within limits by changing the antenna adjustments, but if the full oscillator output is desired, the principal means for obtaining a suitable load resistance must be to employ the proper number of modulator tubes compared with the number of oscillator tubes. Thus, doubling the number of modulator tubes, doubles the load resistance into which each modulator tube works. The load resistance per tube determines the slope of the dynamic characteristic, and its position, which for a given supply voltage depends on the grid bias, should be so chosen that when the grid reaches a negative potential equal to twice the bias, the plate current will have the minimum value permissible in view of curvature of the tube characteristics. The voltage range covered by the dynamic characteristic shows the percentage modulation of the oscillations which can be accomplished without exceeding the proper range of the modulator tubes. For illustration, let us suppose that we wish to modulate a 250-watt oscillator, operating at 2000 volts, and showing an effective input resistance of 8000 ohms. First, we may try a single modulator tube of the type represented in Fig. 5, taking 0.02 amperes as the minimum plate current. To find the proper grid bias, we might draw several parallel curves, each corresponding to an 8000-ohm load resistance, and choose the one which gave equal voltage swings above and below 2000, but it is simpler to try several values of grid bias, in each case, assuming that at double the bias voltage, the plate current is cut down to 0.02 amperes. Find what load resistance this would mean, and pick the grid bias which corresponds most nearly to the actual load resistance. For example, referring to Fig. 5, a bias of − 50 volts with 2000 volts on the plate gives 0.095 amperes plate current. A grid voltage of − 100 and plate current of 0.02 amperes corresponds to 2500 volts on the plate. A dynamic characteristic through these

two points would correspond to $\dfrac{2500 - 2000}{0.095 - 0.02} = 6660$

ohms. The trials may be shown in tabular form.

E_g	E_p	I_p	R
− 50	2000	0.095	6,660
− 100	2500	0.02	
− 55	2000	0.079	11,800
− 110	2700	0.02	
− 52	2000	0.09	8,300
− 104	2580	0.02	

The last value is close enough. An 8000-ohm dynamic characteristic passing through the point $E_p = 2000$, $I_p = 0.09$, would intersect the 1400 volt line at $I_p = 0.165$, and the 1200 volt line at $I_p = 0.19$. Connecting these two points gives the intersection with the vertical line over $E_g = 0$ as $I_p = 0.17$ and $E_p = 1360$. Therefore with one modulator tube, we could control the oscillator voltage down to 1360 and up to 2580. Owing to the slight curvature, equal grid swings do not give exactly

equal plate swings in both directions. Taking the average, which is 610 volts, we may say that the modulation is $\frac{610}{2000}$ or 30.5 per cent. Heavier modulation should not be attempted with the one modulator tube. Characteristics of oscillating tubes show in general that through most of the stable range, the antenna current is a straight line function of the supplied voltage. This being the case, there is no distortion introduced at this stage except that due to the curvature of the modulator tube dynamic characteristic. This distortion is offset by the characteristics of the detectors used in receiving sets which rectify strong currents more efficiently than weak ones. Suppose, for example, that the rectified current is proportional to the square of the amplitude of the incoming waves, which law would represent fairly well the action of most detectors on weak signals. Then the relation between modulator grid potential and rectified receiver current would be as follows:

Modulation grid voltage..............	0	−52	−104
Voltage supplied to oscillator (proportional to oscillation amplitude)......	1360	2000	2580
Square of oscillator voltage ÷ 10^6 (proportional to rectified receiver current).	1.85	4	6.65

This shows a swing of 2.15 in one direction and 2.65 in the other. Had there been no curvature in the modulator tube characteristic and the plate voltage swung 610 volts in each direction, the voltage square factors would have been 1.94, 4.0, 6.8, or a swing of 2.06 in one direction and 2.8 in the other,—a greater wave form distortion than with the curved modulator characteristic.

The next question is how much can we increase the modulation by adding a second modulator tube. With two modulator tubes, the load resistance for each tube is 16,000 ohms and we again find the proper grid bias by trial.

E_g	E_p	I_p	R
− 60	2000	0.06	22,500
− 120	2900	0.02	
− 57	2000	0.07	15,800
− 114	2790	0.02	

The 16,000-ohm dynamic characteristic through the point $E_g = -57$, $I_p = 0.07$, intersects the $E_g = 0$ axis at $I_p = 0.124$, $E_p = 1120$. With a voltage swing of 790 volts in one direction, and 880 volts in the other, the mean modulation is $\frac{845}{2000} = 0.422$ or 42 per cent as compared with 30.5 per cent. with one modulator tube.

With reduced supply voltage, the percentage modulation which can be obtained with a given number of modulator tubes is less. For example, if the supplied voltage is 1600 and the oscillator effective resistance again taken as 8000 ohms, we find that with one modulator tube and a bias of − 38 volts we can obtain a modulation of 27 per cent and with two modulators and a bias of − 42 volts, we can modulate 40 per cent. In both cases, 1600 and 2000 volts supplied, the addition of a modulator tube about doubles the audio frequency power which would be delivered by a receiving set.

The question of how much modulation should be attempted is one which has been much discussed. It should be borne in mind that the 40 per cent modulasion just calculated applies to the extreme peak values of the audio frequency waves, and with most speech or music it would represent an average modulation of less than 5 per cent, which is small compared with most radio telephone practise. In most receiving sets the rectified current varies as some function between the first and second powers of the amplitude of the incoming high frequency waves, being approximately proportional to the square for small amplitudes and more nearly a linear function with stronger signals. With the type of transmitter circuit shown in Fig. 11, the aim is to make the envelope of the oscillation amplitude show the exact wave form of the original audio-frequency currents. This would result in distortionless reproduction by a receiver having a straight line detector, or one giving a rectified current directly proportional to the amplitude of the incoming radio frequency waves. Since practically no receivers have this characteristic, distortion results, but as the percentage modulation is reduced, the distortion becomes less, until at 10 per cent modulation, it is of practically no consequence whether the receiver is a linear or a square law detector. This has been used as an argument for limiting the modulation to a very small value,—perhaps ten or twenty per cent on the peaks. But there are arguments in favor of larger modulation, particularly if the purpose is to obtain the best possible reception with a given average radiated power. In the first place, the distortion which results when, for example, a square law detector is used to receive fairly deeply modulated waves, does not appear to be of an especially objectionable kind, and as already explained is partially offset by the distortion due to the curvature of the modulator characteristic. In the second place, there is a positive advantage in the use of moderately heavy modulation, in that the ratio of the desired sound to static and stray noises is better with large than with small modulation. People who have operated receiving sets will probably agree that the soft passages in musical numbers are rarely so satisfactory to listen to as the louder parts. The "blasting" that frequently occurs in the loudest parts is due to exceeding the proper working range of the modulator tubes, or to overworking some other part of the system, rather than to large modulation itself.

It would appear, then, that a modulator capacity of two, or even four times the oscillator capacity would be desirable in the case of the tubes used in our illustrations. The degree of modulation which can be accomplished is increased by use of low impedance tubes and

increases as the voltage is raised, up to the point where it is necessary to reduce the mean plate current of the modulator tubes below the value that would otherwise be assigned, in order not to overheat the plate.

Plate and Grid Ammeters

It is desirable to design the earlier stages of a power amplifier with ample margin so that if any tube is overworked, it will be the power stage. A very satisfactory indicator, to show when the intensity exceeds the straight line capacity of the amplifier, consists in a milliammeter in the grid circuit and a meter in the plate circuit. If the grid swings positive with respect to the filament, the grid meter will "kick" and perhaps the plate meter also, while too great a negative swing will cause a kick on the plate meter. Careful listening will reveal an impairment of quality which disappears as soon as the intensity is reduced to a point where the meters cease to show disturbance. Listening alone is not a satisfactory substitute since the distortion is not so quickly nor surely noticed, particularly in view of fatigue of attention, and if distortion is noticed, its origin might be elsewhere in the system.

Tubes in Multiple

The increased output from a power amplifier obtained by adding power tubes in multiple, is often disappointing, the gain being slow compared with that which can be accomplished with increased voltage or with tubes of higher rating. However, there are cases in which it is desirable to use several tubes in multiple. With the load impedance already several times the tube resistance, which is the proper relation for maximum output, the addition of a second tube in multiple with the first would not give a perceptible increase in output, but if the load impedance is readjusted to half the previous value, twice the power output can be obtained, corresponding to about 40 per cent increase in sound amplitude, which is a noticeable, but not a striking difference.

When several tubes are connected in multiple, they may form an oscillating system and fill the tubes with high frequency oscillations. This is less likely to occur if the connecting wires are made very short, but with high power tubes, it is frequently necessary to employ some means of stopping the parasitic oscillations, such as an individual resistance or choke connected in series close to the grid of each tube. A few turns of wire on a small solid iron core will suffice, since such a choke introduces a high effective resistance at the extremely high frequencies concerned.

Interstage Connections

With a supply of high voltage available, such as is necessary for the power tubes, the design of the preceding amplifier stages is simple. Resistance-capacity coupling can be used with sufficiently high plate resistance to obtain three-fourths or four-fifths of the full amplification of the tube. Under these circumstances, and with high amplification tubes available, there would be little argument for transformer coupling. In designing a resistance-capacity coupled amplifier, the following points must be kept in mind:

1. The reactance of the coupling condenser at the lowest frequency to be passed, must be less than the grid leak resistance.

2. No grid should swing positive with respect to the negative end of the filament, or, in other words, the grid bias must be greater than the extreme grid swing required. This does not apply to detector tubes.

3. If the expected swing in plate potential of any tube is more than about 20 per cent of the average voltage on the plate or if the plate current is very small, the dynamic characteristic should be worked out to make sure of constant proportionality between plate and grid voltage swings. The load resistance is that of the plate-feed resistance and the grid leak of the next tube in multiple.

4. If a battery of power tubes in multiple is employed, so that the grids constitute a considerable capacity load, or if any of the earlier tubes have very high internal resistance, or are fed through very high plate resistances, calculation should be made of the magnitude of the capacity load at the highest frequency which the amplifier must handle. Owing to the simultaneous swinging of the plate potential the effective capacity of a tube grid may be several times the grid capacity as measured with plate and filament grounded. The capacity reactance of the grid must be high compared with both the internal and external plate resistance of the previous tube; otherwise distortion may result, either because of reduced amplification of the high frequencies, or because the actual dynamic characteristic is steeper than estimated (lower impedance load) with resulting curvature.

With a common source of plate voltage for all of the tubes of a multi-stage amplifier, back coupling with consequent oscillations may occur through the plate supply line, if there is enough resistance in the supply so that the power-stage plate current affects the voltage of the supply line materially. If such back coupling occurs, the cure may be to secure a lower resistance supply, or to reduce the variations in the voltage fed to the earlier tubes, particularly the second tube preceding the power tubes, by filters or potentiometer connections. The filters, if of series resistance and shunt capacity, must be effective at as low a frequency as the lowest at which appreciable amplification takes place. Therefore, the filtering is simplified by designing the amplifier not to pass any frequencies lower than really required.

To obtain a given voltage swing on the grid of the power tube may be easier with resistance connection than with an interstage transformer, in spite of the step-up ratio of the transformer. This is because even the best designed transformers drop to an impedance comparable with the tube resistance at high frequency owing to capacity on the secondary side, and at low frequency owing to magnetizing current. This low

impedance load on the tube may greatly reduce the plate voltage swing, obtainable without distortion.

OUTPUT TRANSFORMERS

If the output of the power stage goes through a transformer, the design of the transformer follows the general principles of audio transformer design, of which the following is a summary:

1. The impedance at the terminals of the tube is equal approximately to the load impedance multiplied by the square of the ratio of primary to secondary turns, and the turn ratio should be chosen to give the desired impedance at the tube.

2. With the secondary open-circuited, the primary reactance should be at least equal to the effective load impedance on the primary side, at the lowest frequencies to be passed.

3. The leakage reactance, found by measuring the reactance of one winding with the other short-circuited, should be low compared with the effective load impedance at the highest frequencies in the working range.

4. The winding resistance loss should be low compared with the power supplied to the load.

5. If the direct current component is sufficient to saturate the core, it will frequently be found that the same number of turns gives more inductance with an air-gap in the magnetic circuit than without. The air-gap should be just sufficient to prevent saturation. The inductance for a given number of turns is then practically proportional to the core cross section, and a heavy transformer is the price of efficiency. If the required air-gap is very short, 0.002 in. or 0.005 cm. or less, there may be an advantage in using special high permeability core material, while with longer gaps, 0.010 in. or 0.025 cm. or more, ordinary transformer steel is satisfactory.

Discussion

G. L. Bayley: I would like to ask the author if it is possible to make an amplifier self-exciting, very much like a d-c. generator. Is it possible to introduce resistance in the plate circuit to give a voltage drop, and to apply that drop to the grid voltage so that the total effect would be much greater amplification.

A. V. Loughren: I wonder if the members of the Institute have ever had called to their attention just how important these limits in operating a tube really are.

At a recent radio show a well-known company which sells resistance-coupled amplifiers, advertising them as panaceas for all disturbances, had a set-up in which there were two amplifiers, one transformer-coupled and the other resistance-coupled. The transformer-coupled amplifier was so arranged that when an audio-frequency input was applied to the grid of the first tube, the mean plate current increased, and the obvious inference which was brought out very strongly by the salesman was that a transformer-coupled amplifier for that reason was very hard on the battery. There was altogether too low a plate voltage in the set, of course, for the grid bias used, and the trouble was that the plate current was decreasing almost to zero on the negative half of the wave, so that when the grid was made to oscillate, the mean plate current rose. Naturally, there was distortion there; but the striking point was that at the same time they had a resistance-coupled amplifier alongside it that was operated without any grid bias, so that when a speech input was put on, the grids all drew current, and for that reason on the positive half of the wave the plate current did not increase as much as it decreased on the negative half. The mean plate current accordingly decreased and the result was that the resistance-coupled amplifier was fine for the battery; but nothing was said about distortion.

As far as experimental results are concerned, the theory is absolutely correct. Last summer, Mr. Kellogg was working on this problem, and I had some work to do on it from a different angle. I found it necessary to get some experimental checks. Working on tubes of somewhat lower rating than the 250-watt tube that he describes, I got experimental verifications of the predictions of power based on the characteristic curves which were good to better than 5 per cent, and the amount of distortion produced by operating under various conditions could be checked to probably 10 per cent. The method of measuring distortion, though, isn't as accurate from an experimental point of view, because it means measuring small quantitites.

G. D. Robinson: Mr. Kellogg speaks of, I believe, "negligible" distortion. It is my recollection (I fail to place it precisely) that either one year ago or two years ago at the Midwinter Convention the statement was made that two tubes working in a push-pull circuit were good for 18 times the output of one tube singly, which, of course, does not check with Mr. Kellogg's statement about the small increase in value.

Another point: There are substantially no broadcast transmitters working with four modulator tubes per oscillator and probably there are substantially no transmitters working with two modulator tubes per oscillator.

In connection with that same thing, we are assured by the Westinghouse Company that it is permissible to run a certain quite observable grid current on the modulator tubes without serious distortion. That probably goes back again to: What do we mean by serious distortion or negligible distortion?

P. W. Gumaer: I wish to emphasize the importance of this subject as affecting future improvements in the quality of broadcasting and its reception. One of the limiting features in perfection of the quality of radio reception has been in the acoustic end, particularly in the connection with loud speakers. Recent developments in loud speakers have overcome that difficulty. There is now a loud speaker that has no distortion that can be detected by the human ear.

The next step in the development of perfect radio reception is now up to the electrical end. In order to reach perfection in the quality of radio reception we need, I believe, a unit of measurement of distortion and a less laborious method of measuring distortion. I do not refer to any particular frequency but to the whole range of audio-frequencies, and it is indeed a difficult problem.

D. F. Whiting: One point occurs in the first paragraph of Mr. Kellogg's paper, where he speaks about the relatively greater energy required to operate a loud speaker satisfactorily in comparison with the energy required to actuate a telephone headset. Considering as a basis for comparison the relative energy requirements necessary to produce approximately the same response in the ears for the two cases, I believe that Mr. Kellogg is somewhat more conservative in his figures than is warranted by the conditions that obtain. Instead of an energy increase of one hundred times, as he has stated, I should be inclined to further emphasize the importance of this paper by favoring an increase in the vicinity of ten thousand times in the energy that is required by the loud speaker in comparison with that necessary for the headset. This value is borne out by the following figures, expressed in transmission units, such that twenty-five transmission units below an arbitrary standard, which we call "zero level" in telephone parlance, represents about the right energy to use on a headset for persons of normal hearing, whereas an energy level of

fifteen transmission units above this same standard is required for good loud-speaker reception. The difference between these two figures is forty transmission units, a voltage and current increase of one hundred times, and an energy increase of ten thousand times. Some people may be satisfied with less from their loud speakers than these figures represent, but it is my feeling with respect to them that they are easily satisfied.

Incidentally, the values which I have quoted represent the amplification derived from two stages of a good-quality amplifier, or about one and one-half stages of amplification in which less attention is paid to frequency discrimination.

In regard to the dynamic characteristics of the vacuum tubes, Fig. 3 of Mr. Kellogg's paper shows a circuit by means of which certain characteristics of the tubes may be secured, but the results obtained from such a circuit are not the true dynamic characteristics of the tubes. The dynamic characteristic is affected by the impedance through which the grid receives its charge, especially when the grid runs positive, but Mr. Kellogg has limited his considerations of the dynamic characteristic, to the effects which take place when the grid potential is negative with respect to the filament, thereby neglecting the determination of the characteristic when the grid is positive. However, the dynamic characteristic covering the whole range in which we are interested may be determined by including a resistance in the circuit of Fig. 3 between the grid and the upper point where the grid supply voltage is measured. If this resistance is equal to the impedance of the circuit normally connected to the grid, the resulting dynamic characteristic will represent the effects which occur under normal operating conditions; and, if this resistance is great in magnitude, the dynamic characteristic will change its slope as the grid runs positive, tending to run in a more horizontal direction, the degree of departure from the static characteristic being dependent on the magnitude of the included resistance. The resulting dynamic characteristic represents a more accurate depiction of the effects which actually take place in the tube when in service. Although Mr. Kellogg has taken care to point out the occurrence of this effect, the curves given in his paper do not show it and the cause of the limitation is not pictured very clearly to the minds of those unfamiliar with the subject.

In reference to the discussion centering around the push-pull form of circuit, I wish to state that this type of circuit displays its principal advantages in comparison with the more simple arrangement when conditions surrounding the tube such as those discussed in Mr. Kellogg's paper—that is, grid and plate voltages, filament currents, impedances connected to grid and plate—are not optimum. However, under optimum or nearly optimum conditions, the push-pull circuit provides an increase in energy-handling capacity of approximately 25 per cent. Relative to what may be accomplished in other ways, this does not represent a very great increase. On the other hand, this increase in power output is gained very cheaply; for no additional apparatus or power is required and, while the amplification of the final stage may be lowered slightly thereby, this usually can be restored more cheaply in the preceding stages.

E. W. Kellogg: May I ask a question at this point? On what basis are you making comparison, on the basis of an equal amount of distortion?

Mr. Whiting: Yes.

Mr. Kellogg: Total energy of harmonics the same in the cases?

Mr. Whiting: Yes. The amount by which the energy capacity increases due to the push-pull circuit feature will vary, of course, with each individual test, with the criterion assumed for the state of full load and with the accuracy with which the conditions imposed on the tubes during the test simulate the optimum conditions for maximum output. The increase I have quoted is based on the results of a rather large number of tests obtained from many tubes of various kinds and under conditions which, to the best of my knowledge, were optimum for those tubes.

In the last sentence under the paragraph entitled "Push-Pull Circuit," Mr. Kellogg states, "As against these advantages, the push-pull circuit calls for an interstage transformer which introduces some distortion." I think this sentence should be modified to state that this comparison is made with reference to a resistance-coupled amplifier, whereas, of course, the same comment would not apply if the amplifier which he was considering in relation to the push-pull amplifier was of the transformer-coupled type already.

The second paragraph under the subject of "Reactive Loads" is exceptionally good, and I want to emphasize especially what it contains. If an amplifier is called upon to transmit good-quality speech or music currents, the maximum energy which the amplifier is required to deliver occurs ordinarily at very low frequencies; and, if the amplifier is to operate without overloading, it should be capable of carrying its maximum load at the frequencies that require the greatest energy capacity. This means that the amplifier should be designed in such a manner that the output impedances of the tubes bear the right relationship to the impedance of the load at the low frequencies where the larger proportion of the energy is likely to occur. This practise is not generally followed in the case of telephone repeaters because matters concerning line impedance termination and impedance balance are of greater importance to the operation of repeaters than is the matter of maximum power capacity.

S. Stern: I have found that, very often the number of amplifying stages that are found necessary, must be decreased in order to prevent feed-back. This feed-back is very rarely due to the inductive coupling between transformers, if the proper shielding precautions are taken. The cause when traced is usually found in the tube itself in which the grid-plate capacity is often of the proper value to act as a coupling capacity between the matched audio-tuned coils of the transformers in the grid and plate circuits. A direct remedy would therefore be to reduce this capacity but this cannot be conveniently done. However, adding capacity to the grid-plate capacity, will decrease the frequency at which feed back can occur to that below the audio range. If the capacities used for this purpose have very little resistance, no decrease in amplification will be experienced.

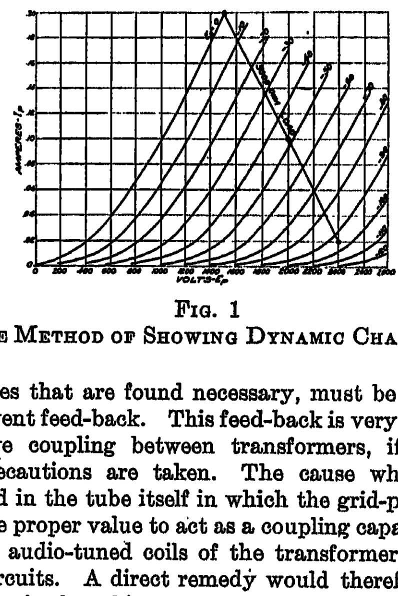

FIG. 1

ALTERNATIVE METHOD OF SHOWING DYNAMIC CHARACTERISTICS

A detailed description of this method and also the construction of a four-stage transformer amplifier, can be found on page 460 of May 1925 number of *The Experimenter* published by the Experimenter Publishing Co. of New York City.

E. W. Kellogg: Since the paper was written, my attention has been called by Mr. John C. Warner of General Electric Research Laboratory, to advantages in using a set of plate current vs. plate voltage curves to show the tube characteristics, instead of plate current vs. grid voltage as used in the paper. The two sets of curves give the same information. Thus the curves of Fig. 1 herewith are derived from Fig. 2. of the paper. When plate voltage is used instead of grid voltage for the abscissas, the dynamic characteristic for a resistance load becomes a

straight line whose slope corresponds to the load resistance. The 5000 ohm dynamic characteristic shown on Fig. 1 herewith is the equivalent of Curve I of Fig. 2. Different values of load resistance, plate voltage and grid bias can be tried and compared very quickly on such a chart as Fig. 1. If the mean plate voltage, E_o, the load resistance, and minimum current are given, we first find the slope from the value of load resistance, then slide a straight edge, maintaining this slope, until we find a position at which the grid voltage for the minimum current is twice the grid voltage corresponding to the intersection with the mean plate voltage line. Thus the dynamic characteristic shown in Fig. 1. crosses the horizontal .02 ampere line at $Eg = -96$ volts (interpolation) and it crosses the vertical 2000 volt line at $Eg = -48$ volts. Using the approximate method given in the paper for estimating distortion, the information is conveyed readily by Fig. 1, distortion in the case of Fig. 1 being shown by the fact that the point on the dynamic characteristic corresponding to mean grid voltage is not at the middle of the characteristic.

While the use of plate voltages as abscissas makes the resistance load dynamic characteristic a straight line, it does not make a true ellipse of the characteristic for a reactive load. For a general understanding of what takes place and for estimating both the kind and amount of distortion, the form of curves used in the paper is to be preferred, since the evidence of distortion is presented to the eye in much more striking form and it is at once evident whether the bend in the characteristic is approximately uniform or is abrupt. On the other hand, for rapid calculations, the second method has a great advantage.

There were a few questions brought up on my paper. The first was whether you could make an amplifier work something like a d-c. generator, self-excited. If I understand the question, it was whether we could use feed-back to get more amplification without distortion (I am putting this into language that is more familiar to radio fans). I have never tried in any thorough way to do it and I don't know what the possibilities are. I can say, certainly, that it is pretty difficult and it is questionable whether it is really desirable. It is so easy to get all the amplification you need in the regular way that it hardly seems worth while to go to the difficulties that you encounter with feed-back when you try to make the feed-back aperiodic.

The question was brought up as to the number of modulators. I was somewhat surprised when I began making calculations on the subject to find how the case stood. I think it is no doubt true that a good many stations do not employ more modulators than they have oscillators, and I think they ought to. Of course, that is tied up with the question of how heavy modulation is being attempted. That subject is discussed in the paper. It is a debatable question how deep modulation is desirable. But the point I wanted to bring out was that if you are going to attempt to use as heavy modulation as is very commonly employed, and considered by many to be desirable, then you need plenty of modulator capacity. It isn't my purpose to say how many modulator tubes are needed, but just to speak of an excess, for the purpose of calling attention to the fact that you need to study the tube characteristics and the oscillator impedance and to find out just how many you do need.

As to working the grids positive, there are possibly cases where it can be done to advantage, by suitable circuits you might reduce the distortion introduced in that way to as low a limit as is necessary, but the task is not simple. In Fig. 2, for example, I have plotted the grid current to the same scale as the plate current, and if you figure out the resistance corresponding to the slope, you will find that by the time you have the grid 20 volts positive, which won't extend your range very much, you are down to a grid impedance of 2500 ohms, which would be a heavy load on the plate of the preceding tube, with which you are trying to push the grid. The curves as I have plotted them don't turn over, because my abscissas are grid volts, regardless of how much current I may have to supply to get the grid voltages. Mr. Whiting has suggested a way of plotting the curves, which will take into account the effect of the grid load, and make apparent the distortion which results from trying to push the grid positive.

I accept Mr. Whiting's correction of my figure for the ratio of input to telephone and loud speaker. It was merely an illustrative figure and I probably put it very mildly.

Metallic Polar-Duplex Telegraph System
for Long Small-Gage Cables

Synopsis.—*In connection with carrying out the toll-cable program of the Bell System, a metallic-circuit polar-duplex telegraph system was developed. The metallic-return type of circuit lends itself readily to the cable conditions, its freedom from interference allowing the use of low potentials and currents so that the telegraph may be superposed on telephone circuits. The new system represents an unusual refinement in d-c. telegraph circuits, the operating current being of the same order of magnitude as that of the telephone circuits on which the telegraph is superposed.*

The following are some of the outstanding features of the present system. Sensitive relays with closely balanced windings are employed in the metallic circuit, and "vibrating circuits" are provided for minimizing distortion of signals. Repeaters are usually spaced about 100 miles apart. Thirty-four-volt line batteries are used and the line current is four or five milli-amperes on representative circuits. Superposition is accomplished by the compositing method which depends upon frequency discrimination, the telegraph occupying the frequency range below that of the telephone. New local-circuit arrangements have been designed, employing polar relays for repetition of the signals; these arrangements are suitable for use in making up circuits in combination with carrier-current and ground-return polar-duplex telegraph sections. New forms of mounting are employed in which a repeater is either built as a compact unit or is made up of several units which are mounted on I-beams, and subsequently interconnected. In the latter case the usual arrangements for sending and receiving from the repeater are omitted, and a separate "monitoring" unit provided for connection to any one of a group of repeaters.

The metallic system is suitable for providing circuits up to 1000 miles or more in length, the grade of service being better than that usually obtained from ground-return circuits on open-wire lines for such distances. About 55,000 miles of this type of telegraph circuit are in service at present.

* * * * *

Introduction

THERE has been developed recently by the Bell System a low-current metallic telegraph system, of the polar-duplex type, which is suitable for superposition on telephone circuits in long small-gage cables. In certain sections where long-distance toll traffic is heavy, it becomes desirable, from the standpoints of economy and continuity of service, to employ such cables to replace existing open-wire lines and to provide for future growth. The new telegraph system is being applied on a considerable scale in connection with the toll cable system, the general features and telephone arrangements of which have been described in previous papers.[3] The present paper outlines the general features of the metallic telegraph system and the method of superposing telegraph circuits of this type upon "two-wire" and "four-wire" telephone circuits in small-gage cables.

The metallic-return or two-wire type of telegraph circuit was chosen in preference to the ground-return type because it appeared to offer a more straightforward solution of the technical problem and to be more economical, sufficient cable conductors being available as a result of the telephone requirements. On a long telephone circuit in a small-gage cable it is necessary to employ a number of repeaters with comparatively large amplification and also to insert loading coils in the line at short intervals. As a result, the interference from superposed telegraph would be excessive unless the telegraph voltages and currents were kept far below the values ordinarily employed for ground-return telegraph. To allow the use of small currents and potentials with ground-return telegraph would require the development of arrangements for neutralizing difference in earth potential and inductive interference from telegraph circuits in the same cable as well as from power circuits. It will be evident that a metallic telegraph circuit possesses certain transmission advantages over a ground-return telegraph circuit in the same way that a metallic telephone circuit possesses advantages over a ground-return telephone circuit.

This development resulted in a telegraph system which in some ways is unique in its refinement. The telegraph line currents are of the same order of magnitude as those of the telephone circuits which use the same wires. Although cable is fundamentally much less favorable to telegraph transmission than open wire, one mile of small-gage cable having as much effect as many miles of open wire, the present system affords satisfactory operation on each pair of the cable for distances up to 1000 miles (1600 km.) or more.

Two improved forms of mounting are employed; in one of these a repeater is built as a single self-contained unit and in the other a repeater consists of several units mounted on upright I-beams. The relays are quiet in operation and sounders are normally made inoperative mechanically as they are seldom used. Altogether, a metallic repeater office bears little resemblance to the older type of office with apparatus mounted on tables and hundreds of sounders in operation.

Principles of Operation

In describing the general principles upon which the present telegraph system operates, it will be convenient to evolve it from the familiar ground-return polar-duplex system, the essential features of which are illustrated in Fig. 1. It will be seen that at each end of the line circuit there are provided a transmitter and a receiving relay. The operation of the transmitter sends current into the line and the artificial line, one polarity being used for "marking" and the other for "spacing." If the artificial line has the same impedance as the real line, there will be no effect upon the receiving relay, since the latter is connected differentially. Currents received from the transmitter at the distant station will, however, cause the receiving relay to operate. The arrangement, therefore, makes it possible to send telegraph signals in either direction, or in both directions simultaneously.

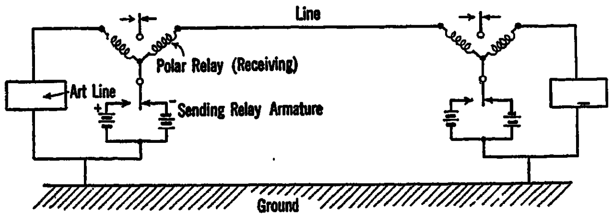

Fig. 1—Differential Duplex on Grounded Circuit

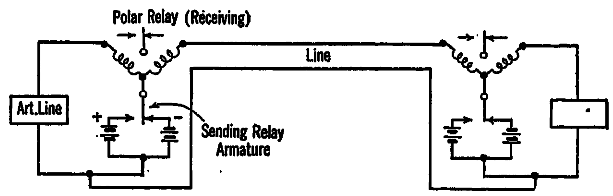

Fig. 2—Differential Duplex on Metallic Circuit

In Fig. 2 the ground-return is replaced by a second line wire so that the circuit is now a metallic circuit.

Fig. 3 differs from Fig. 2 only in that each receiving relay has its windings divided into four parts instead of two, making the circuit symmetrical.

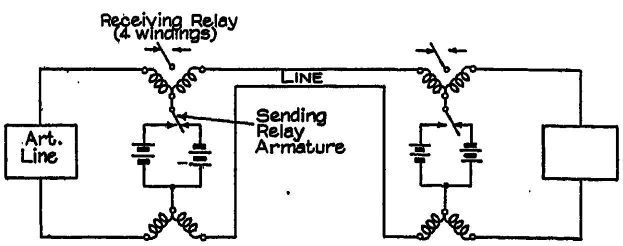

Fig. 3—Symmetrical Differential Duplex on Metallic Circuit

For actual operation involving the working of a number of circuits in a given office from the same set of batteries, it is desirable to make a connection to ground at each station at the point *G* as shown in Fig. 4. These connections stabilize the system and facilitate the clearing of accidental grounds. Although this results in unbalancing the currents in the circuit, there is substantially no effective change in the metallic or two-wire operating currents if the line and apparatus are well balanced, and this arrangement has the essential characteristics of an actual metallic telegraph circuit. It may be helpful, however, to consider that the upper wire is employed for the transmission of signals and the lower wire is used to carry only neutralizing current to offset the effect of currents in the upper wire which are due to earth-potential differences and voltages to ground caused by induction from power or telegraph circuits. Since each pair in the cable is closely balanced, encloses a small loop, and is frequently transposed by twisting, it will be apparent that the currents due to interference are practically equal in the two wires, flowing in the same geographical direction and therefore do not affect the balanced relays.

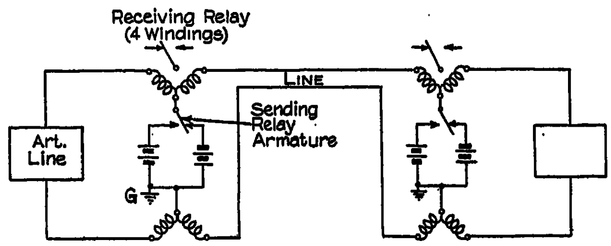

Fig. 4—Metallic Duplex Circuit—Single Commutation

Fig. 5 shows another arrangement of a metallic telegraph circuit in which the transmitter comprises two tongues, reversing the connections to a single battery instead of switching between two different batteries as in the case of Fig. 4. The ground connection at the midpoint of the battery at each station is for the purpose of stabilizing the system and facilitating the clearing of trouble.

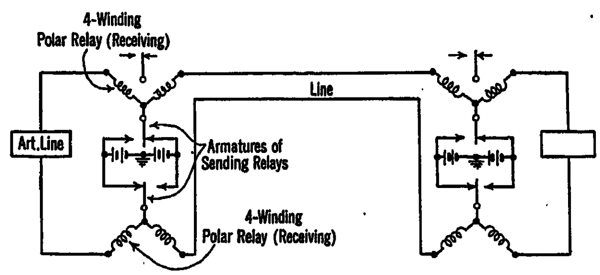

Fig. 5—Metallic Duplex Circuit—Double Commutation

Circuits of the type shown in Fig. 5 were first developed and put into extensive use in preference to the type shown in Fig. 4, largely for the reason that it was not at first practicable to obtain sufficiently close balance of relay windings. With improved relays, telegraph repeaters have been designed to operate on the basis of Fig. 4, effecting certain economies. These two arrangements, which are known respectively, as "double commutation" and "single commutation," may be

operated one against the other in a telegraph repeater section.

The local circuits of the repeaters are arranged so that they may be conveniently set up either for simultaneous operation in both directions (known as full-duplex) or for operation in only one direction at a time (called half-duplex), the latter giving the same communication facilities as a simple open-and-close Morse telegraph circuit.

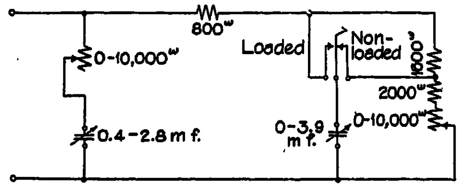

Fig. 6—Duplex Artificial Line

General Features

As in the case of other telegraph systems it is necessary to subdivide a long circuit into sections by means of repeaters to avoid the use of excessive potentials and to limit the distortion of signals. For repetition between two metallic cable circuits a simple arrangement called a "through repeater" is employed. The equipment used at the end of a metallic telegraph circuit is known as a "terminal repeater."

The metallic polar-duplex system operates with a potential of 34 volts, requiring one 34-volt battery for double-commutation and two such batteries for single-commutation. Where both are used in the same office, one of the single-commutation batteries may be used for double-commutation, this being equivalent to the

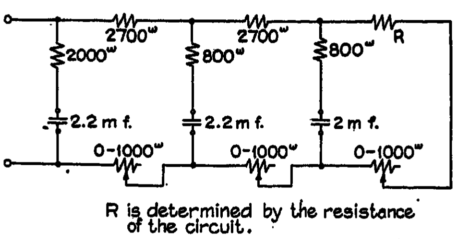

Fig. 7—Artificial Line for 19-Gauge Circuit Loaded with 0.174 h. Coils at 6000-Foot Intervals

regular arrangement with a ground potential of 17 volts in addition. The batteries are ordinarily "floated." Tungar rectifiers are generally used, without causing any noise in the telephone circuits.

The telegraph current in the cable circuit, with the batteries at the two ends aiding, is from about 3 to 15 milliamperes depending on the resistance of the line circuits. With the batteries opposing, the current is, of course, practically zero.

The small-gage cables are made up of No. 16 and No. 19 B. & S. gage (1.29 and 0.91 mm. respectively) copper conductors, and the metallic telegraph system may be operated over conductors of either gage, or over the derived phantom circuits when the latter are not in use for telephone service. The maximum distance between two consecutive repeaters is about 120 miles (195 km.) on 19-gage, composited pairs, or 160 miles (260 km.) on 16-gage. For non-composited circuits the corresponding distances are about 140 miles (225 km.) and 190 miles (305 km.) respectively. The

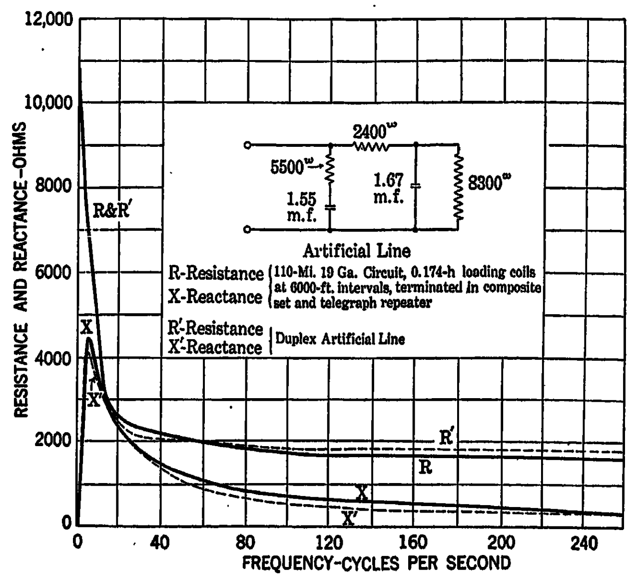

Fig. 8—Impedance of Line and Artificial Line

average telegraph repeater section is about 100 miles (160 km.) in length as a result of the telephone requirements in connection with locating repeater stations. In some cases the telegraph is operated over non-

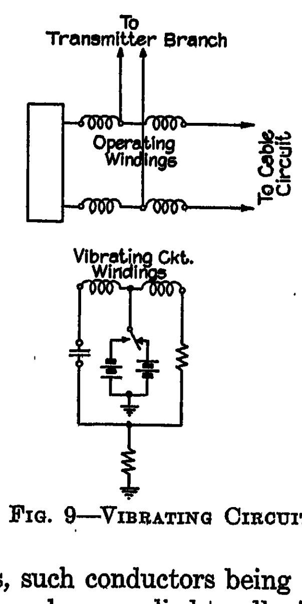

Fig. 9—Vibrating Circuit

loaded circuits, such conductors being available before loading coils have been applied to all wires of the cable. The telegraph transmission is practically the same on non-loaded and loaded circuits.

For maintaining an impedance balance, which, as brought out previously, is essential for polar-duplex operation, two different types of artificial line are used:

a flexible line with adjustable resistances and capacities adapted to balance any type of small-gage cable circuit, and a less flexible line having resistances as its only variable members and designed to balance accurately only 19-gage circuits with a certain type of loading. The first type of artificial line is shown schematically in Fig. 6 and the second in Fig. 7. The former balances with sufficient accuracy for full-duplex operation any circuit which does not contain intermediate compositing equipment. It also balances, well enough for half-duplex operation, circuits containing intermediate compositing equipment. The second type of line can be used for full-duplex service with only the type of circuit for which it was designed and for half-duplex with a limited variety of circuits. It is not so flexible therefore, as the other type. However, it is considerably cheaper and is somewhat easier to adjust, since to obtain a balance it is necessary only to secure a correct d-c. or resistance balance with the three adjustable resistances approximately equal. This line is built in H sections so the structure is similar to that of the real line; the effect of the loading coils on the impedance is simulated however, by the resistances in the three bridged members. Since in cable circuits leakage is negligible and the only effect of temperature changes is variation in resistance, the only adjustable members required in the latter type of artificial line are the three series resistances.

Curves of resistance and reactance versus frequency are shown in Fig. 8, for a representative metallic line section and the corresponding artificial line. It will be noted that there are large variations in these impedance components in the frequency range from zero to about 30 cycles per second, and they tend to become constant as the frequency is further increased. At the lower frequencies the effect of the distant terminal apparatus is, of course, large. Curves for non-loaded lines are similar except that at the higher frequencies the resistance is lower and the reactance higher.

A feature which has an important effect on the quality of the received telegraph signals is the "vibrating circuit" which was devised originally by Gulstad. This circuit comprises two auxiliary windings on the receiving relay, a condenser and two resistances as illustrated in Fig. 9. A current through the resistance branch of the vibrating circuit moves the relay armature to the opposite contact when the effective operating current, in reversing, approaches zero value. While the armature is passing between contacts, the condenser in the other branch partially discharges through both windings in series, the discharge current accelerating the armature. As soon as the armature touches the other contact, a transient current completing the discharge of the condenser and charging it in the opposite direction holds the armature firmly against this contact until the operating current has had time to become large enough to assume control. The vibrating circuit therefore increases the sensitivity, reduces the time of armature travel, lessens chatter of the armature contacts and makes the operation of the relay more positive. Furthermore, the constants of the vibrating circuit are so proportioned as to minimize distortion of signals, the relay being caused to operate near the steepest part of the received current wave.

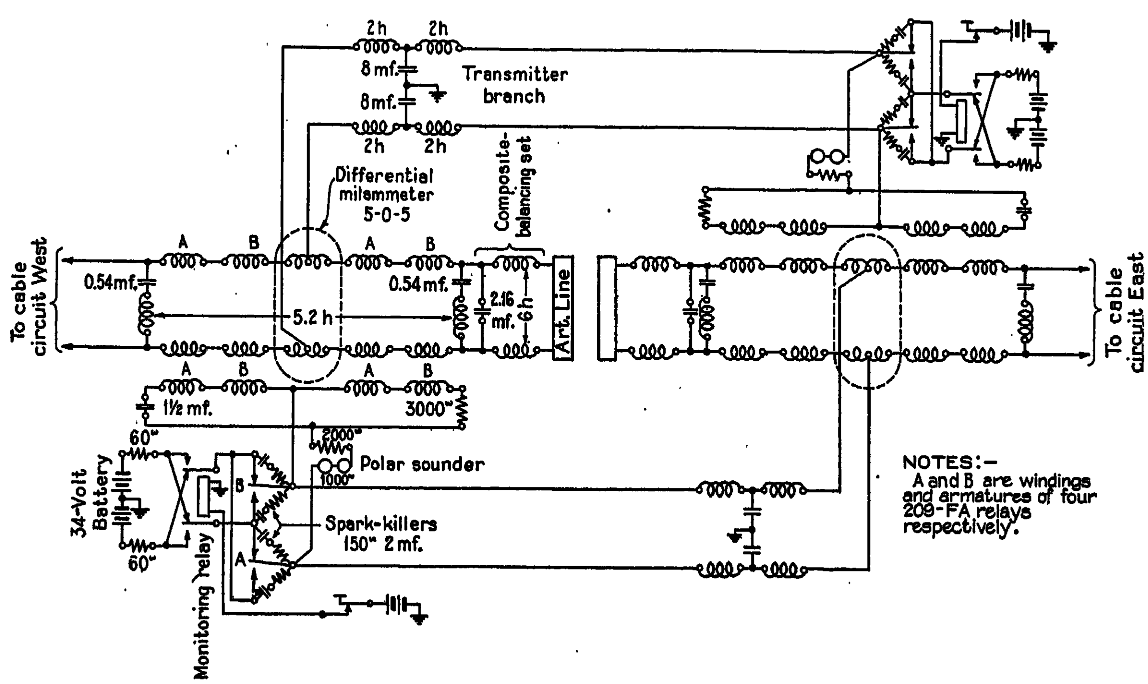

FIG. 10—THROUGH REPEATER

The receiving and transmitting relays used in metallic telegraph repeaters are the 209-F A and 215-A relays, respectively, which are being described in a separate paper. The former is a highly sensitive polarized

relay, furnished with vibrating windings, whereas the latter is of the same general construction but less sensitive and has no vibrating windings. The 215-*A* relay is also used in the arrangements provided for facilitating "breaking." In cases where a terminal repeater is operated between a ground-return circuit and a metallic circuit, relays of this type function as receiving relays for the ground-return section.

local circuit. Polarized sounders and other monitoring features similar to those in the through-type set are provided. The local circuit arrangements are described in detail in the next section.

Local Circuits

To avoid supplying battery at outlying points and to facilitate setting up and changing circuits which have a number of stations in the same locality or have

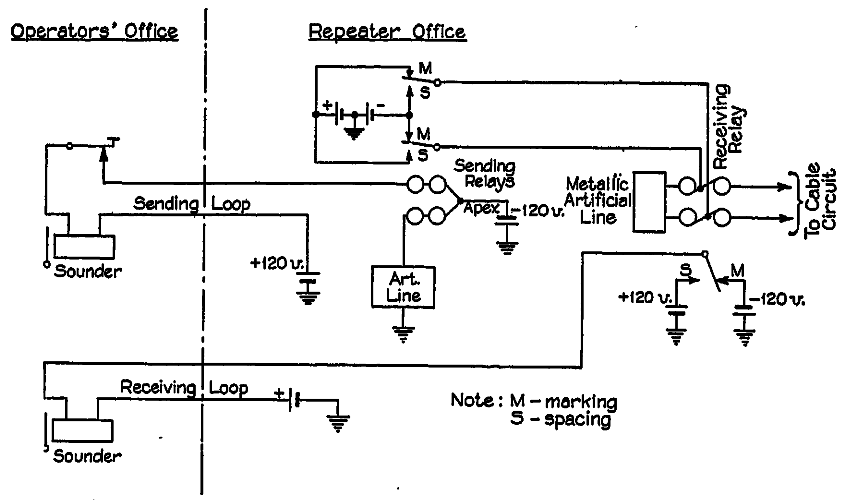

Fig. 11—Terminal Repeater—Full-Duplex Local Circuits

The through-type repeater is a direct-point repeater; the armatures of sensitive polar relays, operated by the line current from one direction, repeat the signal (differentially through the windings of the opposite receiving relays) into the other line in the opposite direction. A simplified diagram of this repeater is shown in Fig.10. This repeater is a full-duplex repeater but is used on half-duplex circuits without change. As shown,

branches, a two-wire circuit or "loop" is extended from the repeater office to each operator's station. For the marking or closed condition the current is approximately 60 milliamperes and for spacing it is zero.

For full-duplex service the arrangement is simple, involving the use of a receiving loop and a sending loop as shown in Fig. 11. In the receiving loop the batteries are aiding when the line relay tongue is on mark-

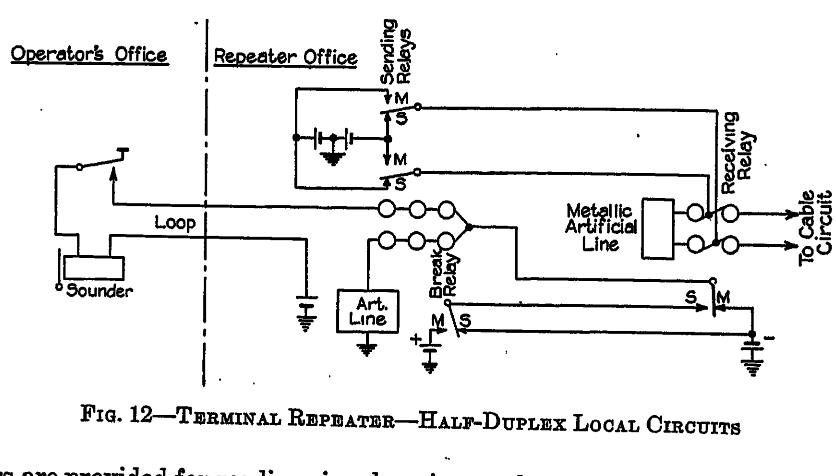

Fig. 12—Terminal Repeater—Half-Duplex Local Circuits

two polarized sounders are provided for reading signals, and a telegraph key controls the operation of local neutral relays, designated monitoring relays, making it possible to send into either line independently, or in both directions at once.

The terminal-type repeater is also a direct-point repeater and is used to repeat signals between a metallic cable section and either a ground-return circuit or a

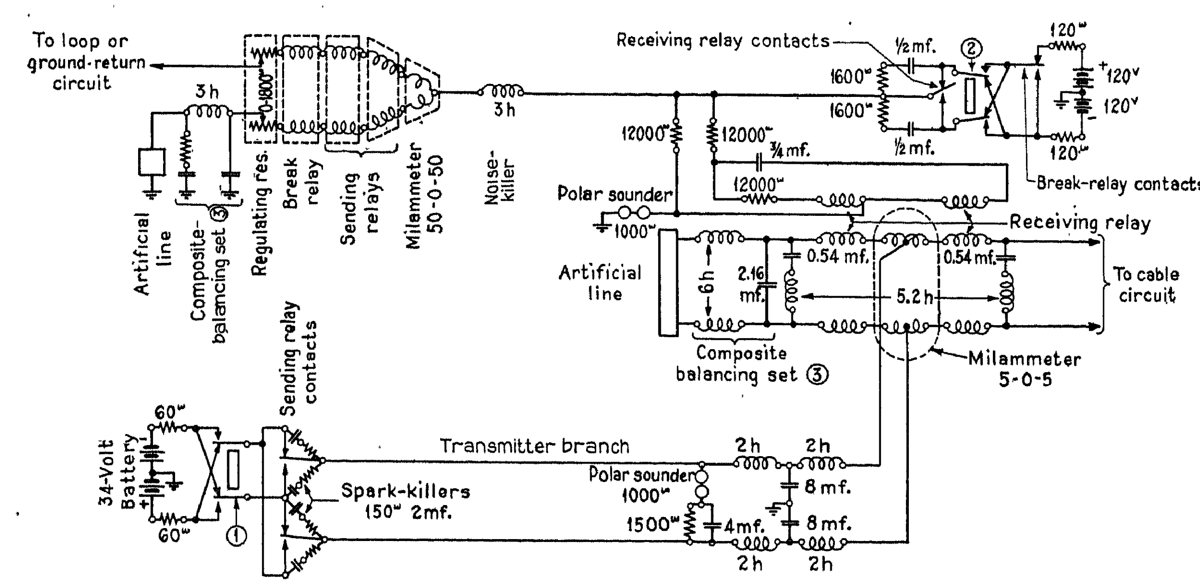
ing, and opposing when it is on spacing. Signals may, therefore, be received by the operator by means of an ordinary Morse (neutral) relay or main-line sounder. The sending loop is opened and closed by the operator's key in sending out signals. The sending relays are of the polar type and may be considered to have a biasing circuit which includes the battery connected to the apex point, the lower windings and the artificial

line. When the key is closed the effect of the biasing current is overpowered by the loop current, as the latter is twice as great. When the key is opened the biasing current moves the relay armatures from marking to spacing.

For half-duplex service, a single loop is used for both sending and receiving as depicted in Fig. 12. Signals are sent out in precisely the same manner as in full-duplex and do not affect the metallic line relay on account of the balanced duplex connection. The sending relays, although connected in the loop, are unaffected by received signals as they are differential as regards current from the receiving relay tongue. This is in fact a duplex connection, and it allows the working of the grounded side of the terminal repeater directly into a long circuit having a standard ground-return peated back into the line, reversed. This would result in a slow and uncertain break.

In using two terminal repeaters to connect an operator's office at an intermediate point to a metallic circuit, the loop or loops are connected in tandem between the two repeaters. In full-duplex the sending leg of one repeater is connected to the receiving leg of the other, and vice versa, with a loop in series with each connection. In half-duplex the two local circuits are connected together with the loop in series, and at one repeater, batteries on the receiving relay contacts are reversed and the connections to the loop and biasing windings of the sending and break relays are interchanged.

Local circuit arrangements of the type just described make the metallic repeaters suitable for use in



NOTES:—

2. Monitoring relay for sending on ground-return circuit, controlled by a telegraph key.
3. Composite-balancing set removed by key for loop or non-composited operation.

FIG. 13—TERMINAL REPEATER

polar-duplex repeater at the distant station. A suitable artificial line is provided for this purpose.

To facilitate interruption of the sending operator by the receiving operator a "break relay" is also provided, operating simultaneously with the sending relays. To understand its function, assume the key in the loop to be opened; as soon as a marking signal is received from the line, the sending relay armatures will be moved to spacing due to the current in the biasing windings and the absence of current in the loop. The break relay at the same time connects marking battery to the spacing contact of the receiving relay so that no matter what signal impulses are subsequently received from the line the sending relays will be unaffected. If the break relay were not used, incoming signals would operate the sending relays and be re- combination with the carrier-current and ground-return polar-duplex repeaters used in the plant. This flexibility has been secured by designing the loop circuits to operate with 60 milliamperes current for marking and zero for spacing. Briefly, the flexibility necessary to permit of setting up long circuits with branches is in no wise sacrificed by the use of the several systems.

The essential features of the circuit of the terminal-repeater are shown schematically in Fig. 13.

For convenience in testing and in patching circuits the loop is connected to the telegraph repeater through a series of jacks at the "Morse board" called a "Morse line terminal." The latter consists of a number of jacks for inserting loops in series and testing the batteries and circuit in case of trouble.

Superposition on Telephone Circuits by Compositing

In superposing the metallic telegraph on telephone circuits, the well-known "compositing" method is used. This is based on frequency discrimination, the telegraph occupying the range below that of the telephone.

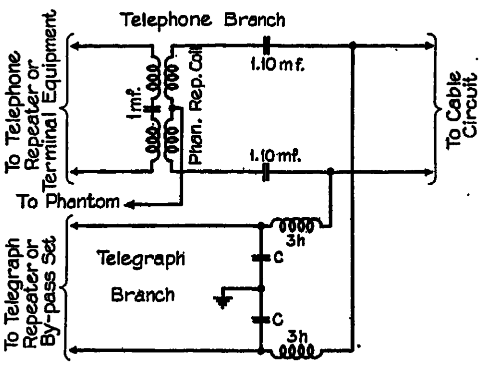

Fig. 14—Composite Set

For satisfactory results, the telegraph and the telephone arrangements, including signaling, as well as the composite sets, must be designed in conjunction with the line circuits so as to avoid serious interference between telegraph and telephone. Furthermore, the compositing means employed should have but little detrimental effect on the transmission of the three forms of communication operating separately, and must not upset the symmetrical circuit arrangement upon which freedom from external interference depends.

Interference from telegraph and telephone manifests itself in two ways. The first of these is telegraph "thump" which is the name given to a low-pitched noise in the telephone due to a small part of the telegraph current passing through the telephone branch of the composite set and entering the telephone apparatus. The thump, in addition to being audible, may effect the telephone signaling equipment to the extent of causing false rings. In addition to the thump at the transmitting end of the circuit, thump is produced at the receiving end by the vibrating circuit through transformer action of the relay windings. In providing protection from thump, both phantom and side circuits have to be considered. The second kind of interference is the flutter effect[4] due to the fact that rapid changes in the telegraph currents momentarily increase the effective resistance of the loading coils, thereby varying the attenuation of the circuit at telephone frequencies.

The telegraph branch of the composite set (see Fig. 14) consists of series inductance and shunt capacity and therefore offers to line currents of telephonic frequencies high impedance and attenuation. It has little effect upon the low frequencies required for satisfactory telegraph transmission, and at the same time sufficiently attenuates the higher frequency components of the telegraph waves to avoid excessive thump. In order that the telegraph branch may be effective in reducing thump voltages in the phantom circuit, the two windings of the retardation coil are made with a negligible mutual inductance, and the bridged capacity consists of two balanced condensers with the midpoint grounded. It has been found necessary to make this retardation coil of very stable inductance by using a comparatively large amount of iron, since a coil with less stable characteristics would cause excessive thump, due to the generation of harmonics.

The telephone branch consists of series condensers and a low-inductance repeating coil or transformer and has high impedance and attenuation for line currents of telegraph frequencies, but has little effect upon telephone transmission. It supplements the telegraph branch in reducing thump and also serves to limit mutual interference between telephone signaling and telegraph. The repeating coil is also used for deriving the phantom circuit in the usual manner.

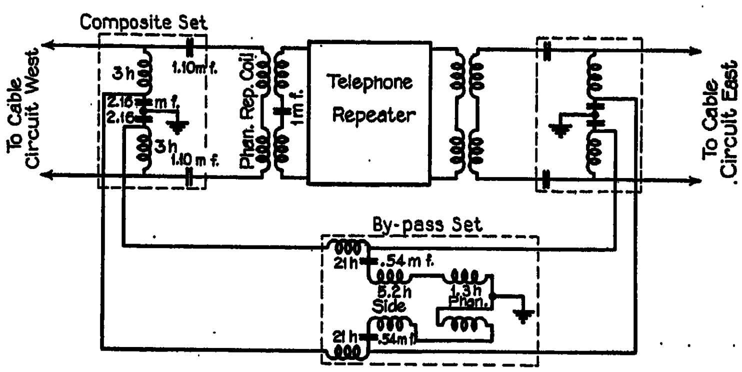

Fig. 15—Intermediate Compositing Arrangements

The composite set is sufficient to limit receiving-end thump to a harmless amount, but greater protection is necessary against sending-end thump. In order that the additional equipment for this purpose may have the minimum effect on telegraph transmission, it is placed in the transmitter branch where it affects outgoing signals only. It consists of series inductances and bridged capacities to suppress the high-frequency

4. Paper by Martin & Fondiller, Transactions A. I. E. E., February 1921, page 553.

components of the telegraph impulses as in the composite set; the mutual inductance of the coils is made small so that they may be effective in reducing thump in the phantom circuit. In single-commutation repeaters, another coil is necessary in the transmitter branch to prevent excessive phantom circuit thump. This coil is connected with its windings parallel-aiding as regards the phantom circuit and therefore is series-

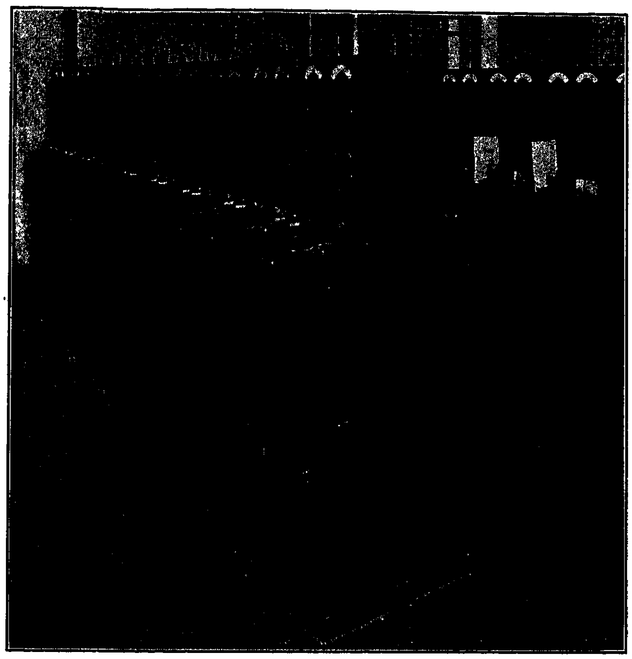

Fig. 16—Installation of Metallic Telegraph Repeaters—Terminal Type

opposed or non-inductive for the metallic telegraph operating currents. An examination of the circuits will show that in double-commutation, operation of the telegraph impresses voltage on the phantom circuit only if the two transmitting tongues fail to operate in exact synchronism; in single-commutation, voltage is impressed on the phantom circuit by the normal operation of the transmitter, since the telegraph current, being unbalanced, has a large longitudinal component.

To preserve the duplex balance when using a composited line, a composite balancing set, consisting of a series coil and a bridged condenser, is provided for insertion in the artificial line branch as shown in Figs. 10 and 13.

To protect the receiving relay from interference from the 135-cycle current used for telephone signaling, a resonant shunt is bridged across the telegraph set on the line side of the receiving relay and a balancing shunt is bridged across the set on the artificial-line side. A single coil is made to serve for both of these shunts, one winding being placed in the line side and the other in the artificial-line side.

Twenty-cycle ringing current, which is used for signaling in the local terminal equipment of the telephone circuit, and operation of the telephone receiver switch-hook, give rise to transient currents which tend to harm telegraph transmission. To minimize this effect, a condenser is connected between windings of the repeating coil.

Since metallic telegraph repeaters are spaced about 100 miles (160 km.) apart and telephone repeaters on many circuits about 50 miles (80 km.), means must be provided for passing the telegraph currents around the intermediate telephone repeaters. This is done by inserting an "intermediate" composite set on each side of the telephone repeater and connecting the telegraph branches together through a "by-pass" set. This arrangement is shown in Fig. 15. The intermediate composite set is very similar to the terminal composite set. The by-pass set consists of a retardation coil of high inductance and little mutual inductance between windings, with or without a resonant shunt. The purpose of this by-pass set is to keep the amplification characteristic of the telephone repeater from being affected by currents feeding back through the telegraph branches of the composite sets from the output

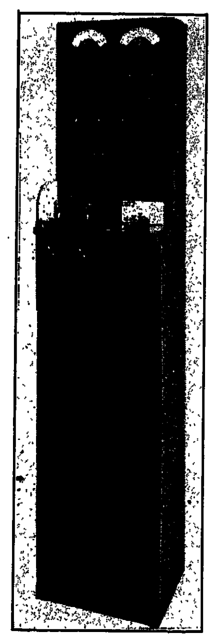

Fig. 17—Metallic Telegraph Repeater—Terminal Type

into the input of the telephone repeater. For four-wire telephone circuits, on which repeaters work with comparatively high amplification, it is necessary to bridge a shunt, resonant at about 135 cycles per second, at one end of the by-pass to prevent excessive feedback at 135 cycles per second and neighboring frequencies. It is grounded in the middle and two coils are provided, connected so that one will be effective for the side circuit and the other for the phantom circuit. For two-wire telephone circuits the resonant shunt is unnecessary.

Equipment Arrangements

The terminal-type repeater is assembled as a complete unit at the time of manufacture and therefore the installation work consists only in arranging the repeaters in rows and connecting the line conductors, loops and batteries to the terminal strips. A typical installation is shown in Fig. 16. A terminal and a through repeater are shown in Fig. 17 and Fig. 18, respectively.

The artificial-line equipment is mounted in the upper section of the repeater. Condenser switches, dial-type resistance switches, milammeters and miscellaneous keys are mounted on a hinged panel of insulating material. On the back of the panel, immediately behind the dial switches are the associated resistance units. The condensers which form part of the artificial line are stacked up in the space immediately behind the panel. The apparatus in the artificial line section is divided, so that the equipment which balances the cable pair is on the right side and that associated with the loop or ground-return section is on the left side.

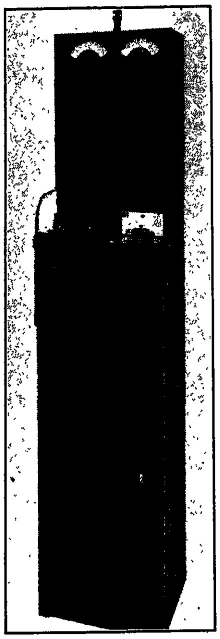

Fig. 18—Metallic Telegraph Repeater—Through Type

Below the hinged panel is the keyshelf, on which are mounted the loop and line sounders and the monitoring telegraph key. At the rear of the keyshelf and fastened perpendicularly to it is a panel on which are mounted the switching keys for controlling the battery connections and for arranging the repeater to work under various circuit conditions. Underneath the keyshelf is a section for the condensers in the transmitter branch, the spark-killers and the vibrating circuit.

In the lower section of the repeater is a small mounting plate carrying the relays and the resistance units associated with the spark-killers and vibrating circuit. The lower end of this mounting plate is hinged so that it may be swung forward, thereby giving access to connections of apparatus mounted on it. Below this is a terminal strip for the lines, batteries and the sending and receiving legs. Below the terminal strip and just above the floor are the retardation coils used in the transmitter branch.

A terminal repeater stands 62 in. (1.57 m.) high and occupies a space 14 in. (36 cm.) wide and 12 in. (30 cm.) deep and weighs about 220 lbs. (100 kg.). The keyshelf is about 40 in. (1 m.) above the floor. On the top of the repeater is mounted the operator's "calling-in" lamp.

The floor-mounted type of through repeater has the same equipment assembly for both the east and west sides and these are practically the same as the portion of the terminal repeater which operates on the cable section. The equipment in the right-hand section of the through panel is for repeating signals from the east line to the west line, and the left vice versa. This repeater weighs about 230 pounds (105 kg.) and occupies the same space as a terminal repeater.

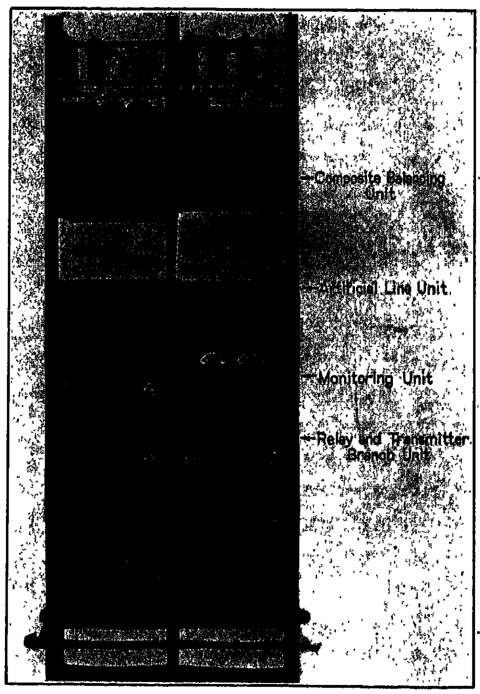

Fig. 19—Rack-Mounted Metallic Telegraph Repeaters—Through Type

The rack-mounted through repeater was developed after experience with the floor-type had shown how little monitoring attention was required. For that reason the repeater was simplified by the elimination of the line meters and monitoring apparatus. A unit termed a "monitoring unit" is provided for a group of about seven repeaters, and it can be connected into any one repeater by means of cords and plugs. A rack-type repeater consists of three units, the relay and transmitter-branch unit, the balancing-composite unit,

and the artificial-line unit. Each of these units consists of a steel panel with necessary apparatus, arranged for mounting on two upright standard I-beams, thus forming a "bay." Generally there are four repeaters, or three repeaters and a monitoring panel per bay. Fig. 19 shows an arrangement of repeaters on racks having a height of about 90 in. (2.3 m.). This type of repeater is supplied for single-commutation operation only, whereas both forms of "floor-mounted" repeaters are supplied for double-commutation operation. Considerable economy in first cost and maintenance is secured by the use of this rack-mounted equipment.

Operation and Maintenance

The metallic telegraph repeaters require comparatively little attention on the part of repeater attendants. Under normal operating conditions one man takes charge of about 24 terminal repeaters or 40 through repeaters. The duties of the repeater attendants consist mostly in maintaining satisfactory impedance balance of the artificial lines against the real lines. This balance is, of course, more exacting for full-duplex operation than for half-duplex. The capacity balance varies only a slight amount. Variations in resistance balance are caused by temperature changes, the average daily variation being about 6 per cent. The differential milammeter is used as an indicator in determining the resistance and capacity values required to obtain a balance.

The equipment maintenance work required for these repeaters is exceedingly small. For a typical installation of 200 repeaters, the adjustment of relays and general maintenance will necessitate not more than four or five man-hours per day.

The maintenance schedule for adjusting the relays is somewhat variable, depending upon the type of circuit in which they are operating. In general, a 209-*FA* relay in a terminal repeater will give uninterrupted service for two to three months and in a through repeater for four to six months. The 215-*A* relays are adjusted about every three weeks when used as "break" relays and every six months operating as pole-changing relays.

With proper maintenance the transmission of the metallic telegraph system is such as to furnish high-grade half-duplex manual service for distances up to 2000 miles (3200 km.) or more. For the longer distances, the signal propagation time is increased to an amount which makes the time required to "break" appreciable, but not objectionable. For half-duplex printer operation the metallic circuits are satisfactory for speeds up to about 19 dots per second, which corresponds to about 300 characters per minute for the start-stop type of printer.

For full-duplex service, the metallic system affords very good transmission with manual operation for distances up to 1000 miles or more. With careful maintenance of duplex balances, such a circuit is satisfactory for full-duplex printer operation at speeds up to about 16 dots per second, corresponding to about 260 characters per minute for start-stop printers and 385 for multiplex printers.

It is of interest to note that metallic circuits in cable are much more dependable and less subject to interruption than open-wire circuits. Such data as are available indicate that the annual lost time on a long metallic cable circuit is only about one-tenth as great as that on a ground-return polar-duplex circuit of the same length over open wire.

Commercial Use

At the present time there are in operation in the Bell System about 55,000 miles (89,000 km.) of metallic telegraph circuits of this type of which 30,000 miles (48,000 km.) are worked on a composited basis. Approximately 20 per cent of the total mileage is operated full-duplex. There are now installed in the plant about 430 through repeaters and 1050 terminal repeaters.

Discussion

R. N. Nicely: In connection with the extensive toll cable program of the Bell System, it has of course, been highly desirable that satisfactory methods be made available for utilizing the cable facilities for telegraph as well as for telephone service. This has been accomplished by the development of the metallic polar-duplex telegraph system and the voice-frequency carrier telegraph system. Each of these systems is adaptable to operation under widely varying cable circuit layout arrangements and each has certain characteristics which make it particularly suitable for use in connection with different specific requirements. In actual practise, each of the systems is a valuable supplement to the other.

The metallic polar-duplex system, in addition to being extensively used on long trunk-cable routes, is well adapted to telegraph-circuit distribution from large centers to outlying towns or cities reached by cable as well as to telegraph stations at the center itself or at outlying points reached by aerial wire circuits.

The metallic system is of value also during the construction of long toll cables which, as in the case of the New York-Chicago cable, may be extended over a period of several years. As the cable is extended it is of course, desirable that heavily-loaded aerial wire lines on or near the cable route be lightened by transferring at least a part of the circuits to completed sections of the cable. The metallic telegraph repeater being adapted for operation on metallic cable circuits in one direction and on aerial wire or grounded cable circuits in the other, is particularly well suited for use at points where the two types of circuits are joined. Furthermore, the metallic repeater being a practically self-contained unit, may be readily moved from point to point if desired, as the cable construction advances.

With the metallic telegraph system, intermediate repeaters are in general, required at more frequent intervals than is the case on aerial wire telegraph circuits but, owing to the greater stability of the cable circuits, this apparent disadvantage is offset by the very small amount of equipment adjustment required by the metallic apparatus during operation.

J. H. Bell: To an old-time telegraph man used to the noises in a large telegraph office, a visit to one of the small-gage cable telegraph repeater stations where practically all the repeaters are of the type described in this paper would be somewhat of a sur-

prise. The quietness of the room is broken only by the click of a sounder during periodic tests by the repeater attendants listening for a moment or two to passing signals. I believe at first it was thought the repeater attendants who had been accustomed for so long to the clatter of sounders would take unkindly to working in a nice quiet office, but in that regard the psychology was wrong. I am safe in saying, I think, that the repeater men much prefer the new conditions.

There is one apparatus unit in the sets to which I would like to refer, namely, the dial-type switch for enabling the value of capacity in the artificial line to be varied. To one accustomed to juggle with five plugs or levers to secure some one of the thirty-one possible values of capacity, the convenience of stepping round a dial, adding, say, 0.1 micro-farad at each step and getting values of between 0.1 and 3.9 microfarads, is immediately noticeable and appreciated. One can strike a duplex balance in a fraction of the time taken with the older apparatus.

In regard to the operation of the system, it should perhaps be pointed out that the speeds of operation given in the paper do not necessarily represent the maximum speeds obtainable. In designing the system the aim was to provide for high-grade service at fast hand speed; that is, about 15 dots per second. The vibrating circuits are consequently permanently set for operation at about that speed so that at higher speeds the vibrating feature would probably be detrimental rather than beneficial.

The most important unit of a telegraph system is the relay. One might say it is the heart of the system, so that it is difficult to discuss a new system without making some reference to its heart. The sensitive polarized relay described in the paper by Messrs. Fry and Gardner was designed primarily for the metallic system, although it has been found particularly applicable to the voice-frequency carrier system and the high-frequency carrier system which was described in a paper presented at an Institute meeting some years ago. With the improvements which have recently been incorporated in it, namely, the accurately balanced windings, permalloy magnetic material, the new contact material, the anti-chatter armature, I think we have in it now a high-grade polar relay which is likely to be our standard for several years to come.

In the discussion of a telegraph paper before the British Institute of Electrical Engineers recently, one of the speakers very cleverly compared the art of communication with the art of transportation. He said the telephone was like the passenger service, a very personal affair demanding quick service, whereas the telegraph was like the express service, where one hands over a message to be transmitted or transported and the operating company does the rest. Of course, this simile does not apply very aptly to the telegraph service of the Bell System. The Bell telegraph service furnishes to each customer or patron a single-track or double-track private express railroad for his exclusive use, and by the ingenious compositing scheme the same lines are made use of for a public passenger service, without any fear of collisions.

Perhaps I may be permitted to borrow the simile and to enlarge upon it by saying that in the metallic cable system and the voice-frequency system we have provided for these private express railroad services a much improved rolling stock.

Synopsis.—*Carrier telegraph systems using frequencies above the voice range have been in use for a number of years on open-wire lines. These systems, however, are not suitable for long toll cable operation because cable circuits greatly attenuate currents of high frequencies. The system described in this paper uses frequencies in the voice range and is specially adapted for operation on long four-wire cable circuits, ten or more telegraph circuits being obtainable from one four-wire circuit. The same carrier frequencies are used in both directions and are spaced 170 cycles apart. The carrier currents are supplied at each terminal station by means of a single multi-frequency generator.*

* * * * *

A TELEGRAPH system has recently been developed which utilizes the range of frequencies ordinarily confined to telephonic communication. It represents a special application of the carrier method of multiplexing telephone and telegraph circuits, which has already been described.[3]

The new system has been designed particularly for application to four-wire telephone circuits. Installations have been made at New York and Pittsburgh, by means of which ten telegraph circuits are derived from one four-wire telephone circuit extending between these cities. Additional installations are planned and under way in which it is expected that a greater number of telegraph circuits will be obtained from each four-wire telephone circuit.

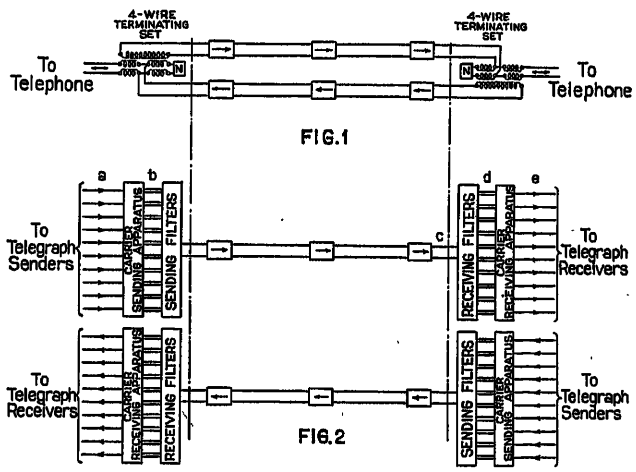
Experience in commercial service extending over a considerable period has fully demonstrated the effectiveness of this system.

General Features

In a general way, the voice-frequency system resembles the high-frequency carrier system for open-wire lines, which has been described in the paper referred to above. The most important differences are that the voice-frequency system uses (1) a four-wire cable circuit instead of a two-wire open-wire circuit, (2) the same frequencies for transmission in both directions, (3) frequencies of the voice range rather than the higher frequencies used in open-wire carrier telegraph systems, (4) a multi-frequency generator instead of vacuum tube oscillators to supply the carrier currents and (5) fixed band pass filters instead of adjustable tuned circuits for segregating the several telegraph circuits.

Fig. 2 shows in a simplified manner the essentials of the telegraph system under discussion. Reference to Fig. 1, which shows a four-wire telephone circuit,[4] will make clear how the line portion of the telegraph system is derived from such a telephone circuit. As indicated in Fig. 1, the four-wire cable circuit uses two pairs of wires, one pair for transmission in each direction. When a voice-frequency telegraph system is applied to a telephone circuit the four-wire terminating sets, which normally terminate the circuit when used for telephone purposes, are removed and voice-frequency carrier telegraph equipment is substituted.

Signal Traced Through System. A general layout of the system is shown in Fig. 3 and, in describing the operation, reference is made to this figure. The path of a signal from the sending operator to the receiving



Figs. 1 and 2

operator, on one of the ten two-way circuits will be considered. To produce a spacing signal the sender opens his key (shown at the left of the figure) which causes the sending relay to operate so as to short-circuit the source of alternating current. To produce a marking signal the key is closed, which causes the sending relay to operate and to remove the short circuit. This permits the alternating current from the generator to flow freely into the filter. This sending filter is so constructed as to permit relatively free passage of current of frequency near the particular carrier frequency for which it is designed. For other frequencies the filter practically shuts off the current.

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., February 9-12, 1925.

After passing through the filter, the current mingles with currents from other channels and all are transmitted over the line as a resultant composite current. After flowing through the line in this mixed-up condition, the currents encounter the receiving filters which resemble the sending filters in that each transmits a relatively narrow range of frequencies in the neighborhood of the carrier frequency for which it is designed, and in that it acts substantially as an open circuit to other frequencies. By means of these receiving filters the currents are separated and each flows freely into its own channel. After passing through the receiving filter the current enters the detector whose function is to convert the alternating-current signals into direct-current signals which are capable of actuating the receiving relay. The receiving relay in turn transmits direct-current signals to the receiving operator's sounder or local relay.

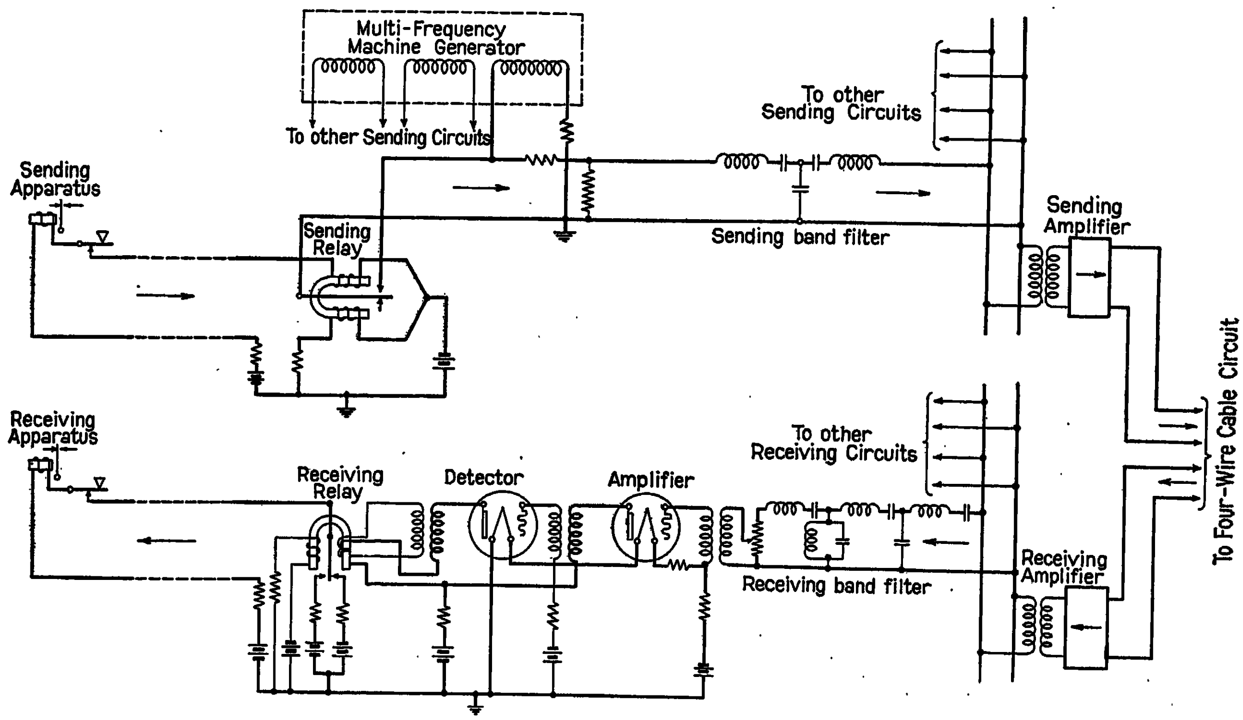

Fig. 3

This sequence of events is illustrated in the series of oscillograms of Fig. 4, which shows the different forms of a group of telegraph signals in the 425-cycle channel from the time, when as d-c. impulses, they flow through the sending relay windings, to the time when again, as d-c. impulses, they flow through the receiving relay and sounder circuit. It shows (a) their form in the sending relay and telegraph key circuit, (b) their translation into alternating current prior to passing into the sending filter, (c) their mingling with other similar impulses of different carrier frequencies after passing through the sending filter and on to the line as a single resulting wave flowing through the four-wire circuit, (d) their form after separation from the other channels by the receiving filter and (e) their final form in the receiving sounder circuit. The points where the oscillograms were taken are shown in Fig. 2 at *a*, *b*, *c*, *d*, and *e*, the cases being correspondingly denoted on the oscillograms.

Carrier Frequencies. The carrier frequencies are so chosen as to be odd multiples of a basic frequency of 85 cycles per second. The lowest frequency used is the fifth multiple of 85 cycles, that is, 425 cycles per second. Starting with this frequency, the carriers are spaced at 170-cycle intervals from their nearest neighbors, so that in the ten-channel system the uppermost frequency is 1955 cycles per second. Each channel has assigned to it a range of frequencies 85 cycles above and below its own frequency. For example, the chan-

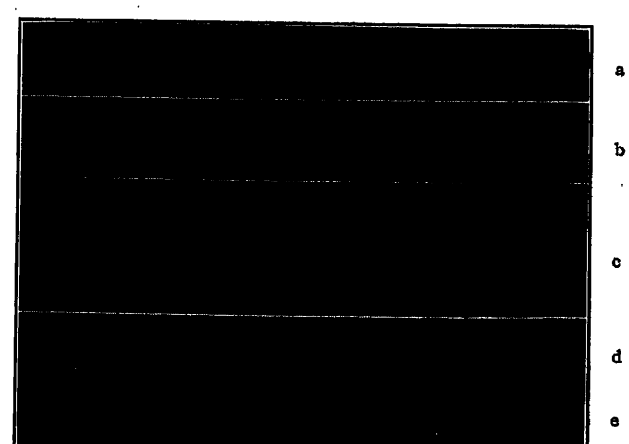

Fig. 4

nel using a carrier frequency of 1105 cycles has assigned to it the range between 1020 to 1190 cycles. Choosing the carrier frequencies in this manner and placing each carrier midway in the band of frequencies assigned to it, has the effect of giving maximum discrimination against interfering frequencies generated in the various vacuum tube repeaters. As is well known, when a number of frequencies are transmitted simultaneously through a vacuum tube, currents which cause interference are generated due to small departures from linearity on the part of the tube characteristic. Some of the most important of these currents have frequencies equal to the sum and difference of the frequencies of the transmitted currents taken in pairs. Since the carrier frequencies are all odd multiples of the common frequency, 85 cycles, it follows that the sum and difference of the frequencies are even multiples of 85 cycles and therefore are located midway between the carrier frequencies. This permits obtaining the maximum discrimination against these interfering frequencies by means of the filters, of which the characteristics are set forth below.

The number of carrier telegraph circuits which can be derived from a single four-wire cable circuit depends on the type of loading and, to a less extent, on the length of the circuit. It has been mentioned above that at the present time ten two-way carrier telegraph circuits are operated simultaneously over a four-wire circuit between New York and Pittsburgh, a distance of about 400 miles (644 km.). This is not, however, the maximum possible number of telegraph circuits which can be derived from the type of circuit used with this installation. Four-wire circuits which are loaded with coils of small inductance transmit a wider range of frequencies and are already in use for telephone purposes. If such circuits were used instead of the type employed with the present installation, at least fifteen two-way carrier telegraph circuits could be obtained.

Description of Apparatus

Carrier Current Generator. Vacuum-tube oscillators are the source of the carrier current in carrier systems previously developed. In this system, however, all the carrier currents for the ten channels are obtained from a compact multi-frequency generator driven by a motor built into the same housing with the generator.

The generator is an inductor-alternator designed to generate currents of ten different frequencies in ten different magnetic circuits electrically independent of each other. The machine has two field coils common to all the stators. The exciting current for these two windings is supplied by a storage battery. On the pole arc of each stator opposite each of the narrow disk-like rotors, mounted in a row on the shaft, are cut a number of slots, the number per unit length depending on the frequency to be generated. The stator windings for each circuit are placed in these slots. The rotor belonging with each stator has a corresponding group of slots cut in it but no windings are placed in these rotor slots. The result is equivalent to ten separate alternators except that the field excitation is common to all. The flux in any stator tooth is greatest when a rotor tooth is opposite it and least when a rotor slot is opposite it. This variation in flux in the stator teeth as the rotor moves induces the voltage in the windings on these teeth. All the windings of a given stator are connected in series, so the total voltage generated in each stator is the sum of the separate voltages in the several windings.

A comparatively small generator is able to supply carrier currents to several ten-channel systems because, by using terminal repeaters or amplifiers (Fig. 3) the amount of energy required to operate each telegraph channel is very small, and no channel produces any noticeable interference in another drawing current from the same stator winding. The terminal voltage

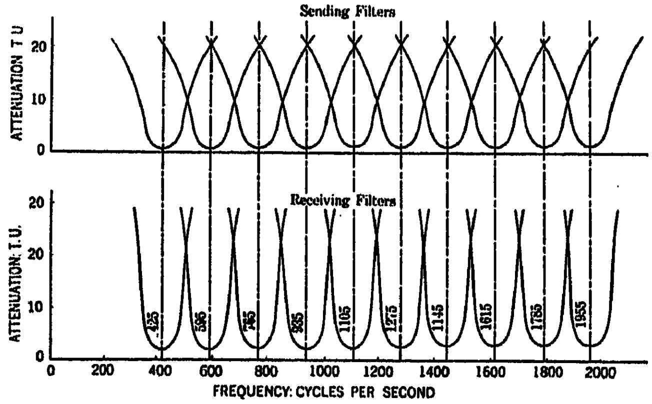

Fig. 5—Characteristics of Filters

of each stator is 0.7 volt and a current of 40 mils may be drawn from it without producing change a in terminal voltage sufficient to cause interference in any telegraph circuit drawing current from the same set of windings.

The driving motor is a small shunt-wound machine which receives its energy from a 24-volt storage battery. The speed of the motor is maintained accurately at 1700 rev. per min. by means of a centrifugal type of governor which controls the amount of current flowing through the shunt field winding. As the stability of the carrier frequencies depends on the constancy of the motor speed, it is necessary that the governor control the speed within narrow limits.

As a means of checking the speed of the generator an electrical frequency indicator is provided. This device is connected to and indicates the frequency of one of the generator circuits. As the frequency of an alternator is directly proportional to the speed it gives an indication of the correctness of the speed and also of all frequencies produced by the generator.

Filters. Fig. 5 shows the transmission characteristics of the transmitting and receiving filters. These filters are designed to transmit as wide a range in the neighborhood of the carrier frequencies as is necessary

to secure the desired quality of transmission and at the same time exclude interfering currents, whether they be caused by foreign interference, direct transmission from other channels, or distortion in the repeater tubes. The principal interfering currents due to the latter are located 85 cycles on either side of the carrier frequencies. The receiving filters have been designed to reduce these interfering currents to about 10 per cent of their original value.

In addition to screening out any undesired frequencies produced in the generator windings, the sending filters have the following more important functions. Each sending filter presents a high and comparatively non-dissipative impedance to the currents issuing from the other sending filters and also "rounds off" the impulses of the modulated carrier wave passing through it. The modulation of the carrier current by the sender's key produces what is called a "square" wave, that is, a wave containing not only the carrier plus and minus the frequency at which the key is operated but also the carrier plus and minus a large number of multiples of the frequency. Some of the component frequencies of this transmitted wave not only are found unnecessary in reproducing the transmitted signal at the receiving end but also lie within the range of adjacent channels and produce interference in them unless screened out by the sending filter in the channel in question.

The effect of the sending and receiving filters in "rounding off" the modulated carrier wave, that is, in screening out the objectionable components of the signal wave, is shown by the oscillograms of Fig. 4. The combined effect of the two filters on the shape of the modulated carrier may be seen by comparing oscillograms (*b*) and (*d*) of this figure, which show respectively the appearance of the modulated wave before it enters the sending filter and after passing through the sending filter, over the line and through the receiving filter. Another interesting point in connection with these oscillograms is the time lag due to the circuit which is shown by the relative differences in position of the two waves referred to above. Owing to the limitations imposed by the ordinary oscillograph all of the traces shown in Fig. 4 were not taken simultaneously. This accounts for minor inconsistencies which are revealed by a careful inspection.

Detector. The detector receives alternating-current signals from the line after the signals belonging to that particular channel have been selected by the receiving filter. It consists of two vacuum tubes in tandem, the first tube (Fig. 3) amplifying the received signals, and the second converting them into direct-current pulses which operate the receiving relay. The receiving relay then repeats these telegraph signals into the receiving direct-current circuit which contains the receiving sounder.

To improve the operation of the receiving relay a device called an accelerating circuit or "kick" circuit, such as is used in open-wire carrier-telegraph systems, is interposed between the detector tube and the receiving relay. This circuit is obtained by introducing a transformer whose high-voltage side is connected in series with the detector tube and a winding of the receiving relay and whose low-voltage side is connected to another winding of the relay. When the current in the high-voltage side is constant, there is no current in the low-voltage side, but if the former current suddenly changes, as at the beginning or end of a marking signal, there is a sudden rush of current in the low-voltage circuit which has the effect of causing the relay to operate promptly and positively.

Relays. As shown in Fig. 3, the sending and receiving relays are of the polar type. These relays are identical and interchangeable with those used in the metallic and open-wire carrier-telegraph systems. They are described in the paper on telegraph relays which has been prepared for presentation at this meeting.

Power and Testing Equipment. In the development of the voice-frequency carrier telegraph system, the central thought was the desirability of designing a system which would fit into the existing cable telephone and telegraph plant. It has been possible to use the standard voltages obtainable from the storage batteries in such plants without exception.

In line with the policy of simplifying this new system as far as possible, the amount of auxiliary testing apparatus was reduced to a minimum. This policy has been assisted by the stability of the cable circuits and the use of a multi-frequency generator as a source of carrier currents. Only two pieces of special testing apparatus are used at each station, namely, the frequency indicator, and a thermo couple voltmeter for checking the alternating voltage in each generator circuit.

Line and Repeaters

As has been pointed out elsewhere in this paper, the voice-frequency carrier telegraph system was designed primarily for use on small-gage, four-wire cable circuits. These circuits are loaded and provided with vacuum tube repeaters at 50 to 100-mile (80.5 to 161 km.) intervals, depending on the weight of loading used. The repeaters used in long toll circuits are similar to those described at an earlier date.[5] The characteristics of the long cable circuits used in voice-frequency carrier telegraph transmission have also been described in a more recent paper.[6]

Equipment Features and Arrangements for Giving Service

The apparatus which is associated with each of the ten two-way circuits in this system has been segregated according to function and each group of apparatus per-

5. *Telephone Repeaters*, by Bancroft Gherardi and Frank B. Jewett, TRANSACTIONS, A.I.E.E., 1919, page 1287.

6. Clark, Loc. cit.

form'ng the same function, such as the detector, has been mounted on a separate steel panel. Each one of these panels forms a unit in itself. This type of construction allows the substitution of new apparatus performing some particular function in the system without an expensive redesign. Thus, it is possible to

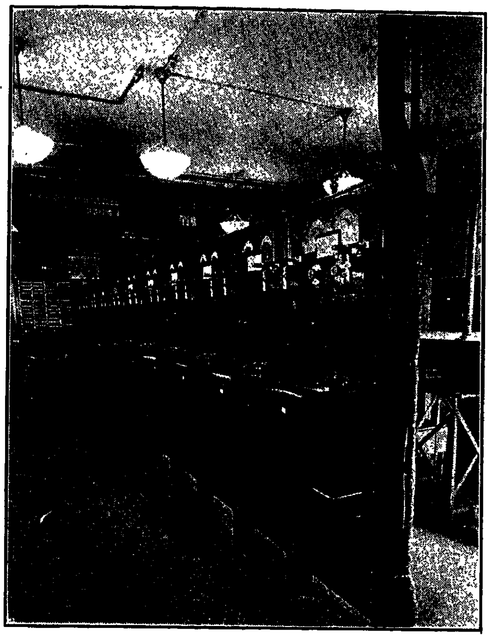

FIG. 6

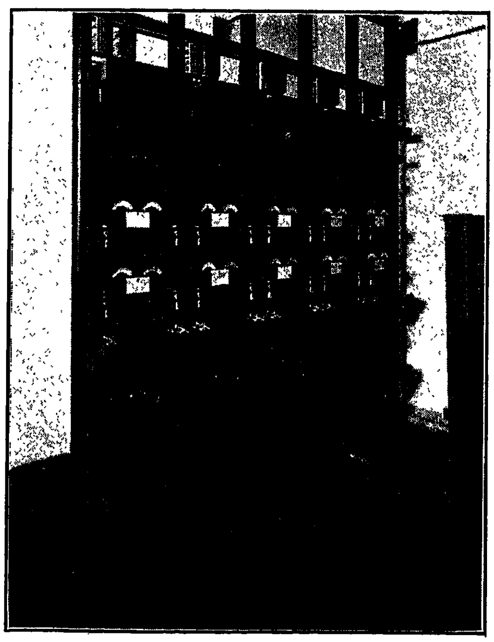

FIG. 7

install future improvements in the several circuits of the system in an economical manner.

These unit panels are mounted on pairs of vertical I-beams and the combination is termed a "bay." The bays are of different heights, depending on the requirements of the office in which they are installed. Fig. 6 shows a line-up of so-called low-type bays (about five feet high) in the Pittsburgh office. Each bay in this line-up contains sufficient equipment to provide for the transmission and reception of signals at the Pittsburgh terminal of one of the ten two-way telegraph circuits. Fig. 7 shows a line-up of similar equipment in the New York office, this layout differing from the one in Pittsburgh in that it uses high instead of low-bays. Each bay in this line-up contains sufficient terminal equipment for two of the ten two-way telegraph circuits.

In addition to the bays described above there are three bays, carrying auxiliary equipment. This auxiliary equipment consists primarily of control and testing apparatus for batteries and carrier supply. Two of these bays, namely, the generator and carrier supply bays are shown in Fig. 8. This figure shows two of the multi-frequency generators (one a spare machine) described above, and the carrier testing equipment. The control

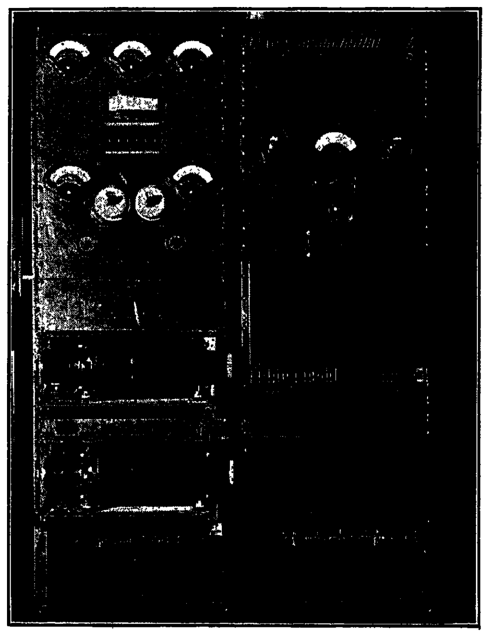

FIG. 8

equipment associated with these machines is mounted on the panels above the generator and the frequency indicator is mounted on the panel to the right of this control apparatus.

Switching and Monitoring Arrangements

The monitoring arrangements, which enable the attendant to check the quality of signals passing over a circuit or to trace trouble quickly and easily, are similar to those now in use in the open-wire carrier and metallic telegraph systems. These arrangements are described in the paper on the metallic telegraph system which has been prepared for presentation at this meeting and, therefore, will not be given in detail here. In a general way it may be said that switches and meters are provided to connect the telegraph batteries to local

apparatus, to provide either one-way or two-way service and to facilitate repeating to other telegraph systems.

Capabilities of System

Field tests over the New York-Pittsburgh system have shown that each telegraph circuit derived therefrom is of high grade, allowing signal speeds of 35 to 40 cycles per second. That is, with machine sending, it is possible to transmit 140 to 160 words per minute (five letters and a space per word) each way over each telegraph circuit. Considerably higher speeds may of course be obtained by widening the frequency range assigned to each telegraph circuit.

The New York-Pittsburgh system may be used in connection with a multiplex printing telegraph system and three printer messages may then be sent simultaneously in either direction on each carrier circuit. Assuming 50 words per minute as the working speed for each of the three printers a total of 1500 words per minute could be transmitted simultaneously in either direction over the ten circuits.

A simple numerical example will indicate what is technically possible by the application of this type of telegraph system to toll cables. A toll cable 2 5/8 inches (6.7 cm.) in diameter contains about 300 pairs of No. 19 B. & S. gage (0.91 mm.) conductors. Utilizing the phantom circuits this gives a total of 225 four-wire circuits. Counting 30 messages in each direction per four-wire circuit it is evident that it is technically possible to transmit 6750 messages in each direction simultaneously.

The "break" feature of this system is satisfactory. It functions in a manner similar to that used with the metallic telegraph system. It takes about 0.1 second to transmit a "break" signal over a 1000-mile (1610 km.) circuit.

Fields of Application

It will be evident that while the foregoing description assumes that this system is applied to four-wire circuits, it could be readily applied to two-wire circuits by transmitting half of the carrier frequencies in one direction and the other half in the opposite direction. Furthermore, if the impedance characteristic of the line could be reproduced with sufficient accuracy in networks to balance the line at the repeaters, the same frequencies could be transmitted in both directions and as many of them could be so transmitted as the natural "cut-off" of the line would permit.

While the voice-frequency carrier telegraph system has been designed primarily for use on an ordinary telephone circuit, the system may be applied to carrier telephone or radio telephone channels without involving radical changes in either the telegraph system or the telephone circuit to which it is applied.

Discussion

For discussion of this paper see page 339.

Polarized Telegraph Relays

BY J. R. FRY[1] and L. A. GARDNER[2]
Non-member Associate, A. I. E. E.

Synopsis.—This paper is to discuss two forms of polarized telegraph relays which have been developed by the Bell System and applied originally to the metallic telegraph system. One of these relays was designed primarily for operation under severe and exacting circuit conditions and the other for application generally. Both relays are of the same general construction except that the former is more sensitive than the latter and is furnished with an auxiliary accelerating winding. Furthermore, this relay has incorporated in it certain refinements in construction and materials, which cause it to be extremely sensitive and to give reliable service for a comparatively long period without attention. The construction is of special interest in that the polarizing force of the permanent magnet is neutralized by the mechanical restraining force of the armature. A magnetic material having characteristics well suited to relay design and a new contact material are employed, which greatly improve the operating characteristics of the relay.

INTRODUCTION

THE development of new types of sensitive polarized relays, for use in the Bell System, was undertaken as a result of a demand which arose in connection with the development of the metallic polar-duplex telegraph system. A paper on this system is being presented at this session.[3] Later these relays were applied to the carrier telegraph systems,[4] one of which is being described in a paper at this meeting.

A number of polarized relays, manufactured in this country and abroad, were experimented with and found inadequate, in certain respects, for application to these systems without extensive modifications. For satisfactory performance, it was found that the relay should meet the following general requirements: 1. Have a high degree of sensitivity, 2. Retain adjustment for a long period, 3. Faithfully and accurately repeat signals with a small amount of maintenance.

From the standpoint of sensitivity, the relay is required to operate on reversals of line current of a minimum of one milliampere and at the same time obtain proper impedance characteristics without exceeding practical limits in the dimensions of the windings. Over small-gage cable conductors having large mutual capacity and high resistance, the wave-shape of the received current is badly distorted. This wave-shape, in addition to the magnitude of the current available, makes more drastic the requirements for sensitivity. It is interesting to note that, under average conditions, the ratio of power controlled by the contacts in the local circuit to that required by the line windings, is about five thousand to one.

In the case of main-line telegraph relays, it is essential that no considerable changes in length of signals take place as such effects are generally cumulative over long circuits, where several relays are employed in repeating signals. As contrasted with relays used for circuit-switching purposes, telegraph relays are called upon to function continuously under severe conditions, and to perform successively hundreds of thousands of times in a few hours.

In order to furnish a good quality of telegraph service, it is essential that very few relay failures occur during service periods. If this is not accomplished, considerable valuable circuit-time is lost and the relay maintenance expense becomes an excessive factor in the cost of giving service.

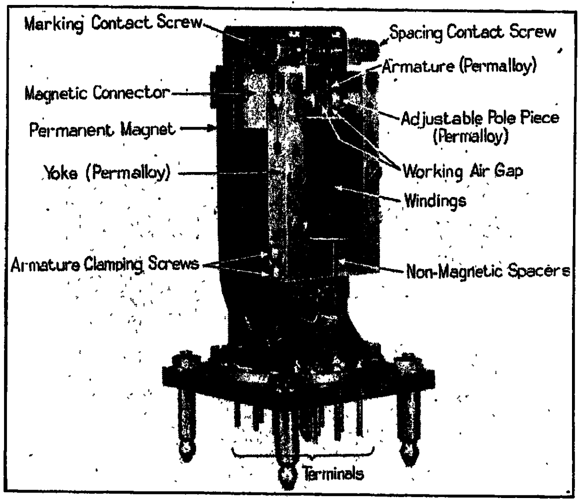

FIG. 1—No. 209-FA POLARIZED RELAY (COVER REMOVED)

DESIGN FEATURES

The relay which has been designed to meet the foregoing requirements is shown in Fig. 1 and is known as the 209-*FA* relay.

A polarized relay is fundamentally different in its operation from the ordinary neutral relay, in that it is selective to the polarity of the operating current and is more sensitive in its operation. A type of magnetic circuit was chosen which, it was felt, would best lend itself to obtaining a relay which would meet, as completely as possible, all of the requirements above outlined.

4. "Carrier Current Telephony and Telegraphy" by E. H. Colpitts and O. B. Blackwell, TRANSACTIONS of the A. I. E. E., 1921, page 205.

Presented at the Midwinter Convention of the A. I. E. E., New York, N. Y., Feb. 9-12, 1925.

Fig. 2 shows the magnetic circuit and the arrangement of the relay elements. It is seen to consist of a Wheatstone-bridge type of magnetic circuit in which the four equivalent air-gaps, two upper and two lower, may be considered as the four arms of the bridge with the permanent magnet placed across two opposite corners of the bridge and the armature and windings in the position customarily occupied by the galvanometer. The operating windings are placed over the armature in the form of a single stationary spool, sufficient clearance being provided to allow the armature to move within the spool. The paths of the polarizing and operating fluxes are shown by the solid and dash lines, respectively, for the armature in its midway or neutral position. When the armature is in the midway position there is no polarizing flux through it, since it connects two points of the circuit of equal magnetic potential; as it moves toward the left pole-piece, the

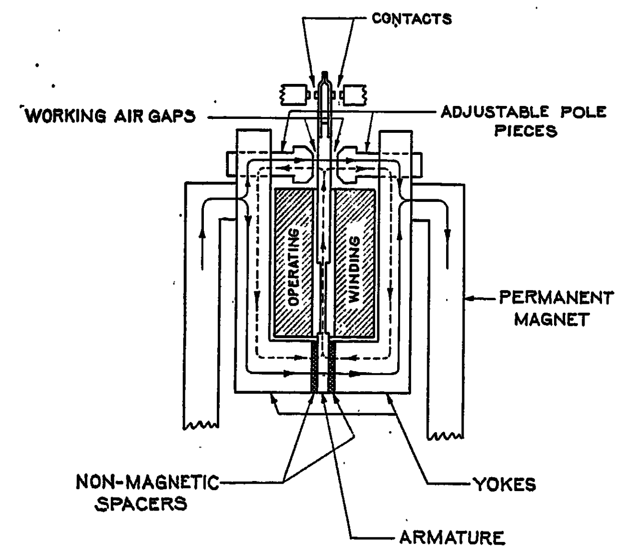

Fig. 2—Diagram Showing Magnetic Circuit and Arrangement of Relay Elements

polarizing flux flows through it in a direction assumed to be positive and when it moves toward the right pole-piece, the polarizing flux flows in the opposite or negative direction. The operating flux, in addition to the two return paths shown through the yokes, has a third path through the permanent magnet, but, substantially, none of this flux returns by this path due to the high reluctance of the permanent magnet as compared to that of the yokes. It is seen that these fluxes aid and oppose each other in the four gaps in such a manner as to produce a torque on the armature about a point midway between the upper and lower sets of air-gaps. With the direction of fluxes shown, the armature would tend to move in a clockwise direction. The forces established in all four of the gaps can be utilized in moving the armature only when the armature is movably supported at a point midway between the upper and lower gaps. In the design of this relay, the armature is not supported at this point, but is firmly clamped and supported at the lower gaps between the yokes, non-magnetic spacers forming proper reluctances to prevent short-circuiting the permanent magnet. This method of suspension, of course, prevents the forces established in the lower gaps from doing useful work upon the armature, but the overall advantages gained by this arrangement more than compensate for the apparent loss in sensitivity. This method of armature support permits of a more simple design of the relay; it eliminates the use of pivots; it permits the use of a single-spool construction instead of a two-spool arrangement; it allows a more practicable adjustment of the relay and more stable operation, and it affords a simple arrangement whereby the stiffness of the armature can be utilized to neutralize the polarizing force acting on the armature, thereby increasing the sensitivity of the relay as will be explained later in greater detail.

The pull acting between the pole-piece and the armature in each gap is expressed, according to Maxwell's law, by the equation:

$$P = \frac{(\phi_p + \phi_i)^2}{8\,\pi\,S} = \frac{1}{8\,\pi\,S}\,(\phi_p^2 + 2\,\phi_p\,\phi_i + \phi_i^2)$$

where P is the force in dynes, ϕ_p is the polarizing flux in the air-gap set up by the permanent magnet, ϕ_i is the operating flux generated in the air-gap by the winding (both expressed in maxwells), and S is the effective area of the air-gap in sq. cm.

This shows that the pull acting on the armature in each air-gap is made up of three components: The first term is the pull due to the permanent magnet and is the force acting on the armature with no current on the relay and is commonly spoken of as the polarizing force. The second is the important component, as it is the force which operates the relay; it is this component which makes the relay selective to the polarity of the operating current because its direction is dependent upon the sign of ϕ_i. Since its magnitude is proportional to the product of the polarizing flux and the flux generated by the operating current it shows why a high polarizing intensity is effective in obtaining a highly sensitive relay. The third term is a pull on the armature which would be the only one to appear if the relay were not polarized and is of twice the frequency of the second term.

As explained above there are two magnetic air-gaps in which forces are effective to produce motion of the armature, and it is the resultant of these component forces in the two air-gaps that controls the relay. In Fig. 3 is shown how the resultant of the polarizing components of force in the two air-gaps varies as the armature is displaced in the air-gap. In the midway or neutral position of the armature the resultant polarizing force on the armature is zero, but as the armature is displaced in either direction the force is one of attraction of increasing intensity between the armature and pole-piece toward which the armature is displaced as

shown by the solid line. The armature, being supported in cantilever beam fashion, will be resistant to displacement from its midway position in the air-gaps due to its natural stiffness. This force of restitution of the armature is opposite in direction or opposing to the polarizing force as the armature is displaced from the midway position and is proportional to the displacement. If the armature is designed so that its force of restitution is approximately equal to the polarizing force acting on it for all positions of the armature

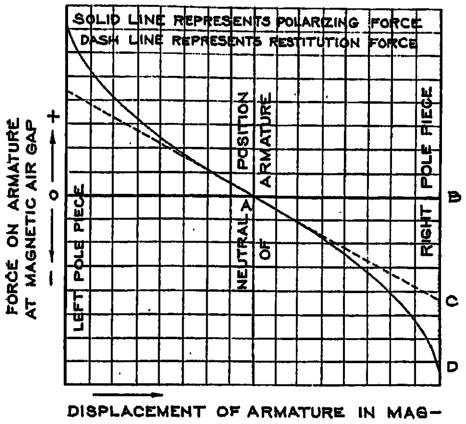

FIG 3—DIAGRAM SHOWING HOW POLARIZING AND RESTITUTION FORCES VARY WITH POSITION OF ARMATURE.

the sensitivity of the relay will be greatly increased. Thus, in Fig. 3, if the polarizing force on the armature were not in some manner neutralized, the work required to move the armature across the air-gap would be represented by the area *ABD*. By balancing the force of restitution of the armature against the polarizing force on the armature in the manner described, the work necessary to move the armature across the air-gap is reduced to the area represented by *ACD*. In actual practise, the motion of the armature is limited by the contacts rather than by the pole-pieces, and the displacement of the armature between the contacts is made small in comparison with the length of the magnetic air-gaps. Hence, the working range of the armature displacement in the magnetic gaps is limited to a short distance on either side of the neutral position shown in Fig. 3, where a very close balance between the polarizing force and restitution force of the armature, can be realized. The armature is practically in a floating condition and can be controlled by the application of a small force. The advantage of neutralizing the polarizing force on the armature by an external force and thus increasing the sensitivity of the relay was pointed out by Mr. D. D. Miller of the Bell Telephone Laboratories, Incorporated.

Fig. 4 shows how the resultant of the operating forces, or the component represented by the second term of the above discussed equation varies in the two gaps as the armature is displaced in the air-gap. The condition of constant strength and direction of current through the relay winding is assumed. It is minimum when the armature is in the midway position and increases as the armature moves toward either pole-piece. Its direction may be either to aid or oppose the direction of the polarizing component shown in Fig. 3, since it is dependent upon the direction of the operating current. It is this component of force which controls the operation of the relay under influence of the operating current and it can be of small magnitude since it need be only of sufficient value to upset the equilibrium of forces shown in Fig. 3. The third component of force, acting on the armature represented by ϕ_i^2 is of small magnitude compared to the first two terms, but its effect is to decrease the sensitivity of the relay and increase the distortion and residual characteristics, since its direction opposes the operating component when the armature moves toward the neutral position and aids it when the armature moves away from the neutral position.

Thus it is seen that when the relay operates under the influence of reversals of current through the relay winding, both the operating and polarizing fluxes reverse in direction through the armature, which causes the relay to be highly sensitive to the magnetic properties of the armature. The parts entering into the magnetic circuit of this relay, except—the permanent magnet—are made of an improved magnetic material known as permalloy[5] recently developed in the laboratories of the Bell System. This material has a very low coercive force compared to customary magnetic materials used in relays, resulting in almost complete collapse of the operating flux when the magnetizing force is removed. As a result, distortion of the re-

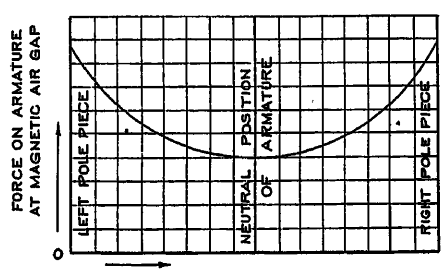

FIG. 4—DIAGRAM SHOWING HOW OPERATING FORCE VARIES WITH POSITION OF ARMATURE

peated signal is less, since the relay is less affected by the previous state of magnetization to which it may have been subjected by the preceding signal. On account of the higher permeability and the smaller residual effects of the material, the sensitivity of the relay is increased. It is evident from Fig. 3 that if the relay retains an appreciable amount of residual mag-

5. "Permalloy, a New Magnetic Material of Very High Permeability" H. D. Arnold and G. W. Elmen. The Bell System Technical *Journal* for July 1923. Page 101. "Electrical Communication", April 1924.

netism after the subsidence of the signal current, it will cause the armature to become biased by upsetting the balance between the polarizing and restitution force and decrease the sensitivity of the relay on the succeeding signal. Thus the use of this material results in marked improvements in the operating characteristics of the relay.

The relay is provided with six separate windings; four are employed as line windings, and two as auxiliary windings connected in a local circuit. The requirements of the metallic polar-duplex telegraph system are such that the four-line windings should be mutually balanced to a high degree both with respect to their impedance characteristics and their operating effects upon the relay. In order to meet these requirements it is necessary that each of the four windings have the same number of turns and resistances and be symmetrically located with respect to the armature and working air-gaps of the relay. This is obtained in practise by spirally twisting four well-insulated copper wires together and then winding as a single conductor on the relay spool in the usual manner. On top of and concentric with the line windings are two conductors wound in parallel. In the metallic telegraph system, these two windings are used in a circuit to form what is known as the *vibrating* or *accelerating* circuit, and this circuit is controlled from the contacts of the same relay. This feature serves to reduce distortion of signals by causing the relay to operate under the influence of the current in a local circuit before the operating current from the line at the time of reversal becomes sufficient to move the armature. It also reduces the armature travel-time and chatter and tends to make the relay more sensitive in its operation.

The relay contacts are required to make and break fairly large currents in circuits having large values of inductance and capacity. On relays used in terminal

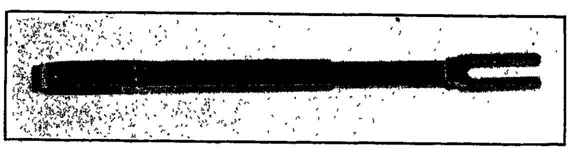

FIG. 5—ARMATURE OF NO. 209-FA RELAY

type repeaters, the voltage between one stationary contact and the corresponding armature contact is 240 volts. Due to the feeble currents which operate the relay, the contact-gap must necessarily be small, which, in practise, is adjusted to about 0.004 in. (0.10 mm.). The work of obtaining an adjustment of this gap is aided by marks on the capstan head of the contact screws. It is highly desirable to have a relay the contacts of which do not rebound or chatter as the armature breaks and makes contact. By eliminating contact-chatter the relay will be capable of transmitting signals at greater speeds and with less distortion, and the life of the contacts will be increased. An extended study of the dynamic action of the armature at the contacts was made with a view of diminishing or eliminating contact rebound. This is an old problem of telegraph relay design and many efforts have been made during the past to solve this problem satisfactorily, but most solutions proposed resulted in devices or designs which were complicated and not adapted for commercial use.

A practical design of armature was developed, which is easy to manufacture and is effective in eliminating contact rebound. This design is shown schematically in Fig. 2 and by a photograph in Fig. 5. The magnetic part of the armature extends through the relay coil and is

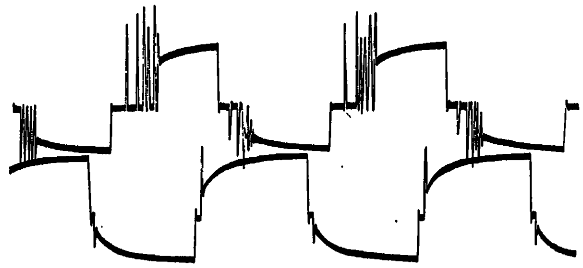

FIG. 6—OSCILLOGRAM SHOWING CURRENT FROM ARMATURE CONTACTS

Upper curve—Armature of ordinary design
Lower curve—Armature of standard design

just long enough to reach through the working air-gaps. The armature is extended to the stationary contact screws of the relay by riveting on to it two nickel-silver springs carrying the armature contacts. These two springs are bent at the free end and tensioned so that they touch and rest upon one another with a fixed pressure between them. By this construction the mass of the moving end of the armature is kept as small as possible so that at the moment of impact the tendency to rebound is thereby reduced. When the armature contact strikes the fixed contact one armature contact spring is displaced with respect to the other spring causing the ends of the springs to slide upon each other. This rubbing action tends to damp out the rebound as the energy of impact is absorbed by friction between the two springs. Other advantages gained by keeping the effective mass of the armature small, are reduction in the travel time of the armature and quicker time of response. In order to prevent the armature from adhering to either pole-piece, small nickel-silver disks are welded to each side of the armature directly opposite to the pole-pieces. Fig. 6 shows oscillograms of the current from the armature contacts with the relay in a terminal type metallic telegraph repeater, operating full duplex. The top wave shows the current from the armature contacts with the relay equipped with an armature of ordinary design, that is, having the contacts mounted directly on the magnetic material which extends the entire length of the armature. The lower wave shows the same relay operating under identical conditions as

above except that it is equipped with the standard design armature shown in Fig. 5. The improvement in the repeated signal of the relay is apparent both with respect to contact chatter and travel-time of the relay.

On account of the high voltage, the energy content of the circuits which the relay controls, the small contact-gaps and the feeble forces available to operate the relay, it was found that contacts made of material usually found on telegraph apparatus would not withstand the large number of operations daily required without excessive maintenance. This problem was studied with reference to the contact requirements of relays operating under the conditions imposed by the various repeaters, and an alloy was developed which is a decided improvement. The use of this improved contact material extends the service period of the relay, without contact failure, to approximately thirty times over that with alloys previously used. Fig. 7 shows photo-micrographs of armature contacts of a relay which had been in service for 8½ months without being removed from service. This amount of service is equivalent to each contact making and breaking the circuit approximately 45,000,000 times.

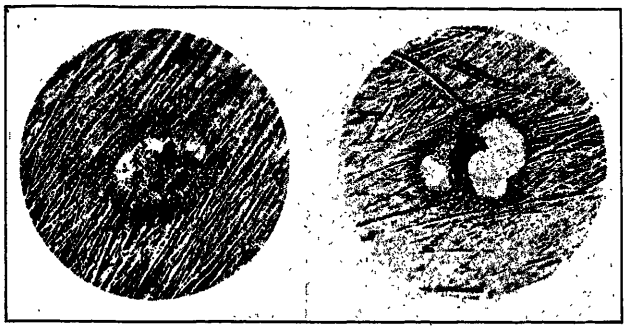

FIG. 7—PHOTO-MICROGRAPHS OF NO. 209-FA RELAY ARMATURE CONTACTS
Right—Marking contact
Left—Spacing contact

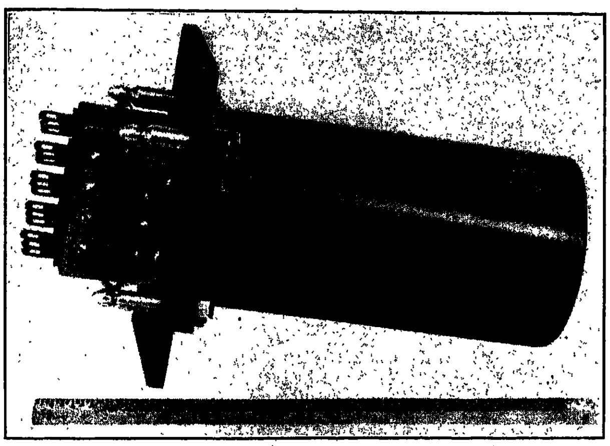

FIG. 8—NO. 209-FA RELAY WITH MOUNTING PLATE AND ASSOCIATED CONNECTING BLOCK

One of the design features of this relay is the arrangement which permits of the ready removal of the relay from the circuit. This feature is illustrated in Fig. 8, which shows the relay with its cover attached to a mounting plate and connecting block. The square phenol-fibre base of the relay is provided with four guide pins which definitely locate the relay with respect to the mounting plate and the connecting block, and is also furnished with 15 terminals on which electrical connections to the windings and contacts of the relay are terminated as shown in detail in Fig. 1. The connecting block is the medium by which electrical connection is established between the circuit and the relay. It is fastened to the rear of the mounting plate, has the same number of terminals as the relay, and the circuit is permanently wired to these terminals. When the relay is inserted into position on the mounting plate, electrical contact between the relay and connecting block terminals is automatically established. Resilient members fastened on the rear of the mounting plate, engage into recesses in the four guide-pins and hold the relay rigidly in position on the mounting plate. In case of relay trouble, the relay may be quickly removed and a spare relay inserted, thus keeping the time of circuit interruptions to a minimum.

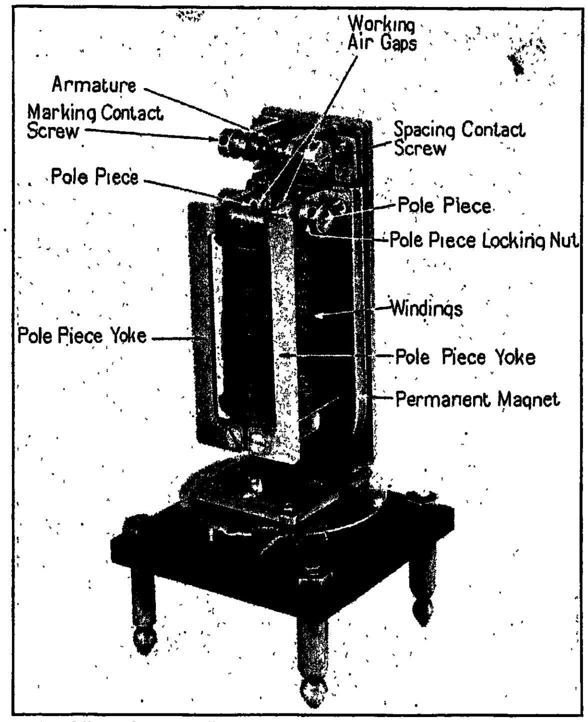

FIG. 9—NO. 215-A POLARIZED RELAY (COVER REMOVED)

There are a number of places in these systems where polarized relays are required, but which do not have to operate under as exacting conditions as the relay just described. For this purpose, a cheaper relay has been developed known as the 215-*A* relay, and this is shown in Fig. 9. It employs the same type of magnetic circuit as the 209-*F A* relay, and the same design features of mounting and chatterless armature springs are also incorporated. It does not have as refined adjusting features, nor will it operate on as small currents. It is provided with two balanced line windings.

Application and Maintenance

At the present time there are in operation about 2500 of the 209-type relays. Of this number, about 2000 are operating in the metallic telegraph system and the remainder in the carrier telegraph systems. These carrier telegraph systems make use of about 1000 relays of the 215-type and in the metallic telegraph system, about 2400 relays of this type are used.

As a result of field experience, it has been found that the maintenance schedules for these relays can be arranged to cover long periods with practically no interruptions occurring in service. In terminal-type repeaters and through-type metallic repeaters, this period is for satisfactory relay operation, approximately three months and six months, respectively.

Means are specially provided whereby these relays may be checked or adjusted quickly and accurately external to the telegraph repeaters; that is, the relays

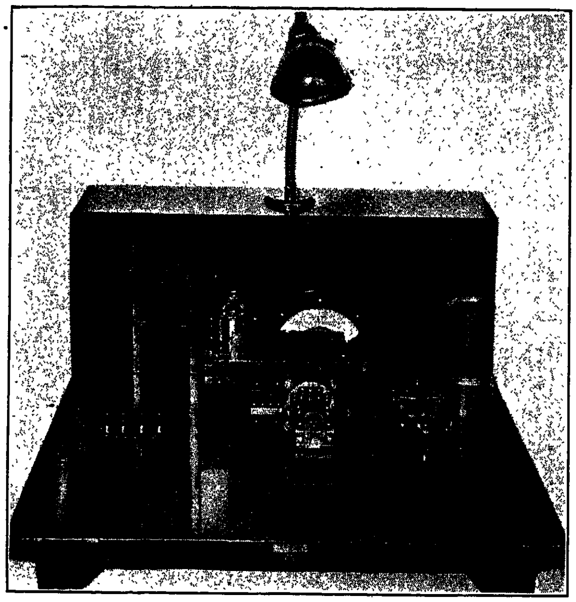

Fig. 10—Relay Test Table

are adjusted to the best operating condition without consideration of the telegraph circuit to which they are to be applied. This arrangement, known as a relay-test table, is shown in Fig. 10. These tests consist of obtaining an inspection and adjustment for sensitivity, differentiality, and freedom from bias. A local vibrating circuit is also provided for testing the 209-type relay so that it will function properly under the influence of the vibrating circuit in the telegraph repeaters.

The essential steps in adjusting a relay consist in withdrawing the contact screws sufficiently to permit inspection and cleaning. The pole-pieces are then withdrawn so that the effect of the permanent magnet upon the armature is made small, thus permitting the armature to stand in its neutral position. Any foreign material may be readily removed from the working air-gaps. Each contact-screw is then adjusted independently so as to have a separation of 0.002 in. (0.05 mm.) from the corresponding armature contact, and this results in a contact travel of 0.004 in. (0.10 mm.). Following this, the pole-pieces are adjusted so that the relay will respond without bias to 20-cycle a-c. ringing current of a magnitude about equal to that available in the telegraph repeaters. In order to have a margin of operation in the repeater, a d-c. sensitivity test is given with less current than above. In addition to the above a vibrating-circuit test on the 209-type is made. In general, the time required to adjust and test a relay is about six minutes.

Appendix

This appendix will consider briefly the advantages derived by the application of permalloy magnetic material to the polarized telegraph relay developed for use under comparatively severe and exacting circuit conditions. As pointed out in the body of the paper, this new magnetic material has a lower coercive force and higher permeability than magnetic materials ordinarily employed in relay construction.

The small amount of residual magnetism existing in this new magnetic material on account of its low coercive force as compared with a commercial grade of silicon steel, reduces appreciably the effect of bias, *i. e.*, lengthening or shortening of the telegraph signals. Also, the sensitivity, the stability and service life of the relay are increased. This increase in service life is on an average of about 50 per cent. A comparative value of the residual effects of the magnetic material used in the armature, yokes and pole pieces of two relays which are otherwise identical in their construction, can be realized from the following:

If a relay is magnetized with 120 ampere-turns, it is found that the contact pressure as a result of the residual properties of the magnetic material is in the case of a relay equipped with the permalloy material about one-seventh of that obtained when ordinary magnetic material is used. This value of 120 ampere-turns is approximately fifteen times that employed under normal telegraph circuit conditions.

Furthermore, the use of this new material causes an increase in contact pressure under average working conditions of about 50 per cent., which is in general a factor contributing towards minimizing contact chatter.

The minimum operating current for satisfactory telegraph signals is decreased on relays equipped with this permalloy material from about two milliamperes to one milliampere. Of course, in telegraph practise, in order to introduce a certain margin of operation, a somewhat larger current than one milliampere is often used.

Discussion

VOICE-FREQUENCY CARRIER TELEGRAPH SYSTEM FOR CABLES

(Hamilton, Nyquist, Long and Phelps)

POLARIZED TELEGRAPH RELAYS

(Fry and Gardner)

New York, N. Y., February 12, 1925

J. J. Pilloid: The three papers, *Metallic Polar-Duplex Telegraph System for Long Small-Gap Cables*, *Voice-Frequency Carrier Telegraph Systems for Cables* and *Polarized Telegraph Relays*, describe two telegraph systems particularly adapted for use on long toll cables, and a relay which is an important feature of the two systems. By long toll cables we mean here cables several hundred, or a thousand or more, miles long, used for telephone or telegraph purposes.

Such cables, as it has been reported to the Institute before, can each take the place of about ten heavily loaded open-wire lines, and they are used in sections where traffic is heavy. That means, of course, that there will be sections of the country where cables will not be placed for a good many years and so the older and existing telegraph systems (that is, the ground-return system) will be used for many years. One of the prime requisites, therefore, of these new systems, as brought out in these papers, is that they shall be adaptable for working with the existing systems.

There is just a mention of this idea on the fourth page of the voice-frequency carrier telegraph system paper, and if I do nothing else, I would like to emphasize that one statement. It is tucked away where you can hardly see it. It reads: "In the development of the voice-frequency carrier telegraph system, the central thought was the desirability of designing a system which would fit into the existing cable telephone and telegraph plant." As I pointed out before, it is also advisable that it fit into the existing open-wire telephone and telegraph plant.

The extent to which these systems will be used depends, of course, upon the development of this long toll cable plant and possibly a word as to the present development of that might be of interest. The cables at the present time are in service, as you know, from Boston to Washington and from New York through to Cleveland and to a point about half-way between Cleveland and Toledo. We expect to finish the cable into Toledo in a few weeks, where it will connect with a cable which is now in service between Toledo and Detroit. Cable is also in service for a distance of about 100 mi. east of Chicago, as far as South Bend, and work is under way on the remaining gap between Toledo and South Bend. It is expected that that section will be completed about October of this year. Also plans have been approved for a cable from St. Louis to Peoria and it is expected that this section will be completed to Chicago in 1926, so that we already have several long toll cables to operate these systems on, and are going to have more.

As the cables reach successive cities along the way toward their ultimate destinations the new telegraph systems and also the telephone systems join the older systems, and it is advantageous that both are easily adaptable and flexible enough for this purpose.

The voice-frequency telegraph system paper refers to the speed and message-carrying capacity of these systems. On the last page something is said about 6750 messages simultaneously each way on one full-sized cable. If such a cable, fully equipped with these systems, were devoted entirely to telegraph service, one could transmit all of the text of the five papers presented in this communication session and all of the discussions, in a fraction of a minute.

R. N. Nicely: The voice-frequency carrier telegraph system, providing as it does, a large number of telegraph circuits with a comparatively small amount of intermediate repeater apparatus, is well suited to use on long trunk routes between widely separated large cities from which distribution to outlying points is made by other telegraph systems. It will satisfactorily transmit signals at considerably higher speeds than is the case with aerial wire grounded polar duplex circuits used in the telephone plant and is therefore well suited to use with start-stop or multiplex printing telegraph apparatus.

It may be of interest to point out that the metallic polar duplex telegraph system and the voice-frequency carrier telegraph system may, if desired, be operated simultaneously on the same cable conductors.

The Rotating Magnetic Field Theory of A-C. Motors

BY K. L. HANSEN[1]

Associate, A. I. E. E.

***Synopsis.**—The predetermination of the performance of a polyphase a-c. machine is greatly facilitated by the fact that at constant voltage and frequency its magnetic field is of constant intensity and rotating with uniform velocity. It is easy to form a mental picture of lines of force moving in space and being cut by conductors, which may be moving or stationary. Furthermore, the rate of cutting, and therefore the generated voltages, which form the basis for quantitative analysis, are readily determined by the relative motion of the flux and the conductors.*

Because of the ease with which a physical conception can be formed of a rotating magnetic field, the idea of considering a single-phase alternating field as made up of two oppositely rotating fields has been found very useful. In a paper entitled "A Physical Conception of the Operation of the Single-phase Induction Motor" TRANSACTIONS A. I. E. E., 1918, p. 627), Mr. B. G. Lamme has given an excellent description of single-phase induction motor operation based on a conception of two oppositely rotating magnetic fields.

From the discussion of Mr. Lamme's paper, it appears to be the concensus of opinion that the method he uses furnishes the simplest and clearest physical conception of the single-phase motor. However, this is not the method usually employed in the quantitative analysis. Reference to text books will show that the mathematical treatment is usually based on the so-called "cross field" theory. In this method the secondary induced voltage is considered made up of two components, one the voltage induced by transformer action of the alternating field and the other the voltage generated by rotation of the secondary conductors in the magnetic field.

It has been argued against the method based on two oppositely rotating fields, also known as the "Rotating Field" theory, that it is more apt to lead to erroneous results, requires more expert handling and that it is an indirect method, being based on the previously determined performance of the polyphase motor. However, the main argument against it seems to be its limitation to induction motors only, and that it must be abandoned when we come to motors of the commutator type. Even those who otherwise favor the method appear to agree that it is not applicable to commutator motors as we are then no longer dealing with induction machines, but with shunt or series motors, as the case may be.

The objection to the rotating field theory, that it is applicable to induction motors only, would be a serious one if it were valid. However, it will be shown in this paper that the theory can be readily applied to commutator machines also, and that so far from being more apt than other methods to lead to erroneous results, it undoubtedly furnishes the simplest and most direct means for mathematical deductions in the more complicated problems where three or more circuits are inductively related and moving with respect to one another.

GENERAL DISCUSSION

IN its general form, the a-c. motor comprises one or more stationary circuits and one or more rotating electric circuits inductively related to the stationary circuits. Energy is transferred from the stationary to the rotating circuits through the medium of a common magnetic field. In this discussion the magnetic field is in general considered the resultant of two fields rotating in opposite directions. These two components are not necessarily equal, in fact one of them may vanish and the resultant is then a uniformly rotating field, as for example in a polyphase machine. Only motors in which the magnetic reluctance is uniform in all directions will be considered, that is, motors with projecting poles are not included.

There are then two main groups of motors to be discussed; the induction type, in which the rotor circuits are short-circuited upon themselves; and the commutator type, in which the rotor circuits are either short-circuited or connected to an external circuit through a commutator. A number of essential features are common to both types. Thus, at any speed, the m. m. fs. of the rotor rotate with velocities which, combined with the velocity of mechanical rotation, are always equal to the velocities of the stator fields. The common magnetic field is produced by an m. m. f., which is the vector sum of the stator and rotor m. m. fs.

When running at any slip, s, there are in general two voltages induced in the rotor circuits of frequencies $s\,f$ and $(2 - s)\,f$, according to whether it is induced by the field rotating in the same or in opposite direction to the rotation of the rotor, where f is the stator frequency. In magnitude the induced voltages are, of course, proportional to their respective frequencies. As this viewpoint obviously eliminates the necessity of considering the rotational and transformer voltages separately, the solution of many problems are greatly simplified thereby. The torque developed by either field is also readily determined, it being in all cases the product of the field, the m. m. f. of the rotor circuits revolving in the same direction as the field and the sine of the angle between them.

As already stated, the voltages induced in the rotor circuits are of frequencies $s\,f$ and $(2 - s)\,f$. In the induction type the rotor currents resulting from these voltages are likewise of frequencies $s\,f$ and $(2 - s)\,f$. However, in the commutator type the resulting rotor currents are at all speeds converted by the commutator into line frequency. In their magnetic reactions the rotor currents become fixed in space by the commutator and the rotor circuits can therefore be considered as remaining stationary in every respect, except as regards the magnitudes of the induced voltages, which are determined by the frequencies of slip, as pointed out.

The rotor currents becoming fixed in space by the commutator is the cause of some essential differences

1. Consulting Engineer, Milwaukee, Wis.

in the operation of the induction and commutator types. Thus, in the induction machine, the reactance of the rotor circuit changes with the slip, while in the commutator type it is the same at all speeds. Also, by shifting the brushes on the commutator, the relative position of the stator and rotor m. m. fs. is changed so that the voltages that are induced in the stator circuits by the rotor currents may be advanced or retarded in time. This becomes of importance when an external e. m. f. is impressed on the rotor as it introduces the possibility of power-factor correction.

The subject of power-factor correction has lately been the object of considerable discussion and the readiness with which the rotating field theory lends itself to the analysis of just such problems, involving a displacement angle between the stator and rotor currents is another marked advantage of this method. Application of the method to the analysis of some proposed schemes for power-factor correction will be taken up in the mathematical section.

However, before taking up the mathematical discussion, it will be shown by way of illustration how readily the method can be applied to the much discussed problem of calculating the performance of a single-phase induction motor.

Consider a single-phase motor and a two-phase motor of the same constants per circuit as the single-phase machine. Then if E be the impressed voltage and I_p the current per phase of the two-phase motor at slip s, the apparent impedance per phase is $Z_a = \frac{E}{I_p}$. Similarly, if I_b is the current per phase when running backwards at the same speed, the apparent impedance at slip $(2 - s)$ is $Z_b = \frac{E}{I_b}$. It is then shown in the appendix that the apparent impedance of the single-phase motor at slip s is $Z_s = \frac{Z_a + Z_b}{2}$ and the current of the single-phase motor is $I_s = \frac{E}{Z_s}$. Let T_a = torque of two-phase motor at slip s and T_b = torque at slip $(2 - s)$. The torque developed in the single-phase motor at slip s by the field revolving in the same direction as the rotor then is $T_1 = \left(\frac{e_1}{E}\right)^2 \times T_a$, where $e_1 = \frac{Z_a I_s}{2}$, and the torque developed by the oppositely rotating field $T_2 = \left(\frac{e_1}{E}\right)^2 \times T_b$, where $e_2 = \frac{Z_b I_s}{2}$. The resultant torque of the single-phase motor at slip s, $T_s = T_1 - T_2$. Herefrom the remaining quantities, power, efficiency and power factor can be determined directly. Thus, by extremely simple calculations the performance of a single-phase motor is derived from the performance of a two-phase motor of same constants per circuit. Which one of the numerous methods that have been devised for calculating the performance of a two-phase motor to use is, of course, a matter of choice.

When it is desired to calculate the performance from the running and locked test readings, the locked single-phase readings can be used directly in calculating the two-phase performance. The single-phase no-load reading with the rotor short-circuited, that is, running light, can not be so used, because the exciting admittance per phase of the two-phase motor is then a little more than one half the single-phase admittance, or, what amounts to the same thing, the two-phase no-load impedance per phase is almost twice the single-phase no-load impedance. The amount by which the two-phase impedance falls short of being exactly twice the single-phase no-load impedance is obviously the apparent impedance per phase when running backwards at full speed. Since this latter impedance is almost independent of the exciting current it can readily be determined to a high degree of accuracy. On the basis of the modified single-phase no-load reading the diagram of the two-phase motor can be constructed and the single-phase performance calculated therefrom.

As a numerical example, the following readings have been taken on a single-phase motor;

Running Light		Rotor locked
110	Volts	110
3.2	Amperes	14.8
78	Watts	982
$\cos \phi_0 = 0.221$	P. F.	$0.603 = \cos \phi_L$
Primary resistance		2.36 Ohms

The no load impedance per phase $Z_0 = \frac{110}{3.2} = 34.4$.

$$R_0 = Z_0 \cos \phi_0 = 7.6 \quad X_0 = Z_0 \sin \phi_0 = 33.6$$

It is known that the two-phase no-load impedance per phase is slightly less than $2\,Z_0$, or the magnetizing current a little more than one half of 3.2 amperes. To determine how much $2\,Z_0$ should be reduced, construct a diagram, using the observed readings, except that the magnetizing current is reduced to approximately one half, say 1.7 amperes.

No refinements are necessary in the construction of the diagram to modify the no-load readings and the simple diagram as shown in Fig. 1 is sufficient. From the current triangle $O\,P\,R$ in this diagram the apparent impedance at slip = 2 is found to be $Z_b = \frac{110}{16.5} = 6.67$.

$R_b = Z_b \cos \phi_b = 3.2$ and $X_b = Z_b \sin \phi_b = 5.85$. Subtracting R_b from $2\,R_0$ leaves 12, and X_b from $2\,X_0$ leaves 61.35, hence the corrected no-load impedance per phase is $\sqrt{12^2 + 61.32^2} = 62.5$. The no-load

values to use in calculating the two-phase performance are therefore 1.76 amperes and 0.192 power factor. Fig. 2 shows the curves of the two-phase motor. Then at some speed, for example 1600 rev. per min., we find,

Forward rotation 4.67 amperes, 0.872 power factor
Backward rotation 16 amperes, 0.49 power factor.

$$Z_a = \frac{110}{4.67} = 23.55 \quad R_a = 23.55 \times 0.872 \doteq 20.55 \quad X_a = 23.55 \times 0.488 = 11.50$$

$$Z_b = \frac{110}{16} = 6.87 \quad R_b = 6.87 \times 0.49 = \frac{3.37}{23.92} \quad X_b = 6.87 \times 0.87 = \frac{5.97}{17.47}$$

Adding

Dividing by 2 $\quad 11.96 \quad\quad 8.735$

Single-phase current $I_s = \dfrac{110}{\sqrt{11.96^2 + 8.735^2}} = 7.43$ amperes at 0.81 power factor.

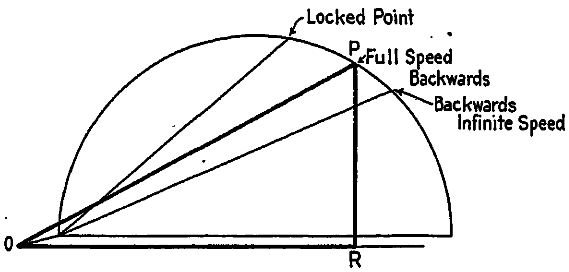

FIG. 1

$$e_1 = \frac{23.55 \times 7.43}{2} = 87.4 \quad e_2 = \frac{6.87 \times 7.43}{2} = 25.5$$

$$T_1 = \left(\frac{87.4}{110}\right)^2 \times 2.875 = 1.808 \text{ lb. at 1 ft. radius.}$$

$$T_2 = \left(\frac{25.5}{110}\right)^2 \times 2.05 = 0.110 \text{ lb. at 1 ft. radius.}$$

$$T_s = T_1 - T_2 = 1.698 \text{ lb. at 1 ft. radius}$$

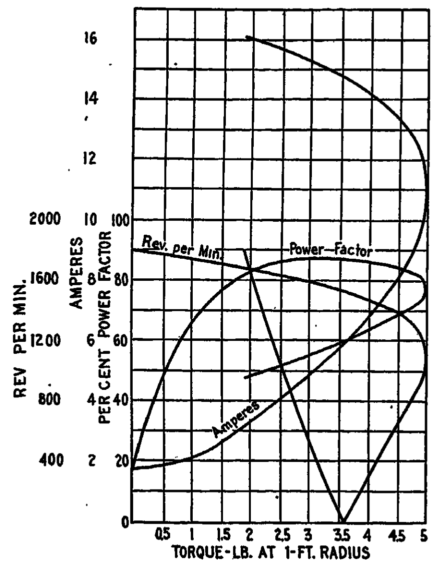

FIG. 2

equals resultant single-phase torque at 1600 rev. per min The complete single-phase performance is shown in Fig. 3.

In this simple method it may be of interest to note the absence of complicated geometrical figures, trigonometric transformations, inversions, equivalent circuits, empirical coefficients, etc., in which the quantitative analysis of the single-phase motor usually abounds. Furthermore, it will be seen in the appendix that a conception of two oppositely rotating fields immediately furnishes sufficient data to write down one set of equations, the solution of which forms the basis of the method described.

To further illustrate the usefulness of the conception of rotating magnetic fields the mathematical analysis will be extended to the somewhat more involved problems of phase conversion and power-factor correction.

Appendix

Mathematical Expression for Two Oppositely Rotating Fields

A current with maximum value I and varying periodically according to the cosine law is usually

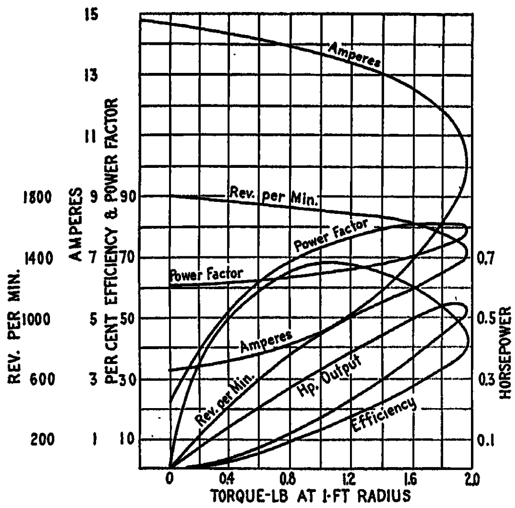

FIG. 3

represented by the expression $I \cos \omega t$, where $\omega = 2\pi f$, f being the frequency. Using the exponential form of the cosine, a sinusoidal current may be represented by a pair of rotating vectors, that is $I \cos \omega t$ may be written $\frac{I}{2}\epsilon^{j\omega t} + \frac{I}{2}\epsilon^{-j\omega t}$. Many cumbersome trigonometric expressions and transformations are frequently avoided by the use of this notation (see for example "Radio Communication," by John Mills). That the expression $\frac{I}{2}\epsilon^{j\omega t}$ represents a vector revolving in counter-clockwise direction with angular velocity ω is readily seen by writing

$$\frac{I}{2}\epsilon^{j\omega t} = \frac{I}{2}(\cos \omega t + j \sin \omega t)$$

and assigning to t a series of increasing positive values. The expression

$$\frac{I}{2}\,\epsilon^{-j\omega t} = \frac{I}{2}\,(\cos\omega t - j\sin\omega t)$$

is likewise seen to represent a vector of same length and revolving in clockwise direction. In Fig. 4 let a current $I\cos\omega t$ be flowing in a coil $N\,N$ of n turns. The instantaneous value of the m. m. f. of the coil then is $n\,I\cos\omega t$ or in the above notation

$$\frac{n\,I}{2}\,\epsilon^{j\omega t} + \frac{n\,I}{2}\,\epsilon^{-j\omega t}$$

As the m. m. f. is a directed quantity in space the first term of this expression represents a m. m. f. of constant intensity $\frac{n\,I}{2}$ rotating in positive direction, and the second term represents a m. m. f. of same intensity rotating in opposite direction. Let the coil

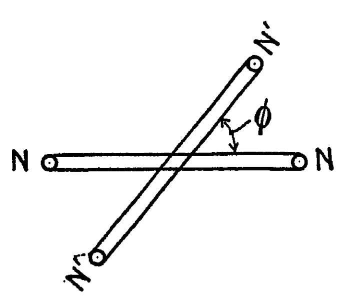

FIG. 4

$N - N$ be turned through an angle of ϕ radians in positive direction and its m. m. f. becomes

$$\frac{n\,I}{2}\,(\epsilon^{j\omega t} + \epsilon^{-j\omega t})\,\epsilon^{j\phi} = \frac{n\,I}{2}\,\epsilon^{j(\omega t+\phi)} + \frac{n\,I}{2}\,\epsilon^{-j(\omega t-\phi)}$$

that is, the m. m. f. revolving in positive direction has been advanced ϕ radians and the m. m. f. revolving in negative direction has been retarded ϕ radians.

The most striking feature of the polyphase system, that it can produce a rotating magnetic field of constant intensity, is most readily deduced by use of this notation. To illustrate, assume m coils, symmetrically based on a cylindrical core, the space angle being $\frac{2\pi}{m}$ radians. The coils are excited by currents I, differing in phase by $\frac{2\pi}{m}$ radians. The m. m. f. of the k^{th} coil then is

$$\frac{n\,I}{2}\left[\epsilon^{j(\omega t+\frac{2\pi k}{m})} + \epsilon^{-j(\omega t+\frac{2\pi k}{m})}\right]\epsilon^{j\frac{2\pi k}{m}}$$

and the total m. m. f. of all the coils is

$$\sum_{0}^{m-1} k\,\frac{n\,I}{2}\left[\epsilon^{j(\omega t+\frac{2\pi k}{m})} + \epsilon^{-j(\omega t+\frac{2\pi k}{m})}\right]\epsilon^{j\frac{2\pi k}{m}}$$

$$= \sum_{0}^{m-1} k\,\frac{n\,I}{2}\,\epsilon^{j(\omega t+\frac{4\pi k}{m})} + \sum_{0}^{m\;1} k\,\frac{n\,I}{2}\,\epsilon^{-j\omega t}\,\epsilon^{0k}$$

$$= \frac{m\,n\,I}{2}\,\epsilon^{-j\omega t} \text{ since } \sum_{0}^{m-1} k\,\frac{n\,I}{2}\,\epsilon^{j(\omega t+\frac{4\pi k}{m})} = 0$$

That is, the resultant m. m. f. is of constant intensity $\frac{m\,n\,I}{2}$ and rotating in negative direction. If the sign of either time angle or space angle be changed the resultant m. m. f. is seen to rotate in opposite direction.

In Fig. 4, let Z_m be the mutual impedance between coils $N\,N$ and $N'\,N'$ when in coaxial position. The voltage induced in the coil $N'\,N'$ by the current flowing in $N\,N$ then is $Z_m I$. When $N'N'$ is turned ϕ radians in positive direction the voltage induced by the positively rotating field of $N\,N$ is retarded ϕ radians and becomes $\frac{Z_m I}{2}\,\epsilon^{-j\phi}$ and the voltage induced by the negatively rotating field is advanced ϕ radians and becomes $\frac{Z_m I}{2}\,\epsilon^{j\phi}$. The voltage induced by both fields is

$$\frac{Z_m I}{2}\,\epsilon^{-j\phi} + \frac{Z_m I}{2}\,\epsilon^{j\phi} = Z_m I\cos\phi$$

SINGLE-PHASE INDUCTION MOTOR

The rotor circuits of the single-phase induction motor being short-circuited upon themselves in all directions constitute a polyphase system and for convenience will be considered two-phase with constants determined accordingly. Assume the rotor to be revolving at slip s and consider its direction of rotation positive. Using the customary notation let $Z_m = r_m + j\,x_m$ = Mutual inductive impedance between stator and rotor circuits.

$Z_0 = r_0 + j\,x_0$ = Self inductive impedance of primary

$Z_1 = r_1 + j\,s\,x_1$ = Self inductive impedance to rotor current of frequency $s\,f$. x_1. x_1 = secondary reactance at standstill in terms of primary

$Z_2 = r_1 + j\,(2 - s)\,x_1$ = Self inductive impedance to rotor current of frequency $(2 - s)\,f$

E = volts impressed on primary

I_s = Primary current

I_1 = Positively rotating component of rotor current

I_2 = Negatively rotating component of rotor current

The voltages induced in the primary then are:
by the primary current $I_s = (Z_m + Z_0)\,I_s$
by the positively rotating rotor current $Z_m I_1$
by the negatively rotating rotor current $Z_m I_2$
the currents I_1 and I_2 being two-phase have full inductive effect. The sum of these voltages equals the impressed volts, hence,

$$(Z_m + Z_0)\,I_s + Z_m I_1 + Z_m I_2 = E$$

The voltages induced in the rotor are:
by the positively rotating component of primary current

$$\frac{s\, Z_m\, I_s}{2}$$

by the positively rotating component of rotor current

$$(s\, Z_m + Z_1)\, I_1$$

by the negatively rotating component of primary current

$$\frac{(2 - s)\,(Z_m)\, I_s}{2}$$

by the negatively rotating component of rotor current

$$[\,(2 - s)\, Z_m + Z_2]\, I_2$$

The sums of voltages of frequencies $s\,f$ and $(2 - s)\,f$ are separately equal to zero, hence

$$\frac{s\, Z_m\, I_s}{2} + (s\, Z_m + Z_1)\, I_1 = 0 \text{ or } s\, Z_m\, I_s + 2\,(s\, Z_m + Z_1)\, I_1 = 0 \text{ and}$$

$$\frac{(2 - s)\, Z_m\, I_s}{2} + [\,(2 - s)\, Z_m + Z_2]\, I_2 = 0 \text{ or}$$

$$(2 - s)\, Z_m\, I_s + [\,(2 - s)\, Z_m + Z_2]\, I_2 = 0$$

The e. m. f. equations of primary and secondary are then

$$\left.\begin{array}{ll} (Z_m + Z_0)\, I_s + Z_m\, I_1 + Z_m\, I_2 & = E \\ s\, Z_m\, I_s + 2\,(s\, Z_m + Z_1)\, I_1 & = 0 \\ (2 - s)\, Z_m\, I_s + 2\,[\,(2 - s)\, Z_m + Z_2]\, I_2 & = 0 \end{array}\right\} \quad (1)$$

Solving these equations

$$I_s = \frac{E\, 2\,\{\, s\,(2 - s)\, Z_m^2 + (2 - s)\, Z_m\, Z_1 + s\, Z_m\, Z_2 + Z_1\, Z_2\}}{2\, Z_0\{s(2 - s)Z_m^2 + (2 - s)Z_m\, Z_1 + s\, Z_m\, Z_2 + Z_1\, Z_2\} + Z_m\,\{\,(2 - s)\, Z_m\, Z_1 + s\, Z_m\, Z_2 + 2\, Z_1\, Z_2\}} \quad (2)$$

$$I_1 = \frac{-\, E\, s\, Z_m\,[(2 - s)\, Z_m + Z_2]}{2\, Z_0\{s(2 - s)Z_m^2 + (2 - s)Z_m\, Z_1 + s\, Z_m\, Z_2 + Z_1\, Z_2\} + Z_m\{\,(2 - s)\, Z_m Z_1 + s\, Z_m\, Z_2 + 2\, Z_1\, Z_2\}} \quad (3)$$

$$I_2 = \frac{-\, E\,(2 - s)\, Z_m\,(s\, Z_m + Z_1)}{2\, Z_0\{s(2 - s)Z_m^2 + (2 - s)Z_m\, Z_1 + s\, Z_m\, Z_2 + Z_1\, Z_2\} + Z_m\{\,(2 - s)\, Z_m\, Z_1 + s\, Z_m\, Z_2 + 2 Z_1\, Z_2\}} \quad (4)$$

The equations of a two-phase motor of same constants per phase are easily found to be

$$(Z_m + Z_0)\, I_0 + Z_m\, I_1' = E$$
$$s\, Z_m\, I_0 + (s\, Z_m + Z_1)\, I_1' = 0$$

where I_0 = primary current per phase and I_1' = secondary current.
Here from

$$I_0 = \frac{E\,(s\, Z_m + Z_1)}{s\, Z_m\, Z_0 + Z_m\, Z_1 + Z_0\, Z_1} \quad (5)$$

$$I_1' = \frac{-\, E\, s\, Z_m}{s\, Z_m\, Z_0 + Z_m\, Z_1 + Z_0\, Z_1} \quad (6)$$

The apparent impedance per phase of the two-phase motor at slip s then is

$$Z_a = \frac{E}{I_0} = \frac{s\, Z_m\, Z_0 + Z_m\, Z_1 + Z_0\, Z_1}{s\, Z_m + Z_1}$$

The apparent impedance at same speed rotating backwards is

$$Z_b = \frac{E}{I_0} = \frac{(2 - s)\, Z_m\, Z_0 + Z_m\, Z_2 + Z_0\, Z_2}{(2 - s)\, Z_m + Z_2}$$

Adding the apparent impedances of both rotations

$$Z_a + Z_b = \frac{s\, Z_m\, Z_0 + Z_m\, Z_1 + Z_0\, Z_1}{s\, Z_m + Z_1} + \frac{(2 - s)\, Z_m\, Z_0 + Z_m Z_2 + Z_0\, Z_2}{(2 - s)\, Z_m + Z_2} =$$

$$\frac{2\, Z_0\{s(2 - s)Z_m^2 + (2 - s)Z_m\, Z_1 + s\, Z_m\, Z_2 + Z_1\, Z_2\} + Z_m\{\,(2 - s)Z_m Z_1 + s\, Z_m\, Z_2 + 2\, Z_1\, Z_2\}}{s\,(2 - s)\, Z_m^2 + (2 - s)\, Z_m\, Z_1 + s\, Z_m\, Z_2 + Z_1\, Z_2}$$

Comparing with (2) it will be seen that the apparent impedance of a single-phase motor at slip s is one half the sum of the apparent impedances of a two-phase motor of same constants at slips s and $(2 - s)$. Furthermore, if the impedance drop $\frac{Z_a\, I_s}{2}$ be substituted for E in (6) the result is identical with (3), showing that the low frequency component of secondary current is equal to the two-phase secondary current at this reduced voltage. Similarly, the high frequency component of secondary current is seen to be equal to the two-phase secondary current at slip $(2 - s)$ and the voltage reduced to $\frac{Z_b\, I_s}{2}$. The torque components of the single-phase motor in positive and negative directions are likewise seen to be equal to the torques of the two-phase machine at corresponding slips and reduced voltages.

It follows therefore that in calculating the performance by the graphical method there is no need of a special diagram for the single-phase motor, the same diagram being applicable to both polyphase and single-phase motors.

Induction Phase Converter

In applications where it is essential to obtain polyphase power from a single phase supply an induction phase converter is often used to effect the desired transformation. The converter consists essentially of a single-phase induction motor with a tertiary circuit on the stator displaced at a certain angle from the primary circuit. Thus, in Fig. 5, R is the rotor of a single-phase motor, P_1 the primary winding and P_2 the tertiary winding displaced 90 deg. in positive

direction from P_1. P_2' is one phase of a load circuit, on which it is desired to impress a voltage in quadrature to the voltage on the other phase, P_1', and as nearly as possible equal to it in magnitude. In Fig. 6 is shown a phase converter with the primary connected in series with one of the load phases, as distinguished from the shunt connection of Fig. 5.

Using the same notation as before, the mutual and self inductive impedances of the tertiary circuit are respectively equal to the mutual and self inductive impedances of the primary Z_m and Z_0. Let Z_a be the

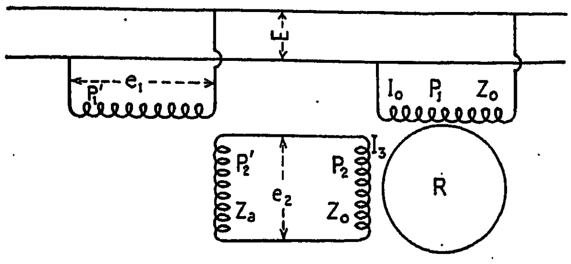

FIG. 5

impedance per phase of the load circuit and let $Z_0' = Z_a + Z_0$. The speed being very close to synchronous, the forwardly rotating component of secondary current can be neglected, that is $I_1 = 0$. The voltage generated in the tertiary circuit by the backwardly rotating component of secondary current is 90 deg. ahead of the voltage generated by this current in the primary circuit and is, therefore, $Z_m I_2 \epsilon^{j\frac{\pi}{2}} = j\, Z_m I_2$.

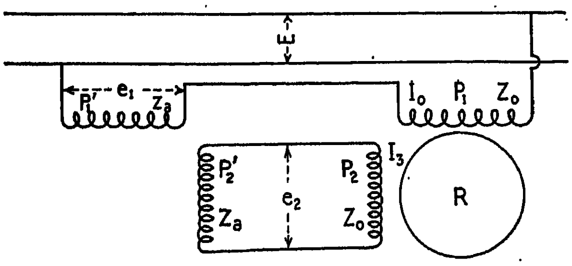

FIG. 6

The double-frequency voltage generated in the secondary by the current in the tertiary circuit is likewise seen to be $Z_m I_3 \epsilon^{-j\frac{\pi}{2}} = -j\, Z_m I_3$.

From Fig. 5 is then readily obtained

$$\left.\begin{aligned} (Z_m + Z_0)\, I_0 + Z_m I_2 \quad\quad\quad &= E \\ Z_m I_0 + (2\, Z_m + Z_2)\, I_2 - j\, Z_m I_3 &= 0 \\ j\, Z_m I_2 + (Z_m + Z_0')\, I_3 \quad &= 0 \end{aligned}\right\} \quad (7)$$

Solving

$$I_0 = \frac{E\,[Z_m^2 + Z_m Z_2 + 2\, Z_m Z_0' + Z_2 Z_0']}{(Z_m+Z_0)[Z_m Z_2 + 2\, Z_m Z_0' + Z_2 Z_0'] - Z_m^2 Z_a} \quad (8)$$

$$I_2 = \frac{-E\,(Z_m^2 + Z_m Z_0')}{(Z_m+Z_0)[Z_m Z_2 + 2\, Z_m Z_0' + Z_2 Z_0'] - Z_m^2 Z_a} \quad (9)$$

$$I_3 = \frac{j\, E\, Z_m^2}{(Z_m+Z_0)[Z_m Z_2 + 2\, Z_m Z_0' + Z_2 Z_0'] - Z_m^2 Z_a} \quad (10)$$

$$e_2 = Z_a I_3$$

Denoting the denominator by D, it is interesting to note that the first term of I_0 is $\frac{E\, Z_m^2}{D}$, which, combined with $I_3 = j\, \frac{E\, Z_m^2}{D}$ produces a m. m. f. rotating backwards, which is balanced by the first term of I_2, which is equal to $\frac{-E\, Z_m^2}{D}$. It is, therefore, the double

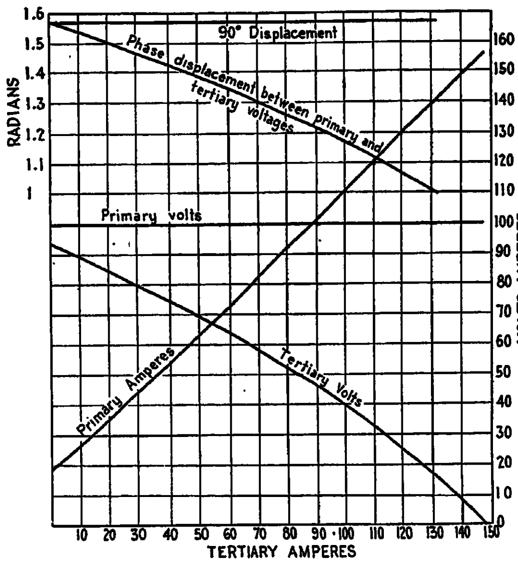

FIG. 7

frequency component of secondary current which increases with increasing load on the tertiary circuit. In Fig. 7 are shown the curves of a shunt connected converter of the following constants: $Z_0 = 0.05 + j\, 0.15$ $Z_2 = 0.05 + j\, 0.03$ $Z_m = 0.975 + j\, 9.9$ $E = 100$. Z_a is assumed to vary so as to maintain a constant power factor of 80 per cent.

For the series-connected converter is obtained the following equations from Fig. 6:

$$\left.\begin{aligned} (Z_m + Z_0')\, I_0 + Z_m I_2 \quad\quad\quad &= E \\ Z_m I_0 + (2\, Z_m + Z_2)\, I_2 - j\, Z_m I_3 &= 0 \\ j\, Z_m I_2 + (Z_m + Z_0')\, I_3 \quad &= 0 \end{aligned}\right\} \quad (11)$$

and here from

$$I_0 = \frac{E\,[Z_m^2 + Z_m Z_2 + 2\, Z_m Z_0' + Z_2 Z_0']}{(Z_m + Z_0')\,[Z_m Z_2 + 2\, Z_m Z_0' + Z_2 Z_0']} \quad (12)$$

$$I_2 = \frac{-E\,(Z_m^2 + Z_m Z_0')}{(Z_m + Z_0')\,[Z_m Z_2 + 2\, Z_m Z_0' + Z_2 Z_0']} \quad (13)$$

$$\frac{j\,E\,Z_m^2}{(Z_m + Z_0)\,[Z_m Z_2 + 2\,Z_m Z_0' + Z_m Z_0']} \qquad (14)$$

$$e_1 = Z_a I_0 \quad e_2 = Z_a I_3$$

In Fig. 8 are shown the curves of the same converter shown in Fig. 7, except that it is connected in series. It will be noted that with the series connection the

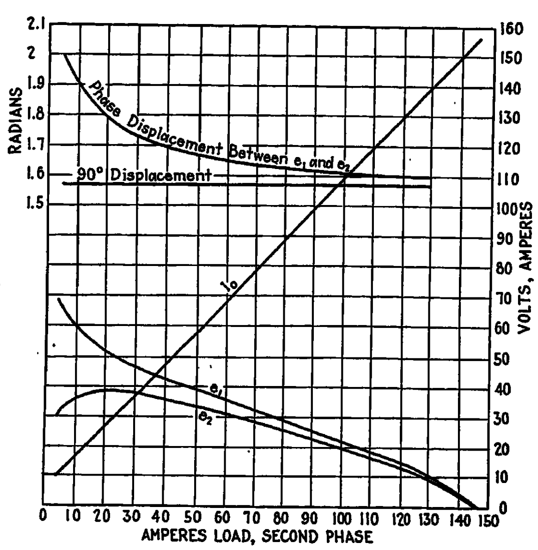

Fig. 8

phase voltages of the load circuit tend towards equality in magnitude and quadrature relation in phase as the load increases, while the reverse is true for the shunt connection.

Repulsion Motor

As illustration of the application of the method to commutator motors, consider the repulsion motor shown diagramatically in Fig. 9. It being at the present merely intended to show that the rotating field theory is applicable to commutator motors also, only the plain repulsion motor will be considered, although the method can be readily extended to the various forms of compensated motors, and to include the phenomena of brush short-circuit currents.

In Fig. 9 let the brushes be shifted λ radians in positive direction from the line $A\,B$, which is the position of maximum mutual inductive effect between stator and rotor circuits. As in the single-phase induction motor, there are two voltages generated in the secondary of frequencies s and $(2 - s)$. However, the currents resulting from these voltages are converted by the commutator into line frequency at all speeds, and consequently combine into one secondary current. The voltage induced in the primary by the positively rotating component of the secondary current is advanced λ radians in phase, and the voltage generated by the negatively rotating component is retarded λ radians. The voltage equation of the primary is, therefore,

$$(Z_m + Z_0)\,I_0 + \frac{Z_m I_1}{2}\,\epsilon^{j\lambda} + \frac{Z_m I_1}{2}\,\epsilon^{-j\lambda} = E$$

Similarly the voltage equation of the secondary is seen to be

$$Z_m\left[\frac{s\,\epsilon^{-j\lambda}}{2} + \frac{(2-s)\,\epsilon^{j\lambda}}{2}\right] I_0 + \left[\frac{s\,Z_m}{2} + \frac{(2-s)\,Z_m}{2} + Z_1\right] I_1 = 0$$

Substituting

$$\epsilon^{j\lambda} = \cos\lambda + j\sin\lambda$$
$$\epsilon^{-j\lambda} = \cos\lambda - j\sin\lambda$$

and the voltage equations reduce to

$$\left.\begin{aligned} (Z_m + Z_0)\,I_0 + Z_m\cos\lambda\, I_1 &= E \\ Z_m[\cos\lambda + j(1-s)\sin\lambda]I_0 + (Z_m + Z_1)I_1 &= 0 \end{aligned}\right\} \qquad (15)$$

Solving

$$I_0 = \frac{E\,(Z_m + Z_1)}{[Z_m^2 + Z_m Z_0 + Z_m Z_1 + Z_0 Z_1] - Z_m^2\cos\lambda\,[\cos\lambda + j\,(1-s)\sin\lambda]} \qquad (16)$$

$$I_1 = \frac{-E\,Z_m\,[\cos\lambda + j\,(1-s)\sin\lambda]}{[Z_m^2 + Z_m Z_0 + Z_m Z_1 + Z_0 Z_1] - Z_m^2\cos\lambda\,[\cos\lambda + j\,(1-s)\sin\lambda]} \qquad (17)$$

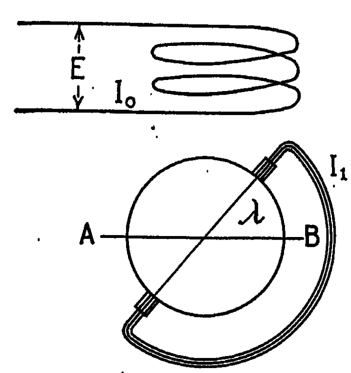

Fig. 9

The exciting current of the positively rotating field

$$I_0' = \frac{I_0\,\epsilon^{-j\lambda} + I_1}{2}$$

$$= \frac{Z_1\,\epsilon^{-j\lambda} - j\,(2-s)\,Z_m\sin\lambda}{2\,\{[Z_m^2 + Z_m Z_0 + Z_m Z_1 + Z_0 Z_1] - Z_m^2\cos\lambda\,[\cos\lambda + j\,(1-s)\sin\lambda]\,\}} \qquad (18)$$

The exciting current of the negatively rotating field

$$I_0'' = \frac{I_0\,\epsilon^{j\lambda} + I_1}{2}$$

$$= \frac{Z_1 \epsilon^{j\lambda}}{2\{[Z_m^2 + Z_m Z_0 + Z_m Z_1 + Z_0 Z_1]}$$

$$\frac{+ j\, s\, Z_m \sin\lambda}{- Z_m^2 \cos\lambda\,[\cos\lambda + j\,(1 - s)\sin\lambda]\,\}} \tag{19}$$

The voltage induced by the positively rotating field

$$e_1 = I_0^1 X_m \epsilon^{-j\left(\frac{\pi}{2} + \psi\right)}$$

and the voltage induced by the negatively rotating field

$$e_2 = I_0'' X_m \epsilon^{j\left(\frac{\pi}{2} - \psi\right)},$$

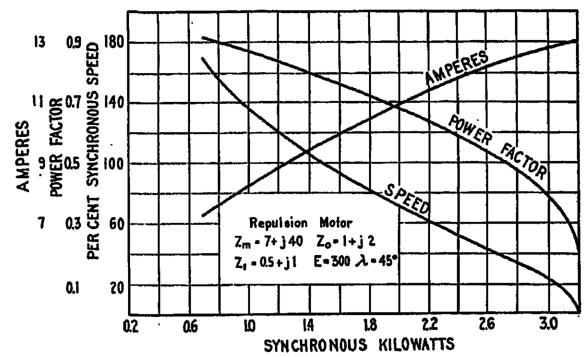

FIG. 10

where ψ is the angle by which the exciting current leads the true magnetizing current

The torque developed by the positively rotating field $T_1 = e_1 I_1 \cos\omega_1$, ω_1 = phase angle between e_1 and I_1.

The torque developed by the negatively rotating field $T_2 = e_2 I_2 \cos\omega_2$, ω_2 = phase angle between e_2 and I_2.

Resultant torque $= T_1 + T_2$.

Fig. 10 shows the curves of a motor of constants $Z_m = 7 + j\,40$ $Z_0 = 1 + j\,2$ $Z_1 = 0.5 + j\,1$ $E = 300$ $\lambda = 45$ deg.

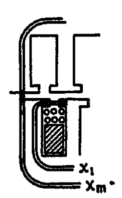

FIG. 11

POWER-FACTOR COMPENSATION

To further illustrate the application of the above method to commutator motors, it may be of interest to consider the case where one of the rotating fields vanishes, that is the symmetrical polyphase motor. There is, apparently, an increasing demand for means of correcting power factor on inductive loads, and the use of commutators in connection with induction motors may, therefore, become of considerable importance in the near future. In Steinmetz's "Theory and Calculation of Electrical Apparatus" (Pages 52-92 and page 379) are discussed a number of methods of power-factor compensation.

The simplest and most economical of the various methods proposed appears to be the so-called Heyland motor. In addition to the ordinary squirrel-cage, the rotor of the Heyland motor is supplied with a compensating winding connected to a commutator and usually placed in the same slots as the rotor bars. By means of brushes bearing on the commutator, a voltage of suitable magnitude and phase is impressed on the compensating winding.

With the compensating winding placed in the same slots as the rotor bars, practically all of the cage leakage reactance becomes a part of the mutual reactance between the cage and the compensating winding. The impedance of the cage Z_1 can, therefore, be considered as consisting of the resistance, r_1, only. The mutual impedance between the cage and the compensating winding, $Z_m' = Z_m + j\,x_1$, where Z_m is the mutual impedance between the primary winding and the cage, and also the mutual impedance between

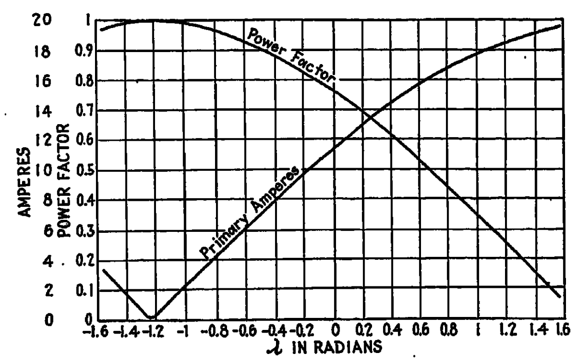

FIG. 12

the primary and the compensating winding reduced to primary terms. $Z_2 = r_2 + j\,x_2$ is the impedance of the compensating winding in terms of primary, x_2, which is the reactance of the leakage flux around the end windings, remains constant at all speeds.

Let I_0, I_1 and I_2 be the current in the primary, the the squirrel cage and the compensating winding, respectively, all in terms of primary. With the brushes shifted λ radians in positive direction, and a voltage $c\,E$ impressed on the commutator, the voltage equation of the three circuits are

$$\left.\begin{aligned} (Z_m + Z_0)\, I_0 + Z_m I_1 + Z_m \epsilon^{j\lambda} I_2 &= E \\ s\, Z_m I_0 + (s\, Z_m' + Z_1)\, I_1 + s\, Z_m' \epsilon^{j\lambda} I_2 &= 0 \\ s\, Z_m \epsilon^{-j\lambda} I_0 + s\, Z_m' \epsilon^{-j\lambda} I_1 + (s\, Z_m' + Z_2)\, I_2 &= c\,E \end{aligned}\right\} \tag{20}$$

solving

$$I_0 = \frac{E\,\{\, s\, Z_m' (Z_1 + Z_2)}{s(Z_1 + Z_2)\,[Z_m' (Z_m + Z_0) - Z_m^2]}$$

$$\frac{+ Z_1 Z_2 - c\, Z_m Z_1 \epsilon^{j\lambda}\,\}}{+ Z_1 Z_2 (Z_m + Z_0)} \tag{21}$$

$$I_1 = \frac{-\,s\,E\,\{\,Z_m\,Z_2 + c\,[Z_m'\,(Z_m + Z_0) - Z_m^2]\,\epsilon^{j\lambda}\}}{s\,(Z_1 + Z_2)\,[Z_m^1\,(Z_m + Z_0) - Z_m^2] + Z_1\,Z_2\,(Z_m + Z_0)} \qquad (22)$$

$$I_2 = \frac{s\,E\,\{\,c\,[\,Z_m'\,(Z_m + Z_0) - Z_m^2\,] - Z_m'\,Z_1\epsilon^{-j\lambda}\} + c\,E\,Z_1(Z_m + Z_0)}{s\,(Z_1 + Z_2)\,[\,Z_m'\,(Z_m + Z_0) - Z_m^2] + Z_1\,Z_2\,(Z_m + Z_0)} \qquad (23)$$

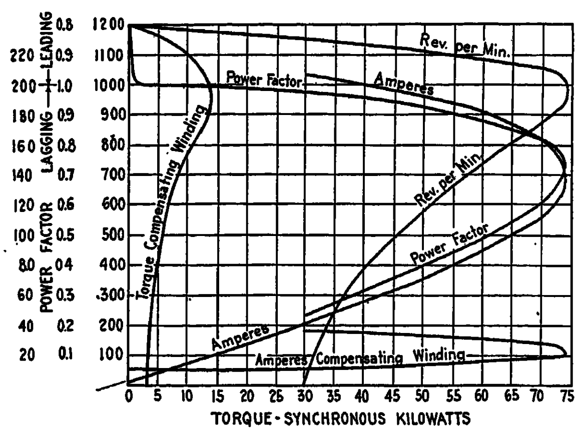

FIG. 13

The exciting current

$$I_0' = I_0 + I_1 + I_2\,\epsilon^{j\lambda} =$$

$$\frac{E\,\{\,s\,(Z_1 + Z_2)\,(Z_m' - Z_m) + Z_1\,(Z_2 + c\,Z_0\,\epsilon^{j\lambda}\,\}}{s\,(Z_1 + Z_2)[Z_m'(Z_m + Z_0) - Z_m^2] + Z_1\,Z_2(Z_m + Z_0)} \qquad (24)$$

$$e_1 = X_m\,I_0'\,\epsilon^{-j\,(\frac{2}{\pi} + \phi)} \qquad e_2 = x_m\,I_0'\,\epsilon^{-j\,(\frac{\pi}{2} + \phi + \lambda)}$$

$$T_1 = e_1\,I_1 \cos\,\omega_1 \qquad T_2 = e_2\,I_2 \cos\,\omega_2$$

Resultant torque $T = T_1 + T_2$

At synchronism $s = 0 \quad I_1 = 0$ and

$$I_0 = \frac{E\,(Z_2 - c\,Z_m\,\epsilon^{j\lambda})}{Z_2\,(Z_m + Z_0)} \qquad (25)$$

$$I_2 = \frac{c\,E}{Z_2} \qquad (26)$$

From formula (25) it will be seen that I_0 becomes equal to zero when c and λ are so chosen that $Z_2 = c\,Z_m\,\epsilon^{j\lambda}$. However, to get complete compensation when loaded the motor must be somewhat over compensated at no load.

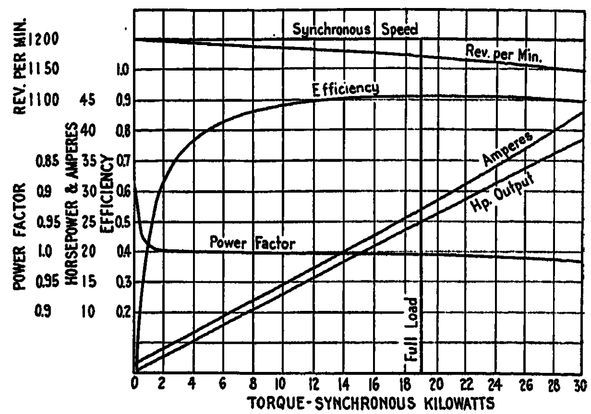

FIG. 14

As illustration a 25 h. p. 3-phase 440-volts star connected motor has the following constants

$Z_m = 2.5 + j\,25 \quad Z_m' = 2.5 + j\,25.6 \quad Z_0 = 0.2 + j0.56$

$Z_1 = 0.3 \qquad Z_2 = 1 + j\,0.25$

Letting $c = 0.0415$, Fig. 12 shows the no-load values for different brush positions. Figs. 13 and 14 show the speed-torque curves and performance over the operating range when c is increased to 0.0435 and λ fixed at 1.3 — radians.

On a Design for a Bifilar Type of Non-Reactive Resistance Coil

BY H. NUKIYAMA[1] and Y. SHOJI[2]
Associate, A. I. E. E. Non-member

Synopsis.—*A bifilar non-reactive coil usually gives a condensive reactance at high frequency. The present paper analyses this frequency error observed over the audio-frequency range. An impedance characteristic curve is recognized, resembling that of an electric cable. From this experimental fact, a cable theory of a bifilar non-reactive coil is deduced. Employing an experimental constant, which the writers call the apparent dielectric constant K, a method is given for designing a 100,000-ohm coil, which gives a phase angle less than 5 deg., at a frequency of 5000 cycles per second, assuming the apparent dielectric constant to be K = 3.*

* * * * *

I—Experiment to Determine the Frequency Characteristic of a Bifilar Type of Non-Reactive Coil

A B. w. g., No. 36 silk covered manganin wire was used, which has the following constants.

d = diameter (bare) = 0.01015 cm.
D = diameter (silk covered) = 0.0198 cm.
R = 46.5 ohms per wire meter.

Two parallel lengths of this wire, as shown in Fig. 1, were put lightly in contact, resulting in a bifilar resistance. This bifilar loop was arranged as shown in Fig. 2, in order to measure its impedance. In Fig. 2, T, is about 5.75 meters and U is about 6.5 cm.

The wire was stretched in a vertical plane, parallel to the wooden wall of the room, and the distance between the parallels was about 13 cm. By the arrangement described above, the mutual electrostatic

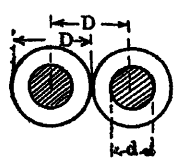

FIG. 1—CROSS SECTION OF THE BIFILAR RESISTANCE

and magnetic effects in the lengths of wire and those between them and earth, which must exist in a practical bifilar coil were minimized. This made an ideal bifilar resistance, which is identical with a simple uniform cable line. The length from A to B (one half of the total wire length) was 215 meters, and 20,000 ohms was selected as the direct-current resistance of this bifilar coil, when B was short-circuited. In order to observe the variation of the impedance of the ideal bifilar resistance with the frequency, the impedance measurement was taken over the audio-frequency range. The measuring arrangement is shown in Fig. 3 where the plieotron oscillator is used as the alternating-current source, and the frequency is changed by adjusting the condenser C_1. By connecting the A end of the bifilar coil (Fig. 2) to the arm A of the impedance bridge, the impedance of the bifilar coil can be measured by adjusting R and C. Curtis coil resistances were used as the non-reactive resistances represented by R_1, R_2, R. These Curtis coils were previously ascertained to be practically non-reactive, compared with the non-reactive resistances of a mannit solution and a graphite-bar. The results of measurement are recorded in Table I. In this Table, Z_s is the impedance when the B end is short-circuited and

$$Z_s = r_s - j\frac{1}{\omega c_s} \qquad \text{Ohms} \angle$$

In the same Table, Z_f is the impedance when the B end is open-circuited and

$$Z_f = r_f - j\frac{1}{\omega c_f} \qquad \text{Ohms} \angle$$

The short-circuit impedance Z_s is vectorially represented in Fig. 4. As can be seen in this figure, the size of the short-circuit impedance Z_s is almost constant up to 1000 cycles per second; but the condensive reactance increases rapidly at first, as the frequency becomes larger. The increasing rate of the condensive reactance becomes gradually smaller, and the decreasing rate of the effective resistance becomes larger. Near the frequency of 2500 cycles per second, the condensive reactance becomes a maximum.

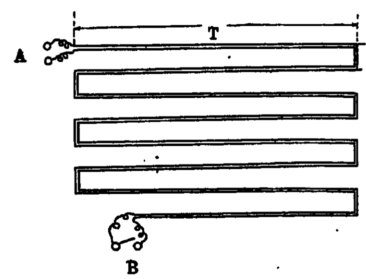

FIG. 2—IDEAL ARRANGEMENT OF THE BIFILAR RESISTANCE

Next, the arrangement of the bifilar resistance was left unchanged, as shown in Fig. 2, but the wire was coated with a paraffin solution over the silk insulation, as shown in Fig. 5. The result of the measurement of this bifilar resistance is shown in Table II and Fig. 6.

---

1. Prof. of Electrical Engineering, Tohoku Imperial University, Japan.
2. Associate Denki Gakkai.

The impedance characteristic curve is similar to that of the previous case, but the curve is elongated on the same locus.

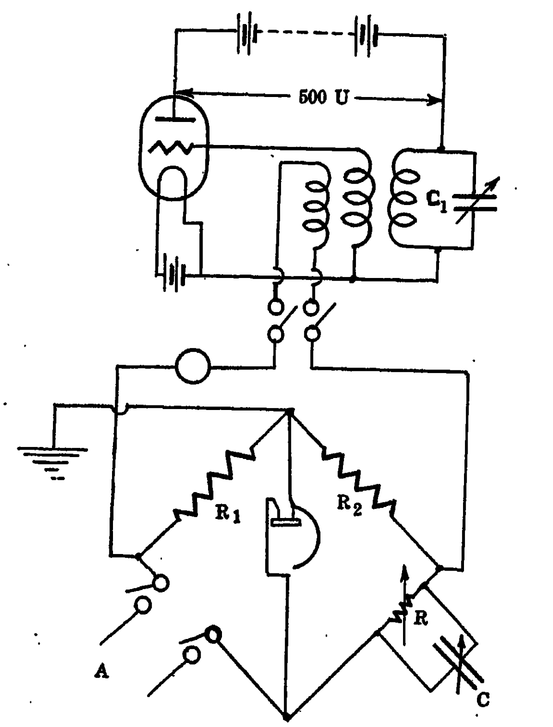

FIG. 3—DIAGRAM OF CONNECTIONS FOR MEASURING THE IMPEDANCE OF THE BIFILAR RESISTANCE

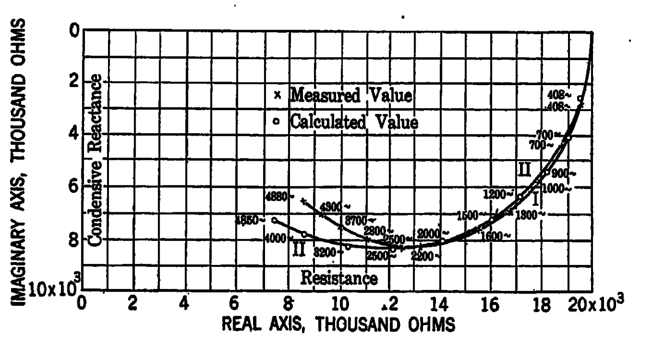

FIG. 4—IMPEDANCE CHARACTERISTICS OF THE BIFILAR RESISTANCE IN THE IDEAL ARRANGEMENT (NOT IMPREGNATED WITH PARAFFIN)

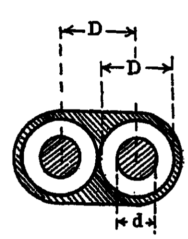

FIG. 5—CROSS SECTION OF THE BIFILAR RESISTANCE (PARAFFINED)

The arrangement shown in Fig. 2 was then taken down, and wound progressively along the axis of a bobbin as shown in Fig. 7. By winding in this way, we reduce the effect of stored electrostatic energy, *i. e.*, the condensive reactance effect, as the turns which have a greater potential difference are thus not contiguous. The impedance of this wound bifilar coil, was then measured. The result is shown in Table III and Fig. 8. In this case, the locus is almost identical with the other two already mentioned, but points of same frequency shift forward on the same locus.

II—Theory of a Bifilar Coil as an Electric Cable

As can be seen from the experimental results stated above, the impedance characteristic of the bifilar resistance is very similar to that of an electric cable. The idea of this similarity can be realized from the construction of the bifilar coil, which has a smaller linear self-inductance and larger linear capacity, as it is formed by wires closely in contact. With this idea, we treated the bifilar resistance as a uniform electric line and found its constants from the short-

is nearly zero, and that of the total admittance Y is nearly 90 deg. From these facts, we can see that linear impedances are approximately pure resistances, and linear admittances are approximately pure susceptances. The quotient of the imaginary part of the linear admittance $y = g + j\,\omega\,c$, divided by ω, is

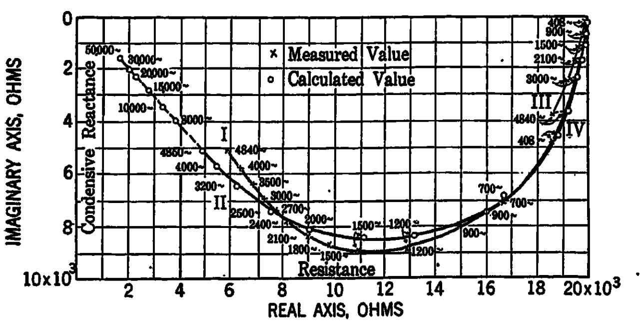

FIG. 8—IMPEDANCE CHARACTERISTICS OF THE BIFILAR RESISTANCE WHEN WOUND ON A BOBBIN

the linear capacity. In Tables I, II and III, column 12 represents these linear capacities in micro-farads per km. The value of these capacities slightly decreases as the frequency increases; but can be considered to be practically constant. Now we take the average value of these linear capacities and derive the equation

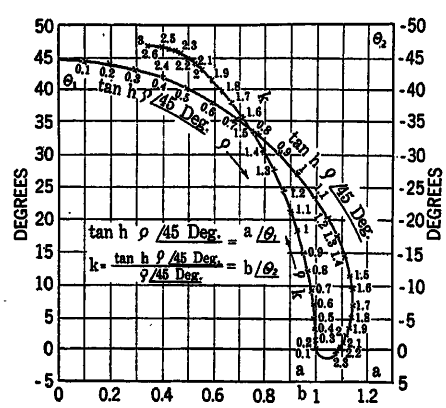

FIG. 9—CHART SHOWING THE VALUE OF CORRECTING FACTOR k

of a uniform line which has the linear impedance of pure resistance r and linear admittance of pure condensive susceptance $\omega\,c$. So $z = r$, $y = j\,\omega\,c$.

The surge impedance and the linear hyperbolic angle are

$$z_0 = \sqrt{\frac{z}{y}} = \sqrt{\frac{r}{j\,\omega\,c}} = \sqrt{\frac{r}{\omega\,c}}\;\backslash 45^\circ \qquad \text{Ohms} \angle \quad (5)$$

$$\alpha = \sqrt{z\,y} = \sqrt{j\,\omega\,c\,r} = \sqrt{\omega\,c\,r}\;/45^\circ \qquad \text{Hyps.} \angle \quad (6)$$

The impedance Z_s of the bifilar coil is

$$Z_s = z_0 \tanh \alpha\,x = \sqrt{\frac{r}{\omega\,c}}\;\backslash 45^\circ \tanh\,(x\,\sqrt{\omega\,c\,r}\;/45^\circ) \qquad \text{Ohms} \angle \quad (7)$$

From these equations, the impedance of the bifilar coil is easily calculated, by the use of a table of semi-imaginary hyperbolic tangents. Fig. 9 shows diagrammatically the semi-imaginary hyperbolic tangent (Bibliography 4, 5). The letters along the curve show the size of the angle, the abscissa shows that of the tanh, and the ordinate the slope of the tanh.

In the case of Table I, $x = 0.215$ km.

$r = 93{,}000$ ohms/km. $c_1 = 0.035\ \mu f$/km.

In the case of Table II, $x = 0.215$ km.

$r = 93{,}000$ ohms/km. $c_1 = 0.0558\ \mu f$/km.

In the case of Table III, $x = 0.215$ km.

$r = 93{,}000$ ohms/km. $c_1 = 0.065\ \mu f$/km.

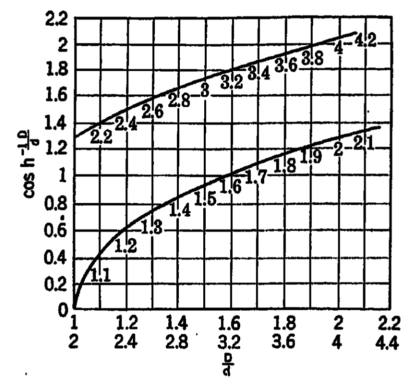

FIG. 10—VALUE OF $\text{COSH}^{-1}\frac{D}{d}$

The value of theoretical impedance which has been calculated from Eq. (7), through the use of Fig. 9, is indicated by Curve II in Figs. 6 and 9. As can be seen in Eq. (7), $\omega\,c$ is always combined as one term, so when r is constant, the change in the value of c does not change the impedance locus, but the point corresponding to a given frequency shifts forward on the same locus by the increase of c comparing these results with the results of measurement, identity can

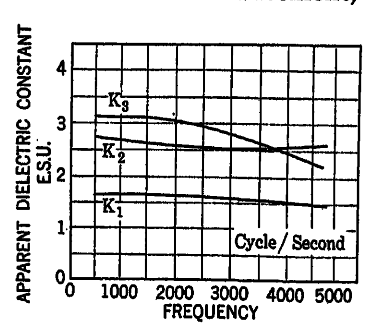

FIG. 11—APPARENT DIELECTRIC CONSTANT

be found in both cases. We can thus treat the problem of the bifilar coil by the theory of the ideal electric cable.

III—Apparent Dielectric Constant

We may compare the linear capacity obtained by experiment with the linear capacity obtained by theory.

When the line is constructed as shown in Fig. 1, and the insulating medium is air, the theoretical linear capacity c_0 is

$$c_0 = \frac{0.02778}{\cosh^{-1}\dfrac{D}{d}} = 0.02135\ \mu f/\text{km}. \qquad (8)$$

Where $d = 0.01015 \quad D = 0.0198$ cm.

Fig. 10 shows the curve of $\cosh^{-1}\dfrac{D}{d}$ for the smaller values of $\dfrac{D}{d}$, for aid in design. In the ideal case of the bifilar coil, the linear resistance is constant for a given resistance wire, and the linear capacity only changes with the arrangement of the wire. From these considerations, we call the ratio of the linear capacity c which is obtained by experiment, with a theoretical linear capacity c_0 as an apparent dielectric constant of a given line arrangement. The calculation of the design will be conveniently made on the basis of this dielectric constant. The apparent dielectric constant

$$K_1 = \frac{c_1}{c_0}, \; K_2 = \frac{c_2}{c_0}, \; K_3 = \frac{c_3}{c_0} \qquad (9)$$

These data in Tables I, II and III are shown diagrammatically in Fig. 11 as a function of the frequency.

In the case of Table I, the apparent dielectric constant K_1 has the value of nearly 1.6, and is independent of the frequency. This value is satisfactory, as silk is used for insulation. As can be seen in Table II, when paraffin is used for the insulation, the apparent dielectric constant K_2 is approximately 2.6, and independent of the frequency. In Fig. 5 the cross-hatched parts are filled with paraffin, which has a dielectric constant nearly 2, so the increase of apparent dielectric constant to the value of 2.6 is reasonable. Next in the case of Table III, when the wire is wound on the bobbin, the apparent dielectric constant K_3 increases to 3.1, and is almost constant in the frequency range up to 2000 ~; but in the higher frequencies decreases remarkably. In this case, turns of the wire at different potentials are in contact with each other, so that the apparent dielectric constant may increase to some extent (in this example approximately 20 per cent) and owing to relative electrical conditions between the wires, complicated electrical phenomena may occur in the winding, consequently the apparent dielectric constant changes with the frequency. But as in this case, if the apparent dielectric constant does not vary beyond a reasonable range, it may be conveniently used for calculation in the design. The inductive effects of the current will probably cancel as the bifilar is wound at random on the bobbin. In the practical design, we should have more experimental constants, but the writers have not sufficient data, so we assume the value of K to be large enough to make allowance for the error.

IV—Method of Reducing the Error in the Bifilar Resistance due to Frequency

The simplest method of reducing the error due to frequency, is to sectionalize the coil into many parts of shorter wire lengths. This can be ascertained from Eq. (7). From Eq. (7)

$$Z_s = x\,r\,\frac{\tanh\left(x\sqrt{\omega\, c\, r}\,\underline{/45^\circ}\right)}{x\sqrt{\omega\, c\, r}\,\underline{/45^\circ}} \quad \text{Ohms} \angle \qquad (10)$$

$z = x\,r$ shows the ideal case where there is no error.

so
$$k = \frac{\tanh\left(x\sqrt{\omega\, c\, r}\,\underline{/45^\circ}\right)}{x\sqrt{\omega\, c\, r}\,\underline{/45^\circ}} \quad \text{numeric} \angle \qquad (11)$$

is the error factor.

As can be seen in Fig. 9, the error factor k is approximately 1 when the total hyperbolic angle $x\sqrt{\omega\, c\, r}\,\underline{/45^\circ}$ of a bifilar coil is very small, so for given ω, C, R, we can reduce the error by sectionalizing the total length of coil into many shorter parts. As shown in Fig. 12,

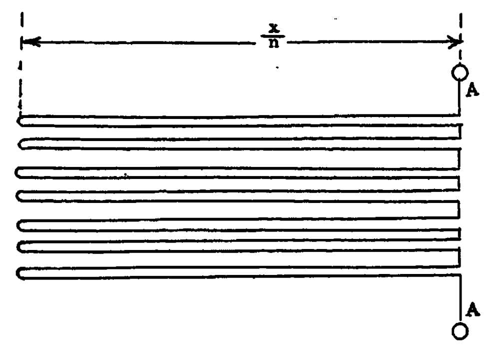

Fig. 12—Sectionalized Bifilar Resistance

if the coil be divided into n sections and connected in series. The impedance Z between both ends A A is

$$Z = n\left\{\frac{x}{n}\,r\,\frac{\tanh\left(\frac{x}{n}\sqrt{\omega\, c\, r}\,\underline{/45^\circ}\right)}{\frac{x}{n}\sqrt{\omega\, c\, r}\,\underline{/45^\circ}}\right\}$$

$$= x\,r\,\frac{\tanh\left(\frac{x}{n}\sqrt{\omega\, c\, r}\,\underline{/45^\circ}\right)}{\frac{x}{n}\sqrt{\omega\, c\, r}\,\underline{/45^\circ}} \quad \text{Ohms} \angle \qquad (12)$$

The error factor

$$\frac{\tanh\left(\frac{x}{n}\sqrt{\omega\, c\, r}\,\underline{/45^\circ}\right)}{\frac{x}{n}\sqrt{\omega\, c\, r}\,\underline{/45^\circ}}$$

will become smaller by increasing the number of sections n.

When the total resistance $x\,r = R$ is given,

$$\frac{x}{n}\sqrt{\omega\,c\,r}\;\underline{/45^\circ} = \frac{R}{n}\sqrt{\frac{\omega\,c}{r}}\;\underline{/45^\circ}$$

As can be seen from the above equations, the error can be reduced by the use of material of larger linear resistance r; but this method will be practically restricted. On the other hand, the method of sectionalizing is simple and efficient, and is not difficult in practise. We divided the bifilar coil which had been used in previous experiment, into four sections. To obtain the value of k when $\omega = 20{,}000$, ($f = 3180 \sim$), $K = 3.1$, $c_0 = 0.02135\ \mu f/\text{km.}$, $c = c_0 = 0.0662$ $\mu f\,/km.$

The linear hyperbolic angle α is

$$\alpha = \sqrt{20{,}000 \times 0.0662 \times 10^{-6} \times 93{,}000}\;\underline{/45^\circ}$$
$$= 11.09\;\underline{/45^\circ} \quad \text{Hyps. } \angle$$

The total hyperbolic angle θ of one section is

$$\theta = \frac{0.215}{4}\,\alpha = 0.597\;\underline{/45^\circ} \qquad \text{Hyps. } \angle$$

From Fig. 9,

$$k = \frac{\tanh 0.597\;\underline{/45^\circ}}{0.597\;\underline{/45^\circ}} = 0.99\;\overline{\backslash 6^\circ}\,5$$

When the coil is sectionalized into four sections, the error is 1 per cent in size, and 6 deg. 30 min. in slope, at $\omega = 20{,}000$. In order to test the theory, we sectionalized the coil which has been shown in Fig. 7 into 20

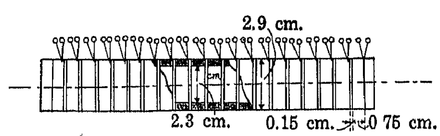

FIG. 13—ACTUAL ARRANGEMENT OF THE SECTIONALIZED BUFILAR RESISTANCE

sections, as shown in Fig. 13. It was first connected as the 4-section coil, and the frequency character of the impedance was measured. The result is shown in

TABLE IV
TABLE OF CONSTANTS WHEN THE BIFILAR RESISTANCE WAS DIVIDED INTO 4 SECTIONS

$f \sim$	r_s ohm	$c_s\ \mu f$	Z_s ohm
408	19960	1.025	19960$-j$ 382
900	19780	0.231	19780$-j$ 765
1500	19620	0.0858	19620$-j$1240
2100	19410	0.0445	19410$-j$1700
3000	19130	0.022	19130$-j$2410
4500	18600	0.0087	18600$-j$3770

Table IV and Fig. 8 by Curve III. Curve IV in Fig. 8 is that calculated by Eq. (**12**), and Fig. 9, and the differences between these curves are very small. Next we made the coil into 20 sections, by suitably connecting the same coils. We could detect no reactance in this sectionalized coil.

V—Calculation Example

Using a resistance material of the following constants. B. w. g., No. 44 silk covered manganine wire.

d = diameter (bare) = 3 mils = 0.00761 cm.

D = diameter (silk covered) = 7 mils = 0.01778 cm.

r = 1.424×10^5 ohms per loop km. ($\frac{1}{2} \times 1.424 \times 10^5$ ohms per wire km.)

The number of bifilar sections is required such that the phase-angle error for a 100,000-ohm coil is less than 5 deg. at $f = 5000 \sim$. From Fig. 10,

$$c_0 = \frac{0.02778}{\cosh^{-1}\dfrac{D}{d}} \times 10^6 = \frac{0.02778}{1.493} \times 10^{-6}$$
$$= 1.86 \times 10^{-8} \text{ farads per km.}$$

Taking the apparent dielectric constant to be 5

$c = 5\,c_0 = 9.3 \times 10^{-8}$ farads per km.

Therefore the linear hyperbolic angle at $f = 5000 \sim$, is

$$\alpha = \sqrt{2\,\pi \times 5000 \times 9.3 \times 10^{-8} \times 1.424 \times 10^5}\;\underline{/45^\circ}$$
$$= 20.4\;\underline{/45^\circ}$$

The total length x of the bifilar of 100,000 ohms is

$$x = \frac{100{,}000}{1.424 \times 10^5} = 0.701 \text{ km.}$$

Therefore total hyperbolic angle is

$$\theta = \alpha\,x = 14.3\;\underline{/45^\circ}$$

By Fig. 9, $\rho = 0.5$ when $\theta_2 = \overline{\backslash 5^\circ}$.

Therefore the number of sections required is

$$n = \frac{14.3}{0.5} = 28.6 \cong 30$$

In Fig. 9, $k = 0.99$ when $\rho = 0.5$. In this case the error in the size of the impedance is 1 per cent. This value is permissible for practical purposes, so three sections per 10,000 ohms would be sufficient.

The Trenton Channel Plant
of the Detroit Edison Company

BY C. F. HIRSHFELD[1]
Associate, A. I. E. E.

Synopsis.—*This plant is the second to be built by this Company well outside the corporate limits of Detroit, the two being connected by a 120-kv. tower line arranged for supplying suburban areas and the outer part of the city. The plant has a planned ultimate capacity of 300,000 kw. It contains both d-c. and a-c. house service, turbine-driven units and nearly all important variable speed auxiliaries are driven by d-c. motors. Coal is used in pulverized form, the paper giving the conclusions which led to its adoption.*

THE Trenton Channel Plant is one of several interconnected plants serving Detroit and surrounding territory. Its location and many of its characteristics are determined by this fact and a brief statement of some of the characteristics of the territory and system is therefore desirable.

Detroit is located on the Detroit River and has a roughly semicircular shape with the river bank serving as the diameter. This can be seen in Fig. 1, in which the territory served by The Detroit Edison Company is indicated. It will be seen that the City of Detroit is on what might be called one edge of this area.

Steam plants generating power for the supply of Detroit and surrounding territory must logically be located on the water front provided by the Great Lakes System since no rivers in this region are large enough to supply the circulating water requirements of stations of modern size. This brings about a situation in which the power is necessarily generated along the easterly boundary of the area, that is externally, except in so far as a few small hydroelectric plants located on the Huron River give what might be called an internal supply.

The first two large steam plants of the company are located within the city boundaries and are known respectively as the Delray and the Connors Creek Stations. The power generated by these stations is carried out underground and most of it at 23,000 volts. The territory external to Detroit was thus necessarily supplied by lines radiating from Detroit and fed by the underground system.

This arrangement came about quite naturally and was quite satisfactory for some years. However, as the density of load in Detroit and in the surrounding territory increased it brought about several very illogical, undesirable and costly consequences. The most obvious were:

1. Power generated in plants located on costly land within the city and subject to high city taxes was transmitted over costly underground structure, also subject to city taxes, for the purpose of supplying overhead transmission lines serving small suburban towns and cities and country areas.

2. The power required for service to the least saturated territory had to be passed through the most nearly saturated territory thus unnaturally increasing the difficulties brought about by congested streets, high property values and the like.

3. The point of power generation was located some distance from a few of the larger suburban loads, as at Pontiac and Port Huron, making regulation difficult or exceedingly complicated and costly.

4. The coal supply for these plants comes in by rail from the South and must be handled through congested city yards and over congested terminal railroads while much of the power generated from this coal was again shipped out of the congested territory.

In addition to these obvious disadvantages it became evident that the total capacity of the combined plants would shortly be required to supply the city alone and that it would not be long before even that capacity would be inadequate for the city's needs. The natural thing to do was to locate future plants outside the city and in such positions as to be of maximum value to both the surrounding territory and the municipal area.

The first of these newer plants was constructed at Marysville near Port Huron. This location was near one end of one of the longest transmission lines and very close to one of the largest concentrated loads outside the city of Detroit. The second of these plants was built almost at the other end of the available water front, namely, just below the city of Trenton and is known as the Trenton Channel Plant.

This location is such that the coal carrying roads run close to the plant on their way to Detroit, so that coal can be delivered to the plant without having to enter the congested Detroit district. The location also has the advantage of placing the plant in a section of the territory which is rapidly developing to a dense industrial district and all indications point to this section as the one which will continue to develop most rapidly in this way. Other advantages of the location will become apparent from subsequent paragraphs. The locations of the two older and the two newer plants are indicated on Fig. 1 and the air-line distances between them are also given.

With these two new plants in existence, an entirely different system of transmitting energy becomes available. A 120,000-volt line which might be de-

[1]Chief Research Dept., The Detroit Edison Co.

Presented at the Spring Convention of the A. I. E. E., St. Louis, Mo., April 13-17, 1925.

scribed as a trunk has been run between them and it has been given such a course that it swings out into the country areas to the north and west of Detroit. The location of this trunk is shown on Fig. 2 by a heavy line. The lighter lines indicate existing 23,000- and 45,000-volt lines which originally transmitted energy from the Detroit plants.

These lines will ultimately be fed from step-down stations located along the high-tension line and some of them will not only supply the smaller towns and country

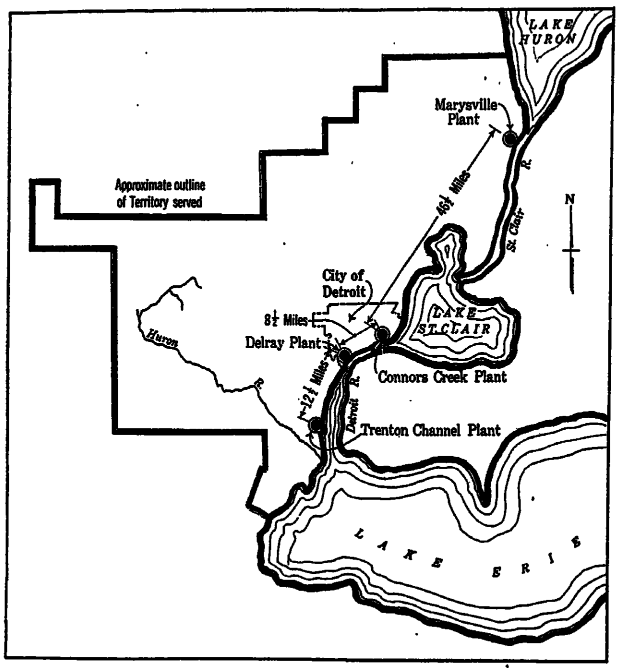

FIG. 1—TERRITORY SERVED BY THE DETROIT EDISON COMPANY

areas but will also feed back into Detroit. This gives a more logical arrangement since large amounts of energy can be brought in through the least congested areas to feed the most congested.

It will be seen in Fig. 2 that the high-tension trunk runs through a place named Brownstown near Trenton Channel and also that high tension lines run roughly north and south from Brownstown. Power generated at Trenton Channel is transmitted to a switching station at Brownstown and is there routed over such circuits of the three radiating lines as may be desired. In addition, some of the power received at Brownstown is there stepped down to 23,000 volts and distributed for the supply of adjacent territory. Power routed to the north is used to supply the industrial area southwest of Detroit and also to supply the west side of Detroit, thus partly relieving the old Delray Station. Power routed to the south now supplies a rather large load in Monroe at the extreme southern end of the territory and will ultimately also supply a heavy industrial development which is expected to follow down along the water front. Power routed to the west supplies the country areas and suburban municipalities and some of it will ultimately be fed back into the northern part of Detroit.

When the lines running out from Trenton Channel are completed there will be three steel-tower lines, each carrying two three-phase circuits of No. 3/0 copper, thus giving six circuits or transmission lines. Four of these will run direct to Brownstown and two will run to one of the outdoor stations lying on the western edge of Detroit. Connections between this station and another of similar character will serve to tie this line from Trenton Channel to the short line running north from Brownstown when desired, thus giving a looped supply to these two important substations.

Arrangements have been made at Trenton Channel to step up to voltages lying between 110,000 as a lower limit and 120,000 as an upper limit. Arrangements are being made for two separate high-tension busses. It is obvious that when completed this will make it possible to supply the loop just referred to at a low voltage and still use the higher voltage on the trunk line if this is required to meet existing conditions of load.

The use of two separate busses also makes it possible to continue and extend a practise which has been a striking characteristic of the operating methods of the company for several years. This practise may be described as a loose linkage or a limited linkage between generating units, using the latter term to mean a group

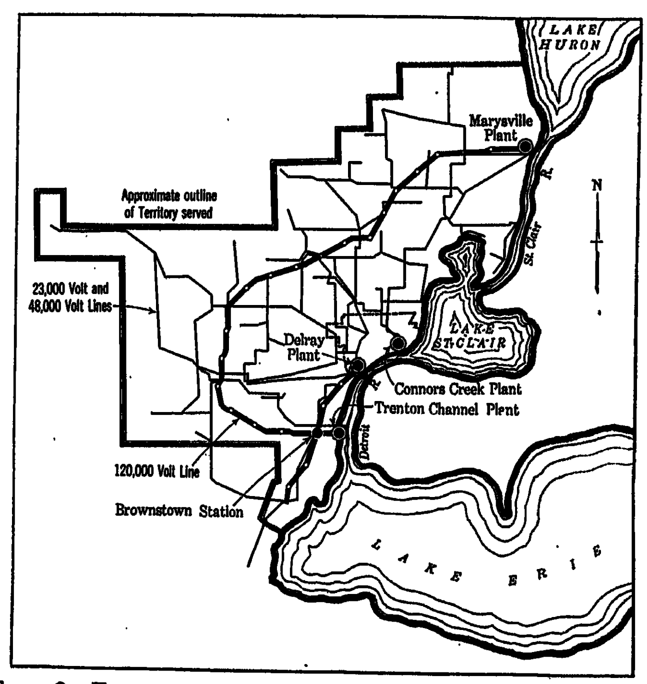

FIG. 2—TRANSMISSION LINES OF THE DETROIT EDISON COMPANY

of turbo generators such as a large section of a single generating plant or an entire plant. The practise was started by dividing up the territory in such a way that each plant supplied the area nearest to it and then connecting the separate areas by the minimum possible amount of copper. As a result, all plants remained in step under normal conditions and even under slightly abnormal conditions such as the loss of a generator at one of the plants. However, a serious fault such as a

bad ground would create sufficient disturbance to break the areas apart, thus confining any subsequent trouble to the affected area. This practise was brought about by an effort to reduce the severity of the service on oil switches.

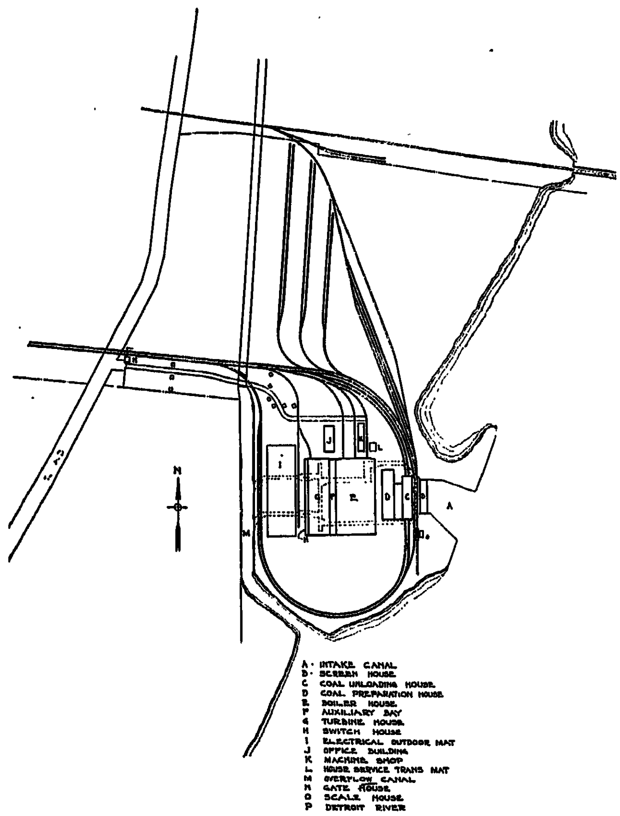

Fig. 3—Ground Plan, Trenton Channel Plant and Yard

The Trenton Channel Plant is located on the southern end of an island in the Detroit River. This island is known as Slocums Island and is or was merely a piece of high ground separated from the high mainland by a narrow marsh. A channel has been dredged through this marsh so that the so-called island is now an island in fact. The plant site is underlain with a good grade of limestone rock at a depth of about 18 to 20 feet beneath the original surface of the ground so that ideal foundation conditions exist.

The plant is so located on the site that its major axes run approximately north and south and the flow of circulating water through it is approximately from the east toward the west. This water is taken from the Trenton Channel of the Detroit River on the east of the island and is discharged into the dredged channel to the west previously mentioned. The general location and arrangement are shown in Figs. 3 and 4.

Starting at the river, the circulating water enters a forebay protected by deflecting piers, booms and skimming aprons and flows through the screen house on its way to the intake tunnel under the turbine house. The usual arrangement of inclined traveling screens protected by stationary rough screens or grizzlies is used.

Next to the screen house is located the coal unloading house. This contains two through tracks located above track hoppers into which the coal is dropped from gondola type cars. Crane rails, supported on the building columns in the usual way, carry a coal spudding device similar to those used for breaking up and unloading coal in the other plants of this company.

All coal entering the plant or going into storage is

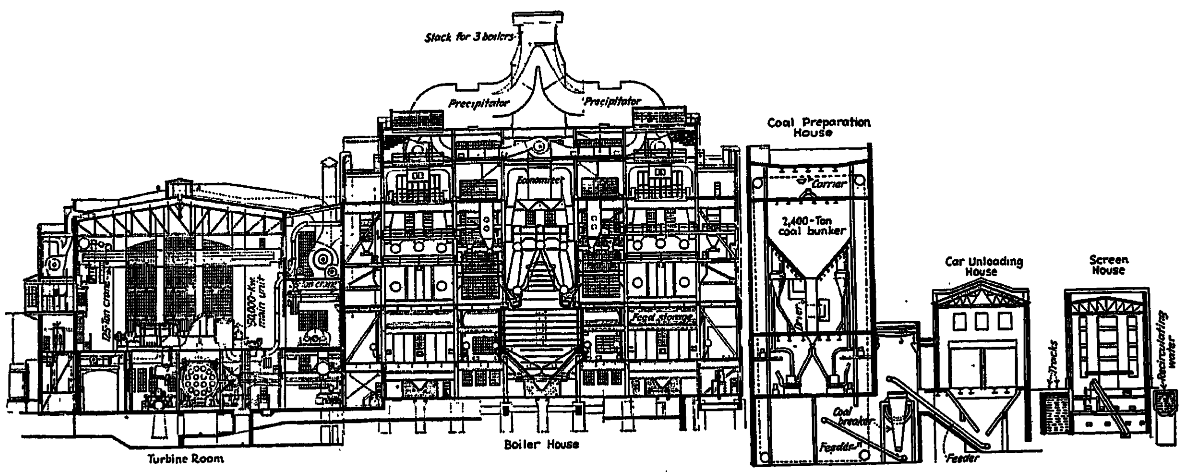

Fig. 4—Cross Section, Trenton Channel Plant

The same practise was adopted with respect to the individual plant. When conditions are sufficiently severe the plant bus is split and the feeders and networks so handled that there is minimum possibility of a serious fault on one part of the bus affecting service from the other part. It will be seen that the double bus arrangement provided at Trenton Channel fits into this method of operating.

weighed on railroad track scales located on a track which runs between the screen house and the unloading house. These scales are indicated in Fig. 3.

Coal dropped into the track hoppers is carried away and elevated by means of pan conveyers which discharge it into the feed end of a Bradford breaker. This arrangement together with subsequent coal handling equipment is shown in Fig. 5. From the breaker

the coal is elevated to the green coal bunker at the top of the coal preparation house. From there it gravitates through steam-heated, air-circulating driers into the pulverizing mills. The pulverized fuel is carried out of the mills by air, separated from the air in Cyclone separators and delivered from these by screw conveyers to the hoppers of Fuller-Kinyon pumps. These pumps are coupled to a duplicate piping system which distributes the pulverized fuel to the bunkers in the boiler house.

Pulverized fuel firing was chosen for this plant after elaborate studies which were based on the best attainable data. It was realized that recent developments in stokers combined with the meagerness of information regarding actual operating costs with pulverized fuel made a study of this kind exceedingly difficult and tended to throw doubt on the correctness of the conclusions. However, the following conclusions seemed to be justified:

1. The pulverized fuel method had been developed to such an extent that continuity of service approximately equal to that obtained with stoker firing could be expected.

2. The total cost of steam, including all operating and capital charges, would probably not be any higher with the pulverized fuel method than with stokers and possibly a little lower when using the same number of boilers with either method of firing.

3. It appeared that it would be possible to obtain a flatter efficiency curve over a wide range with pulverized fuel than with stokers and to obtain high boiler ratings with greater facility, thus making it possible to use a smaller number of boilers advantageously and to reduce capital charges by a corresponding amount.

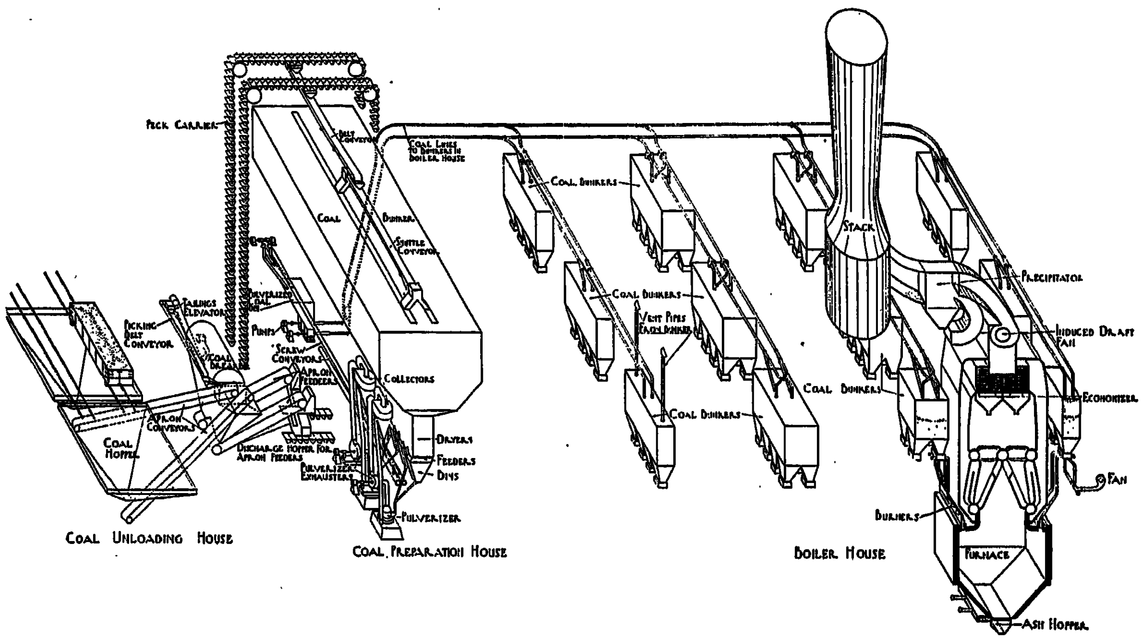

Fig. 5—Coal Handling Preparation, and Firing Equipment

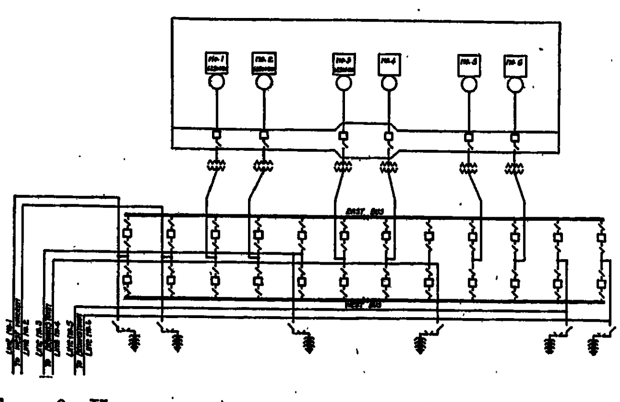

Fig. 6—Ultimate Arrangement of Busses and Lines

4. It seemed certain that a pulverized fuel plant would be less dependent on the supply of a particular quality of coal. This is not intended to mean that it was expected that such a plant could burn all sorts of coal with equal facility but that such variations as must naturally be expected to occur in the deliveries from a given field would not have as great an effect upon capacity and efficiency as had proved to be the case with the older, stoker fired plants. It was also hoped that poorer grades of coal than had been found best suited for stokers of the type previously used might be found to give commercially satisfactory results, thus increasing the flexibility of coal purchasing in several respects.

The decision in favor of pulverized fuel was based very largely upon the fourth conclusion, namely greater flexibility with respect to character of coal. This was particularly important in this case because the plant is so located that cars of poor or questionable coal can easily be dropped there before entry to Detroit. It is thus possible to skim off the best coal, figuratively speaking, for delivery to the Detroit plants and to drop the poorer varieties on the way into the city.

The plant was laid out for an ultimate installed generating capacity of 300,000 kw. The design is based on the use of six 50,000-kw. units. Three have been installed and the fourth will be installed in the near future.

The generators of these units are rated at 62,500 kv-a. at generator voltage corresponding to 120,000 volts on the transmission line. The nominal generator voltage is 12,200. The turbines are designed for best efficiency at a generator output near 43,000 kw. with steam at 370 lb. and 700 deg. fahr., but can carry something over 50,000 kw. at reduced efficiency. Under ordinary conditions the generators will be operated well below their maximum capacity and therefore at low temperatures which should result in long life of insulation. The field circuit has been designed very liberally and the direct-connected exciter is generously large so that occasional operation with high current, as with poor power factor or maximum output at low voltage, is provided for. Great flexibility is thus obtained with respect to generating conditions and full advantage may be taken of the double bus already described and the variation of voltage desirable in feeding from the same plant concentrated loads at short distances and scattered loads at great distances.

Each generator is tied solid to a 25,000-volt, 4000-ampere oil switch which is located in a bay which runs along one side of the turbine room. Beyond this oil switch there is located a disconnecting switch and then the line runs outdoors to the step-up transformers. There are three water-cooled, outdoor-type transformers per generator and they step up through delta-Y connections to bus voltage, that is, to a value between 110,000 and 120,000 as desired. The transformer ratio is fixed, the variation of voltage being obtained at the generators.

The step-up transformers are connected to the outdoor busses through 132,000-volt, 400-ampere, outdoor-type oil circuit breakers with the usual disconnecting switches.

Thus, each generator with its own set of transformers and its switches is a separate unit right up to the high-tension, or transmission line bus. The lower-voltage, indoor switch is used for normal operations such as connecting a generator to the bus after synchronizing. Both the indoor and the outdoor switches, however, are automatic under relay operation.

The neutral point of each generator and the neutral point of each step-up transformer Y is connected solidly to ground. Differential relay protection is provided for each generator and bank of step-up transformers as a unit and differential and overload relay protection is provided on out-going lines, the pairs of lines normally being operated in parallel.

A single line diagram of generator connections, outdoor yard and out-going lines is shown in Fig. 6 in the form which will be assumed when the plant is completed. A cross-section of the electrical end of the house and the outdoor yard is shown in Fig. 7.

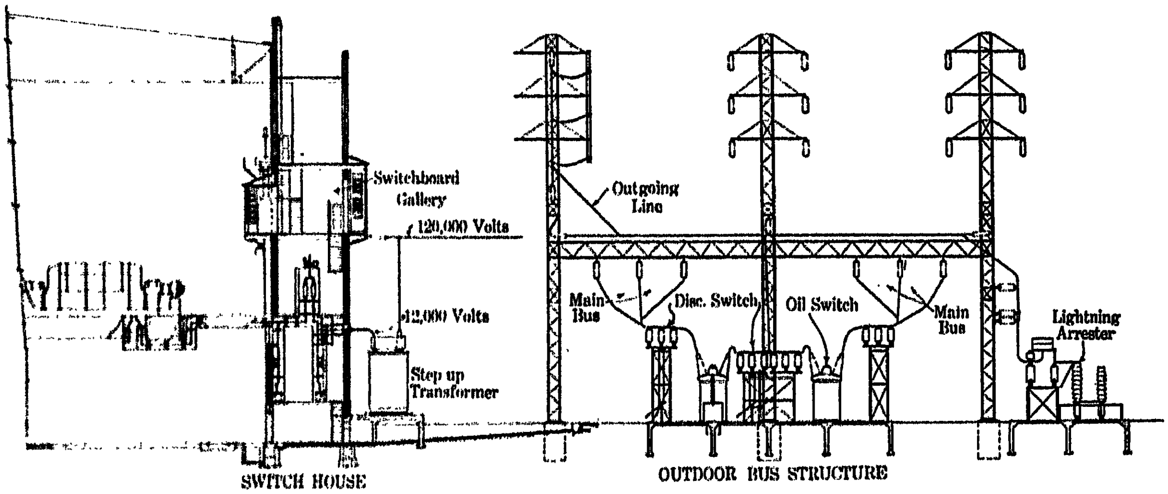

FIG. 7—ARRANGEMENT OF ELECTRICAL END OF PLANT

The uncertainty with respect to what limitations might be discovered in the use of pulverized fuel dictated a rather generous design of boiler room. It seemed probable that eighteen boilers of the size chosen should be sufficient for a 300,000-kilowatt station but the design was so arranged that three more could be added if necessary. To date operation has indicated that eighteen will certainlv be sufficient and it is possible that a still smaller number will prove satisfactory.

The boilers chosen are a double-ended, five drum, curved tube type similar to those used in the older plants of the company. They have, however, been redesigned in the light of experience and tests, with the result that greater capacity is obtained within a given floor area and height with an increase in the boiler efficiency. The boilers installed contain about 29,000 sq. ft. of saturated surface designed for an opera-

ting pressure of 416 lb. per sq. in. Hearth screens add about 1200 ft. of saturated surface. The superheaters give a steam temperature of about 700 deg. fahr. Each boiler is surmounted by two steel tube economizers built into a single housing, the gases flowing from the dampers through flues and economizers toward the center of width of the economizers and thence through induced draft fans to the stacks.

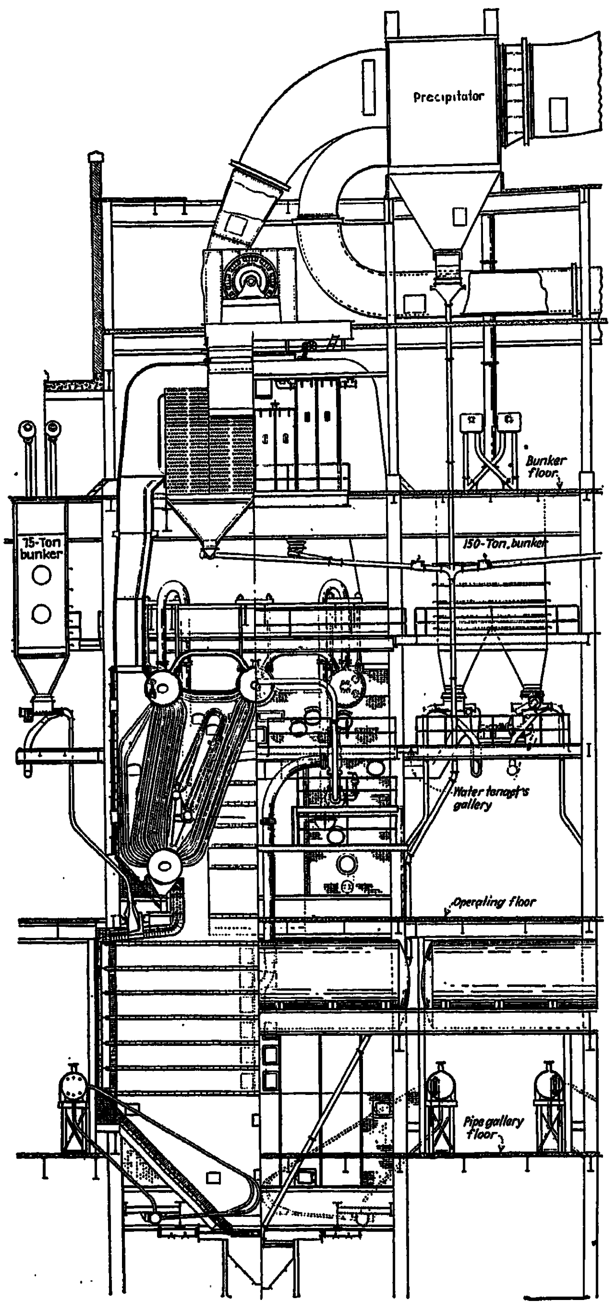

FIG. 8—ELEVATION AND PART SECTION, ONE COMPLETE BOILER UNIT

A vertical, cross section of a complete boiler and furnace unit is shown in Fig. 4 and to a larger scale in Fig. 8. It will be observed that the furnace is of the common air-cooled type and that it is fired from two sides. The ash which collects in the furnace and that which collects in boiler and economizer is all dropped into a sluiceway under the boiler and carried to a settling basin outside the plant. At the present time this material is being used for fill on the property, being transported by means of a dredge pump and moveable pipes.

The Trenton Channel Plant happens to be located within a very short distance of a fine residential community. For this reason it was felt that it would be desirable to determine early in the life of the plant the best means of preventing excessive discharge of ash from the stacks. At the time that the plant was designed the Cottrel precipitator appeared to be the only commercially available device which had been used extensively for separating fine dust from hot gases and such precipitators were therefore installed on two stacks serving six boilers for the purpose of obtaining actual operating experience with them under power plant conditions. The limitations set by dimensions and by cost resulted in the purchase of precipitators intended to remove not much more than 90 per cent of the dust carried toward the stack. Experience to date is not sufficient to justify the drawing of sweeping conclusions but seems to indicate that it is possible by these means to eliminate from 80 to over 90 per cent of the dust without incurring prohibitive capital or operating charges.

The Trenton Channel Plant operates on what is commonly known as the regenerative cycle. That is, the main unit is bled at several points and the steam thus obtained is used for heating that unit's condensate in a series of closed heaters. However, the system as used in this plant is complicated by the use of certain auxiliary generators and other distinctive features and some of these should logically be considered before taking up the flow of steam and of condensate.

The experience of the company which built, owns and operates this plant leads it to believe that auxiliary energy supply should be reasonably independent of the main station bus, that is of the main generators. This is particularly true with respect to the supply for what are commonly known as essential auxiliaries. This experience also leads the engineers of this company to believe that when all things are considered the most satisfactory results are obtained when variable speed auxiliaries are driven by direct-current motors.

A supply of auxiliary energy independent of the main generators of the plant could have been obtained by feed back from the other stations of the company, by the use of auxiliary generators coupled to the shafts of the main units or by the use of independent, steam-driven, house-service generators. The first of these possibilities was eliminated except as will be noted later because of the distance from other stations, the possibility of having to operate the plant isolated from the others at times, and the complications and costs involved in bringing power back from outside in such a way as to make the auxiliary system independent of the

voltage variations planned for the station busses and the outgoing lines.

The use of direct-coupled, house-service units was given serious consideration. It has the great advantages of simplicity and low cost but certain undesirable features when applied to this particular plant. The desire to use both alternating and direct-current auxiliary supply and at the same time to make the auxiliary energy supply independent of other plants would have involved the use of alternating-current house service machines together with converting equipment for direct-current supply. Further, the starting of a single generator with its main auxiliaries driven by direct-current motors would have been practically impossible without an initial supply of energy from an external source. When all of the possible solutions along this line were considered it was felt that the third possibility represented the best solution in this case.

The station as finally constructed may be said to contain three different sets of generating units or to consist of three different generating stations. When completed the six main generating units will constitute one set; eight or ten direct-current generators driven in pairs through gearing by condensing steam turbines will constitute another set; and three or four 2300-volt alternators driven by condensing steam turbines will constitute the third set.

The direct-current units are 2000-kw., 250-volt machines with two armatures mounted side by side on a single shaft which is driven at 360 rev. per min. The turbine driving this double unit with a total capacity of 4000 kw. is a cross-compound affair with the high-pressure unit operating at 4000 rev. per min. and the low-pressure unit at 3000 rev. per min. These turbines drive the generators through pinions on opposite sides of a single large gear, the generator shaft being coupled to the shaft of this gear.

These turbines are arranged for bleeding at a pressure of about 10 lb., gage. The bled steam is used for building heating and for coal drying.

The steam which passes through these turbines is condensed in small surface condensers suspended beneath the individual turbines and each equipped with its own circulating pump, air pump and condensate pump. The condensate is delivered into the main feed water system as will be described later.

The alternating-current auxiliary units are rated at 2000 kw. each at 2300 volts. They are direct-connected to single barrel, condensing steam turbines which are arranged for bleeding but are not bled at present. The condensing equipment is similar to that just described and the condensate also enters the main feed water system.

A list of motor-driven auxiliary equipment with certain important data such as type of motor, speed, etc., is given in Table I. It will be observed that practically all motor-driven equipment in the boiler house is equipped with adjustable-speed, direct-current

motors and that the larger turbine house auxiliaries are similarly fitted. On the other hand, certain pieces of equipment located in the coal handling and coal preparation buildings and which require adjustable-speed motors are equipped with alternating-current drive. This was done because of the practical impossibility of preventing the generation and settling of coal dust in such places. It was felt that the greater freedom from danger of sparking together with the lower maintenance cost to be expected under such conditions of operation justified the use of adjustable-speed, alternating-current motors for such service. Constant speed motors are of the alternating-current type throughout.

operate a 500-kw. motor-generator set to supply the necessary direct current for starting a boiler in addition to operating such alternating-current motors as must be used during the starting up of the plant from cold.

The arrangement of auxiliary busses together with sources of supply and driven equipment is shown in Fig. 9. The direct-current bus is operated throughout at a nominal 240 volts and takes the form of several rings so arranged as to give maximum assurance of continuity of service. Structurally, this bus consists of copper bars supported by steel frames hung from the ceiling, the copper being insulated from the frame by blocks of alberene stone which are notched to receive the bars and are shaped to fit properly in clamps which

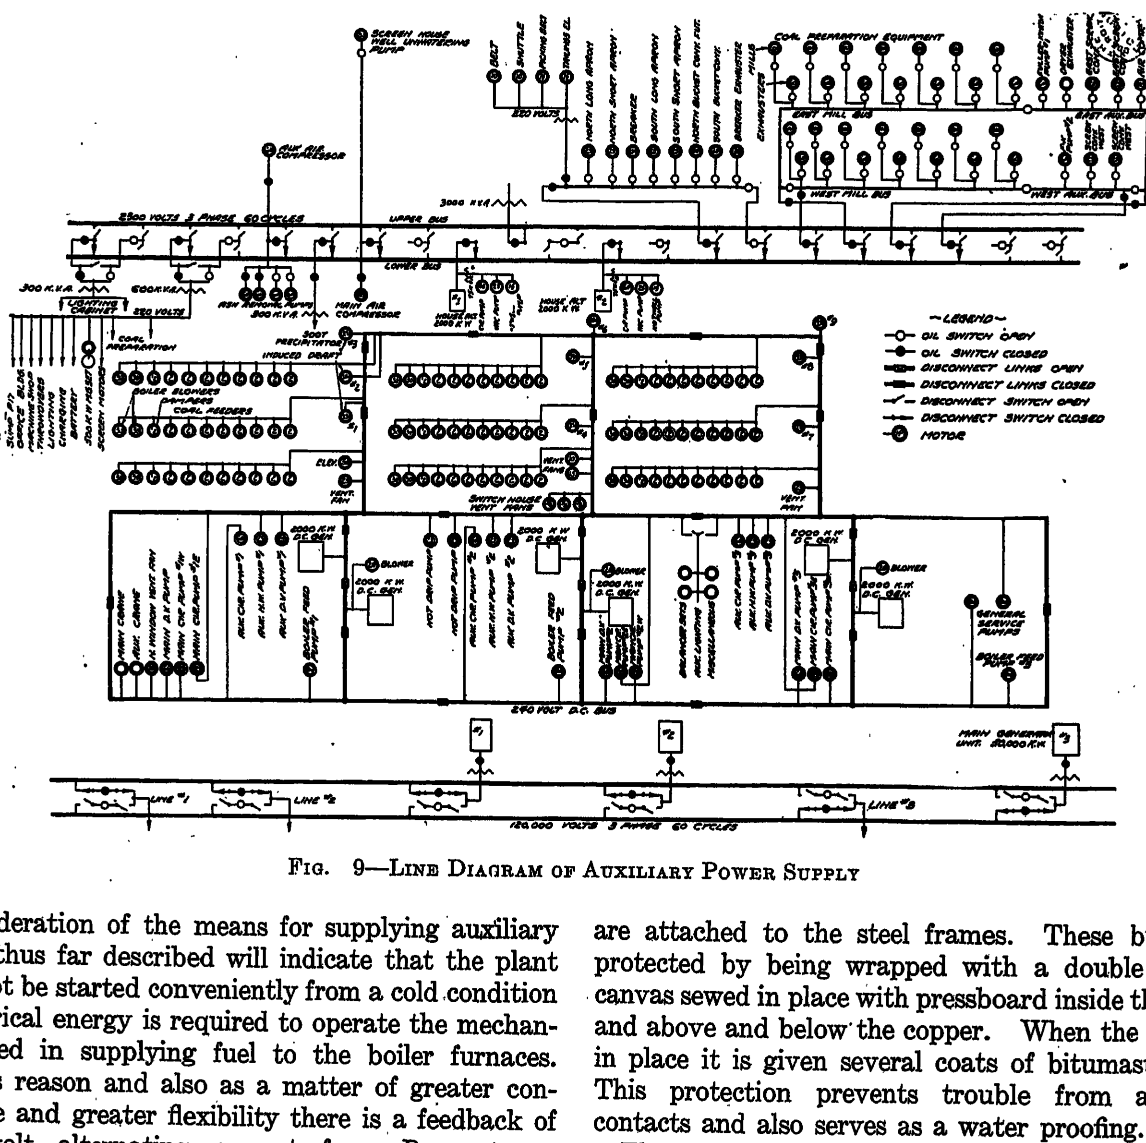

Fig. 9—Line Diagram of Auxiliary Power Supply

Consideration of the means for supplying auxiliary energy thus far described will indicate that the plant could not be started conveniently from a cold condition as electrical energy is required to operate the mechanisms used in supplying fuel to the boiler furnaces. For this reason and also as a matter of greater convenience and greater flexibility there is a feedback of 23,000-volt alternating current from Brownstown. This supply is stepped down through a 3000 kv-a. transformer and may be connected to the 2300-volt alternating-current bus. Ultimately this feedback connection will merely be a tap on the 23,000-volt distribution system in this territory.

This supply from outside the plant can be used to

are attached to the steel frames. These busses are protected by being wrapped with a double layer of canvas sewed in place with pressboard inside the canvas and above and below the copper. When the canvas is in place it is given several coats of bitumastic paint. This protection prevents trouble from accidental contacts and also serves as a water proofing.

The alternating-current bus is merely a duplicate bus of conventional type operating at 2300 volts. Throw-over switches for the larger motors or groups of motors together with provisions for connecting the two busses together give ample flexibility.

The plant and yard lighting is carried on the 2300-volt bus as shown at the extreme left hand end of Fig. 9.

Certain emergency lights throughout the power plant buildings have an automatic throw-over to the battery. Special outlets are provided throughout the plant for extension-cord lights at 28 volts alternating current. The use of such low voltage for extension cord work has been common in the plants of this company for many years and has been found exceedingly desirable because of the safety against severe shock. The lamp used for extension cords is the standard railroad coach light and is exceptionally rugged.

Returning now to the feed water circuit, it has been stated above that this is arranged for regenerative heating. A diagrammatic representation of the entire system is shown in Fig. 10. The normal water circuit may be traced by starting at the hot well of the main condenser in the lower left hand corner of the illustration. Water flows through the lower line from the hot well to the motor-driven condensate pump and then rises vertically to the 19th stage heater. It flows successively through the 19th and 17th stage heaters, the evaporator vapor condenser and the 14th stage heater and then vertically downward to the suction of the motor-driven boiler feed pump. This pump forwards it to the feed water headers from which the water flows through the various economizers to the feed drums of the boilers. The lower horizontal line in the diagram represents a bypass around all feed water heaters which makes it possible to pass water direct from the discharge of the hotwell pump to the suction of the boiler feed pump.

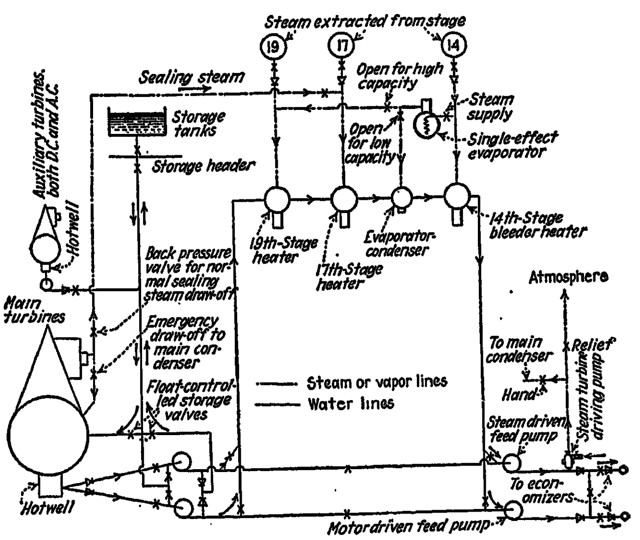

Fig. 10—Diagrammatic Representation of Condensate System

The motor driven hotwell pump and the motor driven boiler feed pump are coupled together and driven by the same motor. They are shown separated in Fig. 10 merely as a convenience in drawing the lines of flow. In effect these two pumps are equivalent to a single, multistage pump with provision for taking the water out of the pump at the discharge of one intermediate runner and returning it again to the suction of the next runner. Each main unit is supplied with one of these combination pumps driven by a variable speed, direct-current motor. The motor speeds are controlled by hand to regulate feed water pressure and distribution of condensate flow between main units.

It is quite obvious that the speeds at which these pumps are operated depend upon the demands of the boilers and that some other provision must therefore be made to maintain a proper rate of condensate removal from the condenser. Also, the total quantity of water held by the boilers varies greatly with load so that a certain amount of flexibility is required with respect to the water content of the system. This is provided in two ways. First, the lower part of the condenser shell is built in the form of a large, deep box or "bath tub" giving a hot well of large storage capacity and capable of permitting a relatively great variation of condensate level. Second, further flexibility is secured by introducing large storage tanks.

Floats operated by high and by low water in the condenser hot well put these storage tanks into and out of use in the following way. If the water level rises too far it indicates that the condensate pump is not removing water fast enough, that is, that under existing conditions, the boiler feed pump is not taking water as fast as the condenser is making it. If the water level rises far enough, the high level float opens the right hand valve of the two marked "Float Controlled Storage Valves" in Fig. 10, thus permitting the condensate pump to discharge into the storage tank in addition to discharging into the suction of the boiler feed pump. On the other hand, if the water in the hot well drops to the limiting lower level the low level float opens the left hand valve of the two indicated and permits water to flow from storage to the condenser, thus giving the condensate pump a supply commensurate with the demands of the boiler feed pump. To prevent excessive oxygen content and resultant rapid corrosion of the steel tube economizers, provision is made for steam sealing of the storage tanks and, in addition, the water discharged from them into the condenser is admitted in such a way and place as to ensure maximum deaeration.

The condensate discharged by the hotwell pumps of the condensers on the auxiliary turbines already described is discharged into the lines connecting with the storage tanks as shown in Fig. 10. This arrangement results in the deaeration, in the main condenser, of all water coming from the small units which are more apt to develop air leaks at low pressure turbine shaft seals and at hotwell pump shaft seals.

Each main unit is provided with a duplicate steam driven combination pump. This is exactly like the motor-driven outfit just described, except that it is driven by a single-stage steam turbine instead of by a motor. This steam driven unit will be used only in emergency and then it will be started without prelimin-

ary warming up, if necessary, and will exhaust to the atmosphere as shown in Fig. 10. If the conditions require this pump to operate for any length of time the valve shown to the left of its exhaust line will be opened so that the turbine driving it will discharge into the main condenser. Such operation will be resorted to merely for the purpose of saving the steam which is all made from distilled water.

It will be noted from the diagram in Fig. 10 that the make-up for the station is supplied by a single effect evaporator taking its steam from the 14th stage bleeder connection and normally discharging its vapor to a condenser located on the high side of the 17th stage bleeder heater. When operating in this way the evaporator is capable of producing about 1¼ per cent make-up. A greater production can be obtained by increasing the temperature head and provision is therefore made for discharge of evaporator vapor to the 19th stage bleeder heater connection as shown.

Under normal operating conditions the temperature of feed water entering economizers will vary between about 200 and 250 deg. fahr., depending upon the vacuum carried in the main condensers and the loads on the main turbines. Higher values could have been obtained easily but the values chosen seemed to give the best commercial solution when cost and performance of economizers were taken into consideration. Higher values could have been used if air heaters had been installed instead of, or even possibly in addition to, economizers. However, at the time this plant was designed the air heater was considered to be very decidedly experimental. In addition, the furnace walls were to be air cooled and nothing was known about maximum permissible temperatures for air used for this purpose nor maximum permissible temperature for air entering the furnace interior.

The summary at the end of this paper gives essential data with respect to all major equipment and the more important minor equipment. Taken in combination with the motor data given in Table I it gives in convenient form most of the important information in connection with the apparatus installed. Further details of the ideas and theory underlying the design of the plant and of the equipment can be obtained by referring to the following three articles which have been published in the technical press:

1. The Trenton Channel Plant of the Detroit Edison Company; C. H. Berry; *Power*, May 27, 1924; Page 848.
2. Design Features of Trenton Channel, P. W. Thompson; *Electrical World*; May 31, 1924; Page 1115.
3. Unusual Electrical Features Found in Trenton Channel Station; *Electrical World*; January 31, 1925; Page 247.

SUMMARIZED STATEMENT OF MAJOR EQUIPMENT

Main Generating Units. Three 50,000-kw. single-barrel horizontal turbines driving three 62,500-kv-a., three-phase, 60-cycle generators with direct-connected exciters. Turbines operate at 1200 rev. per min., have 21 stages, a water rate (at 42,500 kw. without bleeding) of 9.4 lb. per kw-hr. when supplied with steam at 375 lb. gage and 700 deg. fahr. Turbines are bled at 19th, 17th and 14th stages. The nominal generator voltage is 12,200.

Generator Air Coolers. Horizontal, finned-tube cooler contained in housings within generator foundations. Coolers arranged for circulation of condensate or water from intake tunnel of plant.

Main Condensers. Three 47,300-sq. ft., single-pass condensers arranged with steam belt. Tubes are made of 70 per cent Cu, 28 per cent Zn and 1 per cent Sn alloy, 1 in., No. 18 Stubbs gage and are arranged in single lines converging from a maximum spacing at top of condenser of 4 in. to the minimum possible with 1 in. tubes at entrance to air cooler. Each condenser is equipped with two 60,000-gal. per min. circulating pumps driven by direct-connected variable speed d-c. motors; two condensate pumps one of which is mounted on shaft of motor-driven boiler feed pump and one on shaft of steam-driven boiler feed pump; one vertical reciprocating dry vacuum pump.

Main Hotwell and Boiler Feed Pumps. Hotwell and boiler feed pumps are mounted on same shaft. There are two for each main unit, one driven by 700-h. p. adjustable-speed d-c. motor and the other by a 750-h. p. steam turbine. The steam-driven pump has a capacity of 1300 gal. per min. at 1700 rev. per min. and the motor-driven pump has a capacity of 1300 gal. per min. at 1200 rev. per min.

Main Generator Switches (12,200-volt). Three switches one for each main unit. Each switch is a 4000-ampere, 25,000-volt oil switch with motor-operated mechanism.

Main Step-Up Transformers. Each main unit has three, single-phase, 21,000-kv-a., 12,000, 120,000-volt, oil-insulated, water-cooled, outdoor-type transformers.

Main Generator Outdoor Switch (132,000-volt). Each main generator has two three-phase, 400-ampere, 132,000-volt outdoor-type oil switches, each phase in separate oil tank. Each switch is motor operated by centrifugal operating mechanism.

Direct-Current House Service Machines. Three 4000-kw. units, each unit consisting of cross-compound steam turbines driving through a reduction gear, two shunt-wound, interpole, 2000-kw., d-c. generators mounted on a single shaft. High-pressure element operates at 4000 rev. per min., low pressure at 3000 rev. per min. and generators at 360 rev. per min.

Condensers for Direct-Current House Service Machines. Three 7500-sq. ft., two-pass condensers completely equipped with circulating pumps, hotwell pumps and air pumps.

Alternating-Current House Service Machines. Two single-barrel turbines each driving one 2000-kw. three-phase, 60-cycle, 2300-volt generator with direct-connected exciter, at 3600 rev. per min.

Condensers for Alternating-Current House Service Machines. Two 4100-sq. ft. two-pass condensers equipped with circulating pumps, hotwell pumps and air pumps. These auxiliaries are driven by a-c. motors and can be brought up with machine if desired, priming being taken care of by priming header running the length of the plant.

Main Steam Piping. Van Stone joints with gaskets.

Main Turbine Room Crane. One 125-ton crane with span of 97 ft. 6 in. Can handle circulating pumps and other auxiliaries on condenser room floor as well as main unit parts.

Boilers. Eight 29,085-sq. ft., five-drum, curved-tube boilers built for operating pressure of 416 lb. on drums and equipped with two superheaters per boiler which give total steam temperature of 700 to 725 deg. fahr. A hearth screen is used at the bottom of furnace under each boiler but is entirely separate from the boiler in so far as circulation is concerned. Each hearth screen consists of two separate boilers with independent feed. Steam made in these boilers joins steam made in main boiler and the combination passes through superheater of main boiler. Boilers are arranged in groups of three across main axis of boiler house and are fired from both ends thus giving four firing aisles running lengthwise.

Pulverized Fuel Preparation and Handling Equipment. Fourteen steam-heated air-circulating driers feeding coal to 14 pulverizing mills. Pulverized coal raised from mill to cyclone separator by No. 12 mill exhauster, one exhauster per mill. Exhausters driven by 60-h. p. a-c. motors. Mills driven by 100-h. p. a-c. motors. Coal from cyclone separators forwarded by four screw-conveyors running lengthwise of house to hopper over three 10 in. pulverized coal pumps. These pumps driven by 60-h. p. a-c. motors.

Pulverized Fuel Burning Equipment. Sixteen burners per boiler, eight on each end, fed by duplex feeders driven by two-h. p. adjustable-speed d-c. motors. Primary air for each boiler supplied by two 55-in. blowers driven by 30-h. p. variable speed d-c. motors.

Boiler Furnaces. Air-cooled, refractory-wall type with eight burners at opposite ends. Distance, arch to hearth screen, 20 ft; distance between opposing rows of burners 29 ft; distance center line of burners to adjacent wall 2½ ft.; distance between burners 2 ft. 4 in.; distance end burner to side wall 3 ft. 4 in.; inside width furnace 23 ft.; total volume from hearth screen to peak of furnace 25,140 cu. ft.

Ash Handling. All ash collecting in furnace and in boiler passes, flues and economizer hoppers, is discharged to hydraulic sluiceway running longitudinally in boiler house basement and is sluiced to settling basin. Material removed from settling basin by centrifugal dredge-type pump and used for filling on property.

Economizers. Two, steel-tube economizers per boiler with 9492 sq. ft. of surface per economizer. Tubes are plain, 2-in. tubes rolled into rectangular forged headers.

Induced Draft Fans. One double-inlet, 193,000-cu. ft. per min., at 375 deg. fahr., induced draft fan per boiler, capable of producing maximum draft of 7.15 in. water at fan. Each fan driven by 350-h. p. adjustable-speed d-c. motor. Three fans serving one row of three boilers discharge through curved flues into single stack.

Stacks. One stack for every three boilers. Stacks have Venturi shape with inside diameter of 15 ft. ½ in. at throat and 21 ft. at top. Top of stack is 192 ft. above burners. Stack is self-supporting steel, carried on building steel and is brick lined.

Discussion

H. R. Woodrow: The Brooklyn Edison generating plants are laid out for a different method of operation from that discussed by Mr. Hirshfeld. The three generating plants are operating continuously in parallel with heavy tie lines between stations. One of these stations is 25-cycle and the other two 60-cycle and a 35,000-kv-a. frequency changer ties the 25-cycle station to the 60-cycle system.

The base load of the entire system is carried on the most economical units in the most economical plant which is, at the present time, Hudson Avenue Station. It is intended that these stations should hold in step during the major number of troubles and sectionalizing reactors are very generally used to segregate the trouble and limit the value of the short-circuit current.

For a detailed description of the Hudson Avenue plant and system connections of the Brooklyn Edison Company, I would refer to the April 1925 issue of the *Electric Journal.*

In all cases second-line defenses are provided in the form of automatic switches segregating certain groups of feeders in case of the main feeder switch failing to operate and each feeder is provided with reactors and reactors are installed between sections to maintain voltage for high continuity of service under disturbance conditions.

The auxiliaries in the power house are all electrically driven with the exception of reserve boiler feed pumps and all auxiliaries are provided in duplicate for the so-called essential duties, each half of which is supplied from different sources although tied together through reactors.

F. A. Scheffler: I want to compliment Mr. Alex Dow on his wonderful "sticktoitiveness," you might say, in adhering to the design of the type W Boiler that he selected about fifteen or twenty years ago to use in the Delray plant of the Detroit Edison Company.

I had the opportunity and great pleasure of working out that design of boiler with Mr. Dow, and the results were eminently satisfactory in producing a type of boiler at that time which was four times the size of any other boiler in the country. I think Mr. Dow deserves a great deal of credit for introducing, in this country, the large unit type of boiler for public-service stations.

He has continued to use that type in all of his other plants, and, today, I believe they have thirty-five to forty boilers of that type operating at from 300 per cent to 400 per cent of rating on peaks.

H. W. Brooks: Many writers on combustion in the past have stressed the importance of turbulent flow, agitation and mixing in pulverized-fuel furnaces as an aid to the natural diffusivity of the burning gases upon which speed of combustion, length of flame travel and hence combustion volume depends. A practical means of accomplishing this mixing has heretofore remained undiscovered.

Several years ago it occurred to one of the engineers of the Fuller-Lehigh Company that one of the most intense manifestations in Nature of turbulent flow and agitation of gases and particles in suspension was in the tornado, where it had been repeatedly demonstrated that materials of considerable tensile strength had actually been torn apart, disintegrated and reduced to fine pieces and sometimes to powder by the intense centrifugal action of the air. Experiments were started at Fullerton on a small furnace 18 in. square by 3 ft. deep in which the jets were placed to throw the flame tangent to a tornado of fire within the furnace, the flame of the first jet being deflected before it reached the refractory walls by the impingement with equal velocity at right angles of the flame from the second jet, the third jet again changing the direction 90 degrees, and the fourth jet completing the tornado within the pot. Fig. 1 shows in plan, the application both to the circular and the square-pot furnaces.

It was well known that the external walls of the tornado of nature had been observed to be rather sharply defined from the surrounding air. Thus it was decided to adapt this principle by placing the pulverized fuel jets in such relation to the refractory walls that there was little, if any, impingement of the fuel tornado on the furnace walls. As was anticipated, therefore, the refractory walls showed little damage due to erosion, and thermocouple temperatures taken on the inner refractory surface of the furnace showed that the inner face of the brick never exceeded 2700 to 2900 deg. fahr.

It has also long been recognized that the transmission of sensible heat from the hot gases from the furnace through the tubes of the boilers to the water on the other side was limited by the existence at the boundary surface of a "dead film," generally assumed to be about 1/40 in. in thickness, of relatively cool gas in which convection currents apparently did not take place, and which owing to its low conductivity offered a high resistance to the passage of heat (other than radiant) through it. This "dead film" is the main and most potent obstacle to rapid heat transmission in the boiler, and it follows that its complete or even partial destruction will greatly assist the flow of heat and hence the efficiency of the boiler. Prof. J. T. Nicolson of the Manchester School of Technology demonstrated a formula proving that the heat transfer was a direct function of the velocity of molecular travel of gases passing the tubes. Thus it was anticipated and tests subsequently proved that with the higher scouring action of the swirling gases in meeting the boiler tubes there would not only be a higher rate of heat transfer and higher

boiler efficiency, but also a cleansing action which would keep the tubes clear of deposited ash.

Early during the experiments the nature of the ignition and combustion taking place in the well, proved quite unlike anything experienced pulverized-fuel engineers had hitherto seen in powdered-coal combustion. The flame itself resembled that of a blow torch, virtually a "ball of fire," combustion apparently taking place in a limited zone within the well. By regulating air admission and air pressure it was possible to move the hottest zone into the well itself or to a point just in front of the well. Appreciating further the gains due to the more efficient transfer of heat by radiant energy as a result of this "ball of fire," the inventor had still further reason to expect efficiencies higher than had been before demonstrated in pulverized-fuel combustion, as well as a flatter over-all performance curve at high ratings.

These experiments were kept secret for several years; until finally a few of the larger operators were shown the experimental furnace at Fullerton. Several immediately volunteered to install a furnace of the new type, but the results which indicated heat releases many times greater per cubic feet of combustion volume than had ever been accomplished before were so revolutionary in character that the company felt it best to withhold a commercial-scale installation until they had finally and thoroughly convinced themselves that no practical operating difficulties would intervene.

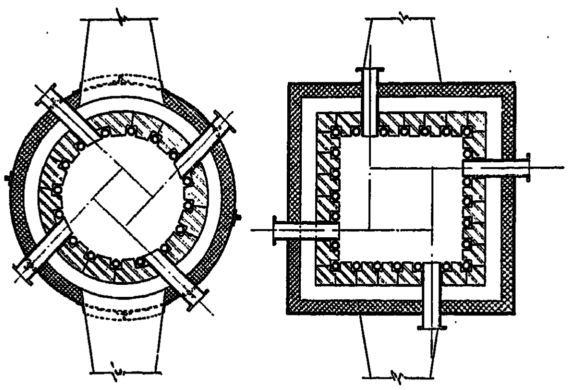

Fig. 1

Finally on February 5, 1924 an agreement was entered into with the United Electric Light and Power Company of New York City by which a commercial-scale experimental installation of the new furnace would be made at their Sherman Creek Station alongside five other boilers fired by the older pulverized-fuel firing methods.

The operating company expressed the desire to make the tests entirely with their own personnel. Today it is understood these tests have been completed. Although full details cannot be made public we are permitted to state that the efficiencies have actually proved approximately 3 per cent higher than with any other method of firing, and the curve of efficiencies at various ratings has been much flatter than anything heretofore demonstrated.

Fig. 2 shows one of the more recent applications of this furnace. It will be noted that above the well there is provided a dispersion chamber in which the hot gases after burning are allowed to expand before reaching the boiler tubes, thus reducing the tornado effect to a value which can cause no possible erosive effect on the boiler tubes. The theory of this chamber is to allow just sufficient velocity to scour off the "dead film" from the boiler tubes without going any further in attacking the tubes themselves. It is not possible to state at this time the minimum size to which this chamber may eventually be reduced. It has definitely been established, however, that the combined volume of well and dispersion chamber can be made substantially less than the combustion space provided in the old-fashioned stoker setting. Knowing that we can convert present stoker-fired settings by this means, and attain the highest boiler ratings, we have at this time no occasion to go further until the application is extended to other services, such as transportation and marine. Fig. 3 shows a plan of the water-cooled well as actually applied on the later designs.

Simultaneous with the tests at New York, research has been continued at Fullerton on a furnace consisting of an 8-ft. cube. In this furnace the coal equivalent of a 1500-h. p. boiler at 632 per cent of rating has been burned in the volume of an 8-ft. cube.

It is felt that the "well-type" furnace is a demonstrated success

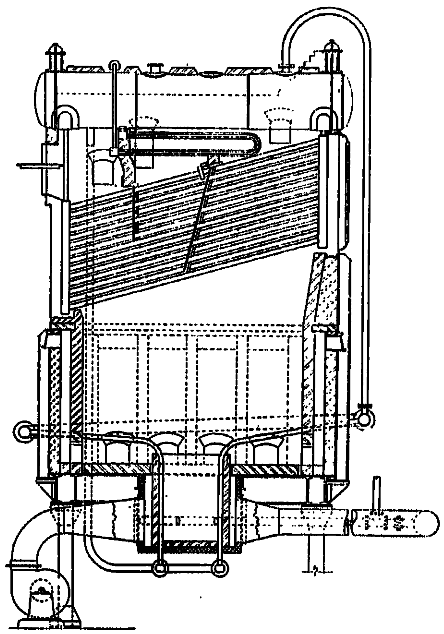

Fig. 2

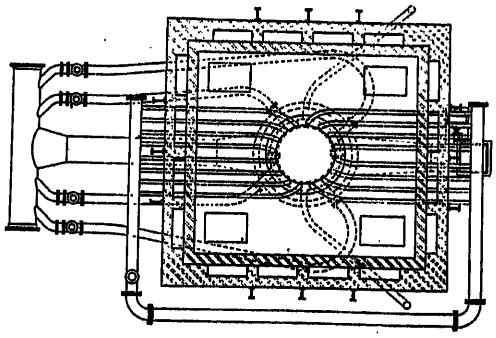

Fig. 3

and that for the first time in the history of pulverized coal the problem of turbulent flow and hence the problem of combustion volume has been solved. Not only may pulverized coal be efficiently burned in combustion volumes as small as those previously employed for stokers but actually smaller furnaces may be installed where necessary. For the first time, completely successful application of pulverized coal to transportation and marine service becomes possible, as does also the conversion of present stoker-fired furnaces to the advantages of pulverized coal without the necessity in many cases of more than slightly modifying the present furnace construction.

H. R. Summerhayes: The voltage selected for the Trenton Channel Station is 120,000, and 132,000-volt apparatus has been used. That, we might say, is commendable conservatism, but as

manufacturers, we think it is unnecessarily conservative. We have evidence from experience that the Institute tests are about right. We think the equipment would stand 132 kv. and if it is to be used at 120 kv. it would seem to us unnecessary to have so large a factor of safety. On the Western Coast, we have used for 220-kv. circuits apparatus designed for high-potential tests corresponding to 187 kv., which has given good service.

The next point that I want to comment on is along the lines Mr. Woodrow mentioned, namely, that the plants of Detroit system are tied together rather loosely, with weak linkage, whereas, it is the practise in other large systems to tie the plants together rather solidly, using reactors, and I am inclined to think that as the plans of the Detroit Company progress they may find it advantageous to have a tighter linkage and links capable of transferring more power.

The other point is the old question of direct-current auxiliaries and I suppose that will never be settled. It appears that means of obtaining direct current, perhaps, cost more and auxiliary motors may cost more, but you do obtain very perfect control, and I think that the question has yet to be settled as to whether the perfection of the control obtained is worth the money it costs.

K. M. Irwin: It is brought out in this paper that theDetroit Edison Co. ties its stations together loosely. This must mean that the Delray, Connors Creek and Trenton Channel plants take the loads of their particular districts, and therefore, the load factors of their particular districts. As the Trenton Channel plant does not operate as a base-load plant, but operates on the load factor of its district, it must have been more difficult to justify the cost of equipment than it would have been if this plant had operated on the base of the load, and in that way had a higher load factor and a greater divisor to divide its investment costs.

In the reasons given for the choice of pulverized coal, the statement is made that a reduced number of boilers could be used with pulverized coal than could have been used with a stoker installation. I wonder whether Mr. Hirshfeld has found that the limitations in boiler capacity are in the fuel-burning equipment. With the type of boiler adopted at Trenton Channel, I would believe that the limitation would be found in the boilers and not in the fuel-burning equipment. Tests have been run on a stoker installation in which ratings have been obtained in the neighborhood of 500 per cent without serious falling-off in efficiency. I do not believe that these ratings could be exceeded in Detroit even with pulverized coal.

In the list of motors, the 2000-kw. house-generator sets have their auxiliaries a-c. driven, and the 4000-kw. d-c. house sets have their auxiliaries d-c. driven. It would be interesting to know the reasons for the changes of the current for the auxiliaries on these house sets.

Louis Elliott: The recent putting into operation of the Philo and Crawford Avenue stations, with the low fuel consumption reported, makes of particular interest a decision such as that made for Trenton Channel,—to install 375-lb. turbines working on the regenerative cycle, as against a higher pressure plant designed for reheat.

A recent estimate for a moderate-sized station indicated an excess cost for a 650/550-lb. reheat plant, as compared with 425/375-lb. of about 7 per cent. With a capacity factor of 60 per cent annual, this additional investment would entail an increased fixed charge around 0.3 mills per kw-hr. If it be assumed that the 550-lb. station would permit a saving in production cost equivalent to 10 per cent of the fuel cost, this saving with 10,000 B. t. u. coal at about 1.1 mills per lb. in the pulverized bins would amount to between 0.15 and 0.2 mills per kw-hr. output.

For this situation therefore the recommendation was made that 425-lb. boilers be installed, with turbines good for 375 to 400 lb. at the throttle. On the above basis coal would have to cost nearly double its present price in order to give an equivalent cost of energy for the two pressures. Different assumptions as to load factor, coal cost, or other factors would, of course, modify the result. In general an expensive high-efficiency installation should justify itself for the first few years of operation, for as the years go on the reduction in load factor will tend to counterbalance any increase in fuel cost.

Aside from the estimated saving in combined fixed and production cost of energy, the lower-pressure equipment is more thoroughly developed and therefore probably more reliable, and the 375-lb. regenerative-cycle plant would be simpler to operate than the 550-lb. reheat station. The 375-lb. pressure is now standard, and it is uncertain as to what the next higher standard will become,—whether 550, 750 or higher. It is believed that in general there should be a considerable saving assured before newly developed equipment and designs are adopted.

It would be of great interest if the author would give the expected economy in B. t. u. per kw-hr. output,—with fuel available and with load factor as anticipated. A statement also as to any estimate of comparative plant cost for the pressure adopted as against a 550-lb. reheat plant, and the estimated comparative economies would be of great value.

C. F. Hirshfeld: When I spoke of pulverized fuel as being advantageous in that it would enable us to take advantage of variable qualities of coal, I did not mean that we could use West Virginia coal one day and Illinois coal the next day. Buying as carefully as we know how with men who live in the coal fields, it is impossible for us to bring to Detroit one grade of coal.

Some of the coal we get is poorer than the rest. Our stoker-fired plants in the past have proven very touchy with respect to the grade supplied. If we can get the grade of coal for which the plant was designed, it does very nicely. If we get a greater quantity of ash, we lose both in capacity and efficiency, and it was in that respect that we had considered variable qualities of coal in making this decision.

Improvements in the manufacture of stokers since the time this decision was made (which is several years ago) have greatly extended the capabilities of the stoker in this direction. At least, some varieties of stoker are not now limited to the same extent as they then were.

In connection with the use of d-c. auxiliaries, I stated quite flatly that it was a case of personal prejudice on the part of the engineers responsible for the designing of this plant.

It may be of interest to you to know that the cost of obtaining our d-c. auxiliary power, with the separately driven d-c. generators, is practically the same as though we took a-c. power from our main units and converted it. There is, however, an advantage in our d-c. power supply not being tied to the operation or performance of our main units. We admit that our investment charges are higher but we prefer our system nevertheless.

With respect to Mr. Sheffler's comment on boilers, we now have forty-four, varying in size from 1250 h. p. to approximately 3000 h. p. boilers. He was not correct in his statement regarding the ratings at which those boilers are operated. The old stoker-fired boilers reached limitations at about 200 per cent in some cases and 250 per cent in others. The boilers at Trenton Channel Station, which are pulverized-fuel-fired have been driven to about 350 per cent of rating. In no case in which the double-ended or Type W boiler was used has the limit been found in the boiler.

Referring to Mr. Erwin's discussion, the matter is something like this: There is no question but that you could get a stoker to give ratings equally as high or higher than obtained in Trenton Channel Station. Parenthetically, it is also true that we could drive the ratings at Trenton Channel very much higher than those obtained. As we saw the problem at the time we designed this plant, the rating to which a stoker-fired boiler could be driven was dependent only upon the grate area or the area of the stoker and the ability to maintain the furnace wall.

However, we do not believe and we have not yet seen any proof that a stoker can be built which is capable of driving a boiler to ratings in the neighborhood of 400 per cent or higher,

which will give a reasonably high efficiency at those ratings and maintain a reasonable efficiency at very much lower ratings. In other words, you sacrifice considerably in what you might call the combination of flexibility and efficiency when you attempt to get a stoker-fired equipment to carry over a wide range of rating. I do not know if the stoker manufacturer is going to be able to remove that limitation or not. So far as I have been able to obtain proof he has not yet done so.

Mr. Elliott asked about the performance of this station. The station was designed to give a net kilowatt hour, that is a kilowatt hour of output, for about 16,000 B. t. u. when operating with an annual load factor of the order of 50 per cent. The station has now been in operation, in one way or another, for something over six months, possibly eight months, and the performance has been improving monthly. Some weekly figures have already dropped below 16,000 B. t. u., the value which we assumed when we designed the station. We are not able to say whether those figures are correct, but the figures that we are willing to give you hit close to the 16,000 B. t. u., which was the design point and we may do better.

The cost of preparing pulverized coal is always one of the contentious points. I have here the figures for three months, January, February and March, the March figures being incomplete. In these figures, we have included every item of operating cost for coal handling and preparation from the time when the coal finds itself in the track hopper and until it finds itself in the pulverized-fuel bunker, ready to be fired into the boiler furnace. We have included all labor costs, both operating and maintenance. We have included all power, we have included all steam, both the steam used in drying the coal and the steam used for heating the preparation house and you will notice that this was during the two severe months of the year. We have included all operating material and all maintenance material. The figure runs at approximately 30 c., pulverized, during January and February. In January, it was 29.14c. In February, it was 30.36c.—the increase in February being due to the fact that maintenance was quite a bit heavier in that month than the preceding month.

To make these figures of real significance, I should say this: They are obtained from a plant which is using small pulverizing mills, nominally six-ton mills. They are obtained on a preparation house which is designed to handle exactly twice the amount of material that is now being handled. The labor used will be the same when handling twice the material as it is now. The maintenance will, of course, go up. As near as we can estimate, if this plant were used to capacity and all the charges were made as they have been outlined, the figure for preparation would be a little under 22c. per ton. In charging steam and in charging power in these figures, we have used cost of steam and cost of power as actually shown on our books for steam sent out from the boiler room to the turbine room, and for power sent out over the lines to our customers, so that we haven't either overloaded or underloaded those items.

With respect to Mr. Woodrow's and Mr. Hays' discussions, in which they refer to our, let us say, loosely linked system, I believe that we may ultimately come to a more tightly linked system. We have followed the other method principally for three reasons. In the first place, it fitted our conditions ideally. In the second place, we were fairly sure that it would work, and experience has shown that it does work moderately well. Third, we did not like to contemplate the cost of reactors and places in which to place them and all the trimmings that go with them.

I believe it was Mr. Erwin who worked around from that loosely linked system to the conclusion that our Trenton Channel plant, which is our most efficient, could not be used to the best advantage. To a certain extent, that is true, but only to a very limited extent. Immediately adjacent the Connors Plant and the Delray Plant there is sufficient load to load the plant properly. Trenton Channel can obtain quite enough load to operate as near base load conditions as we care to approach by supplying the so-called down-river industrial load, that part of the industrial load that it can pick off from the Western side of the City of Detroit, such load, very largely industrial, which can be obtained in the outlying district, combined with such industrial load as can be obtained through feeding back into the city from the 120-kv. bus or trunk referred to in the paper. So our loose linkage has very little effect on our efficiency. On the other hand, it is not the policy of our company to load up its new plants at the expense of its older plants. It pays us, or at least it has paid us in the past to go a certain distance in that direction, but not as great a distance as has been proven advisable in other cases.

As Mr. Brooks was describing his new furnace, it passed through my mind that if one could use a small furnace but had to add to it a large mixing chamber, it did not make a lot of difference since you ultimately used the same number of cubic feet as you do with the older designs. I can't see that there is much choice. Mr. Brooks rather implied that one could do away with that mixing chamber if forced to do so, but I am wondering if that furnace were brought too close to the boiler tubes, whether you would not carry up so much fused ash as to put the equipment out of commission very quickly. I do not believe the manufacturer has had sufficient experience with the device to be able to answer that question. I followed the tests at Sherman Creek very closely, but they were not planned in such a way that that question could be answered by them.

Mr. Woodrow's discussion reverts to tight linkage as against loose linkage. He refers to safety devices intended to function serially. No matter how you plan you may never be sure that this thing or that thing will really work. On that account we have preferred to cut out all such trimmings and limit ourselves to loose ties which would break loose or burn themselves up.

Mr. Erwin asked me why we used a-c. auxiliaries on the a-c. house-service machines. That is due to another one of our "hobbies." If we have steam, we can start the a-c. machine and with the a-c. machine we can start everything else. We felt that if we faced a situation in which we wanted to start that little house-service unit in a hurry, we wanted to start with the minimum of manipulation. The a-c. driven auxiliaries are so connected that they come up with the machine and we feel that this is the simplest starting scheme we could get. That is why we used the a-c. driven auxiliaries with the a-c. house-service units. It is not the first time we have used that scheme and it has worked very well in all cases so far.

With respect to deaeration, we have used in this plant steel-tube converters. The natural conclusion would be that we should be very careful not to have any more than the minimum feasible oxygen content in the water. Our experience in Detroit has been that our water is of such a character that we can stand more oxygen than is commonly given as the maximum limit consistent with reasonable life of steel tubes. Our experience with steel tubes at the old Delray plants leads us to believe what I have stated.

The system at Trenton is built so that there is a surge tank. The surge tank is arranged so that it can be sealed with steam if necessary, but it is not so sealed now. The water passes into the condensers where it is reasonably well deaerated, although we have not provided separate deaerating devices. It is too early to say whether this system works or not. Four or five years hence we will be able to tell if it doesn't work.

With respect to the pressure on the suction of the boiler-feed pumps; when we purchased these pumps, we had all the characteristic curves modified until we got what appeared to be a combined pump unit, which would be safe against flashing at the boiler-feed pump suction. Up to date, we have had no trouble from that source. We have had a little trouble due to hammering of the hot-well pump. The reason for that is that the pump does not have a sufficient head of water above it. We are now attempting to rectify that and expect to succeed in doing so.

Use of Frequency Changers For Interconnection of Power Systems

BY H. R. WOODROW[1]
Fellow, A. I. E. E.

FOLLOWING an extensive study into the cost of power as delivered to the customer, the Brooklyn Edison Company adopted the policy of supplying all the increase in business at 60-cycle alternating-current and curtailing the direct-current load within the capacity of the existing substations. With the 25-cycle generation confined primarily to the supply of power to the direct-current system all new prime movers are being installed with 60-cycle generators. The 25-cycle system is therefore left in a position of barely holding its own.

The new 60-cycle developments being considerably more economical than the old 25-cycle, there is a large economy factor in carrying the maximum amount of the combined system load on the 60-cycle generators. The installation of frequency changers between the 25- and 60-cycle systems made it possible to carry the base load of the 25-cycle system on the new 60-cycle developments and in addition thereto made it possible to pool

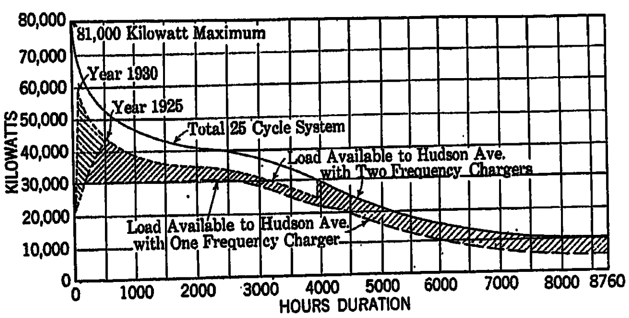

FIG. 1—LOAD-DURATION CURVE OF 25-CYCLE SYSTEM

the reverses on the two systems thereby giving greater utilization and availability of the generating capacity.

In Fig. 1 is shown the load-duration curve of the 25-cycle system with amount of load convertible to the 60-cycle prime movers by the installation of first, one 35,000-kv-a. frequency changer; and second, two 35,000-kv-a. frequency changers. The area in the first block represents 160,000,000 kw-hr. per year with a unit cost saving, which for this feature alone, more than pays for the carrying charges and losses of the first frequency changer installation.

The 25-cycle generating capacity amounts to 125,000 kw. with a possible peak load of 85,000 kw. and in addition there is available 15,000 to 20,000 kw. in 25-cycle tie capacity with other companies. The installation of the first frequency changer added 30,000 kw. in reserve generating capacity to the 60-cycle system, and the second unit would add an additional 25,000 to 30,000 kw. This 50,000 to 60,000 kw. of reserve made available to the 60-cycle system is of considerable value with the new 60-cycle generating developments using 50,000-kw. units. This feature alone can easily be said to more than justify the cost of the first frequency changers since the completed installation costs less than $20.00 per kw. while generating station capacity costs upwards of $100.00 per kw., and there was a deficit in 60-cycle generating capacity in 1923.

The frequency changers are of additional value in providing reserve to the 25-cycle plant for a case of unusually bad luck of machine outages in the station.

The metropolitan companies have for a number of years followed the policy of operating at all times with sufficient generating capacity to be capable of carrying the load should the largest generator be dropped from the system. It is, therefore, evident that the continuous parallel operation of the 25- and 60-cycle plants saves the operation of one turbo-generator unit. This permits an economical loading on the units and especially at light load period effects a real saving in production cost.

The installation of the second frequency changer would make it possible to shut down the 25-cycle station for one watch or nearly 3000 hours a year.

The interconnection of systems through frequency changers is of the same general character with similar problems and possible economies as inter-connection of systems through tie lines. The total savings under either condition run into large figures if all concerned cooperate in the operation of the more economical units for base load and shut down the plants and units of less efficiency for use only on peak.

Where two or more companies are concerned in the interconnection, the rate for interchanged power complicates the situation, and it is essential than an equitable rate be established in order to allow operation for maximum economy.

It may be unnecessary to say that the only way to use interconnecting tie lines for obtaining the maximum over-all economies is to operate at all times with the systems in parallel. This allows full advantage to be taken of the three separate points previously mentioned, namely:

1. Greatest utilization of the most economical plants and units.

2. Maxumum availability of spare capacity.

1. Brooklyn Edison Co., Brooklyn, N. Y.

Presented at the Spring Convention of the A. I. E. E., St. Louis, Mo., April 13-17, 1925.

3. Reduction in number and amount of idle or lightly loaded turbo-generator units at all times.

The parallel operation of large systems through frequency changers or tie lines necessitates that these ties have the proper characteristics to hold the systems in step for the major number of operating disturbances. It may not be possible, or even desirable, to hold the systems in step during all disturbances, but it must be a rare case when they are allowed to fall out of step and provisions must be made for the systems to break apart through automatic oil circuit breakers on these rare occasions. Although the Brooklyn Edison Company

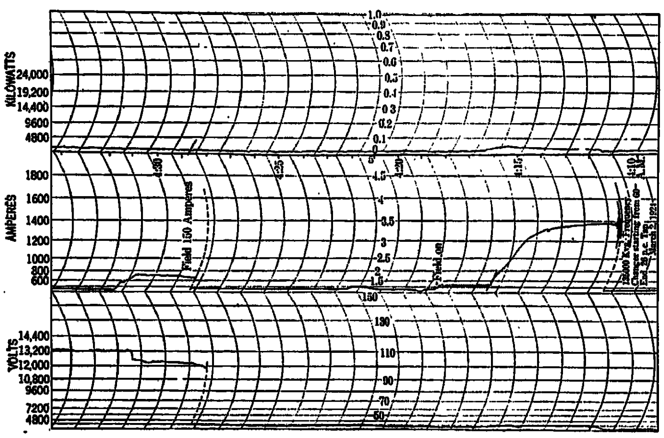

Fig. 2

had a number of smaller frequency changers in operation, converting from 25- to 62½-cycles they were discarded for the larger more efficient unit which would permit parallel operation.

The character of the normal fluctuations of load or disturbances is, therefore, the determining feature of the characteristics of the ties. The loads on both the 25- and 60-cycle systems of the Brooklyn Edison Company are of a rather steady character and the maximum

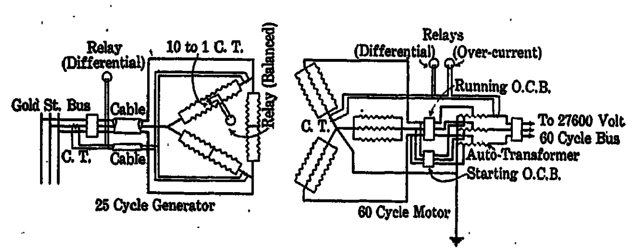

Fig. 3—Relays for Induction Type Motor Shown for One-Phase Only, the Other Two Phases Being the Same

amount of load which can be thrown from one system to the other may be considered as the capacity of the largest 25-cycle unit. This condition may occur were this unit to be automatically tripped from the system, and, as previously stated, this operation is considered a normal function in the metropolitan territory, and, therefore, the two systems should remain in step under these conditions.

When a sudden load is thrown from one system A to another system B, there is necessarily brought about a reduction in the speed of system A to give the phase-angle displacement for transfer of power. It therefore follows, that at the instant when the phase-

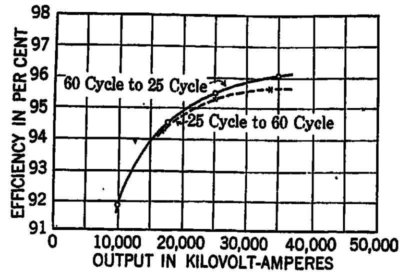

Fig. 4—Efficiency Curves, 35,000-Kv-a. Frequency Changer

angle is reached for the transfer of this amount of power the speed of system A is lower than system B and overshoots the mark. For purely elastic systems, this would require a maximum power transfer of double this value when the oscillations are not accompanied by an impetus at each swing, such as caused by improper governor operation. Tie connections having a maximum synchronizing capacity of double the permissible fluctuation of load should hold the systems in stable operation. Under usual conditions the load on each system provides a dampening characteristic which makes the factor two a rather safe figure to use.

The largest generator on the 25-cycle system of the Brooklyn Edison Company is 30,000 kw. and therefore,

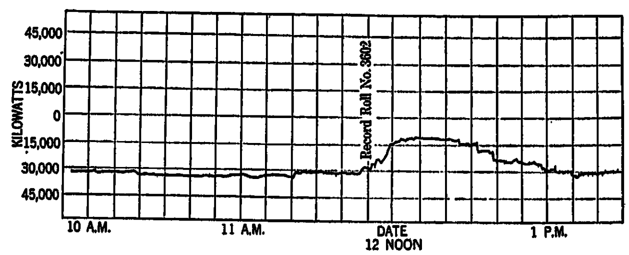

Fig. 5

a frequency changer having a pull-out point above 60,000 kw. was chosen. The 35,000 kw. unit selected has a pull-out point of a little over 70,000 kw. and although a number of system disturbances have occurred while the systems were in parallel through this unit, the two systems have never pulled apart. These disturbances have at times reduced the voltage and as the synchronizing power is a function approaching the square of the line voltage, the synchronizing power at such times was reduced considerably below 70,000 kw. In one case, a direct 3-phase short occurred on the 25-cycle generating station bus with three generators and the frequency changer operating, and although two of the turbine tripped off, the frequency changer and the other generator held in and carried the entire load.

The fluctuation in load through the frequency changer very seldom reaches more than 5000 kilowatts, and in Fig. 2 is shown a typical record of a graphic kilowatt meter in this tie connection.

A one line diagram showing the relay connections on this 35,000-kv-a. frequency changer is given in Fig. 3. The balanced and differential relays are for the protection of the system and the frequency changer in case of short circuits within the machine. The overload relay is for the purpose of automatically tripping out the tie connecting oil circuit breaker in case the two systems fall out of step and the relay is set for sufficient current and time to accomplish this result without tripping out on momentary short circuits.

The synchronous-synchronous type of frequency converter was selected as, for our purpose, it gave the following advantages:

Greater flexibility in voltage control on either system.

Elimination of voltage disturbances passing from one system to the other under short circuit conditions. With somewhat different operating conditions some engineers have felt the electrical tie is an asset under disturbance condition so that a voltage dip will be reflected from one system to the other.

Slightly higher guaranteed efficiency.

The efficiency of the first 35,000-kv-a. unit exceeded the guarantees throughout the full range of operation with the results as shown on Fig. 4.

Amortisseur windings are provided on the 60-cycle end for starting with quarter voltage tap on the transformer whereas the unit when started from the 25-cycle end is connected directly to a turbine with both units started from standstill. In Fig. 5 is shown the current, voltage and kilowatts at the time of starting the frequency changer from the 60-cycle end. The ease with which this machine comes up to full speed is rather remarkable and you will note in the curve at the various points the speed relations of the revolving field with the rotating armature flux as it passes the critical points.

Discussion

R. W. Wieseman: I should like to ask Mr. Woodrow about the pull-out torque of this frequency-converter set; this is given as a little over 70,000 kw., or over twice the normal torque of the set. Is this pull-out torque the actual synchronous torque which the set can furnish for an appreciable time or is it the momentary torque of this set which includes the inertia torque of the rotors? The inertia torque is useful in a synchronous motor for a small fraction of a second only. The energy stored in the rotors of this frequency-converter set could furnish over twenty times normal load for but a few cycles. However, the limiting feature of the power output of the set is the ability of the generator to transmit power to its system. The power output of the generator, for a fraction of a second, is limited by the leakage impedance and not by the synchronous impedance because the generator magnetic flux can not change quickly and therefore it cannot be influenced by the opposing armature magnetomotive force. Thus, only two or three times normal load can be delivered by the generator for a small fraction of a second.

Therefore, to say that a frequency-converter set has a high pull-out torque without fully explaining the conditions, is misleading. The rational basis upon which synchronous machines can be compared is the constant or steady-state overload for an appreciable time, such as thirty seconds. Unity-power-factor machines of this type are usually designed with a short-circuit ration of unity and, consequently, the *true* synchronous pull-out torque is only 150 per cent of the normal torque.

Mr. Woodrow states that the synchronizing power is a function approaching the square of the voltage. In any simple circuit with constant impedance the power varies exactly as the square of the voltage. Two duplicate generators operating in parallel through a transmission line have a synchronizing power which also varies as the square of the line voltage assuming that both generators have approximately the same voltage. With a frequency-converter set operating between two systems the capacities of which are much greater than the capacity of the set, the maximum power that can be transferred varies approximately as the first power of the line voltage because, Maximum instantaneous power = (line voltage × machine virtual voltage) ÷ (transient impedance) or Maximum steady-state power = (line voltage × machine nominal voltage) ÷ (synchronous impedance). Since the virtual voltage (flux) or the nominal voltage (excitation) are constant, respectively, the maximum power varies approximately as the first power of the line voltage.

It follows that a frequency-converter set which has a steady-state maximum power of only 50 per cent above normal can carry 100 per cent overloads with a reasonable drop in line voltage for a small fraction of a second.

H. R. Woodrow: The 35,000-kv-a. frequency changer has a pull-out point of 70,000 kw. for the first few cycles covering the first oscillatory swing of surging between the systems. The sustained pull-out point is about 55,000 kw.; that is, after the magnetizing action of the motor field comes into play.

The equation for maximum instantaneous power given by Mr. Wieseman is approximately correct where the resistance of the circuits is small compared with the reactance and when his term "transient impedance" represents self inductive reactance and resistance and "machine virtual voltage," the generated voltage in the motor. The maximum steady-state power is represented by exactly the same formula, but Mr. Wieseman has used an imaginary expression, "machine nominal voltage" which represents the motor generated voltage multiplied by the ratio of another imaginary term synchronous impedance and real impedance.

Under normal operations the real impedance drop through the machine is small and therefore the voltage generated in the motor is approximately the same as the line voltage and therefore the maximum instantaneous power is equal to the line voltage squared, divided by the real impedance.

The exact expression for maximum instantaneous power between two synchronous machines having the same generated voltage is

$V^2/Z \times (1- R/Z)$ where V = voltage, Z = impedance and R = resistance.

Eight Years Experience with Protective Reactors

BY JAMES LYMAN[1] LESLIE L. PERRY[1] and A. M. ROSSMAN[1]
Fellow, A. I. E. E. Fellow, A. I. E. E. Associate, A. I. E. E.

Synopsis:—*In 1914 the authors presented before the Institute two analytical papers on Protective Reactors. During 1917, 1918 and 1919 three large power stations embodying what seemed to be the best system of bus and feeder reactors were placed in operation. The present paper gives brief accounts of sixteen accidents on the busses or feeders of these power stations. In each case the reactors effectually kept the power concentration within such limits that the damage was localized, and no troubles were experienced from mechanical displacement of conductors and insulators elsewhere.*

In concluding, the authors state that their experience with reactors leads them to believe that short circuits in the largest power stations can be so controlled by a properly designed system of reactors that their destructive effects will be confined to the immediate vicinity of the arc, and that it will be possible so to tie together power stations and power systems of any magnitude that a short circuit will be of merely local significance and will not jeopardize the service of other parts of the system.

IN February, 1914, the authors presented before the A. I. E. E. a paper entitled "Protective Reactances in Large Power Stations." In October of the same year they presented a second paper entitled "Protective Reactances for Feeder Circuits of Large City Power Systems." These studies were made for the purpose of determining the best reactor system for two large steam power stations on which preliminary design studies were then being made.

In the second paper it was shown by a series of curves[2] (Curve Sheet No. 6) that after a certain number of generators are connected to a ring bus, with reactors between adjacent generators, the number may then be increased to infinity without appreciably increasing the amount of current flowing into a short circuit on the bus. Based on the reactance values of generators and bus bar reactors which at that time seemed most desirable and which experience has changed but little, the following figures derived from the curves[2] will be of interest:

1. After three generators are installed, the number of generators can be increased to infinity without increasing by more than 50 per cent the amount of current that can flow into a short circuit on the bus.
2. With an infinite number of generators, the maximum amount of current that can flow into a short circuit on the bus is about 3½ times the short-circuit current than can be obtained from a single generator.

The system of connections finally adopted was a ring bus with five per cent bus reactors between adjacent units, based on turbo-generator units of the order of 25,000 kw. to 30,000 kw. at 0.8 power-factor, and a radial system of feeders with three per cent feeder reactors, based on feeders of 6000 kv-a. to 7500 kv-a. at 11 kv. to 13.2 kv. The bus reactors are shunted by oil circuit breakers which are so controlled that when one or more generators are disconnected from the bus, the corresponding set of adjacent bus reactors is automatically shunted, thereby preventing more than one set of bus reactors from being in circuit between any two adjacent running generators. This scheme of connections with eight generators in service is shown diagrammatically in Fig. 1. In Fig. 2 and Fig. 3 are shown the connections when but one-half the generators are in service. This system of connections limits the flow of current into a short circuit on a generator or on any section of the bus after a lapse of 0.1 sec. to a value of approximately 750,000 kv-a. The flow of current into a feeder short circuit is limited to a value of approximately 250,000 kv-a.

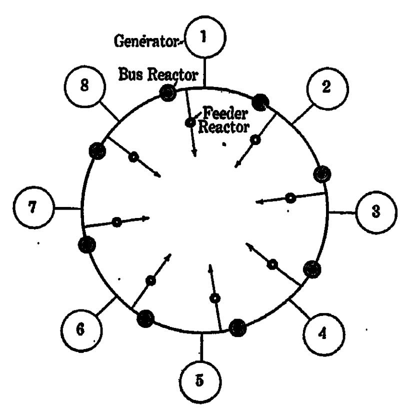

FIG. 1—SCHEME OF CONNECTIONS—ALL GENERATORS IN SERVICE

It is the object of this paper to recount some of the actual operating experiences in power stations where this reactor system has been in service for several years.

In 1916 construction work was started on the Windsor (West Virginia) Power Station of the American Gas & Electric Company and the West Penn Power Company. This station was placed in operation during 1917 with one 30,000-kv-a. turbo-generator. The following table shows its growth:

Year	Units Started Operation	Total kv-a. Capacity
1917	One—30,000-kv-a.	30,000-kv-a.
1918	One—30,000-kv-a.	60,000-kv-a.
1919	Two—33,333-kv-a.	126,666-kv-a.
1923	Two—33,333-kv-a.	193,333-kv-a.

During the years that this station has been in operation, there have been several short circuits of sufficient

2. These curves give current values which correspond approximately to the 0.1 sec. values on the latest decrement curves.

Presented at the Spring Convention of the A. I. E. E., St. Louis, Mo., April 13-17, 1925.

severity to test the effectiveness of this scheme of reactors, and to demonstrate its ability to keep down the flow of short circuit current to a value well within the interrupting capacity of moderately heavy duty oil circuit breakers and to localize the damage to the immediate vicinity of the arc. Below are given brief narratives of several of these short circuits:

1. On August 15, 1919, with three generators running, an employe accidentally placed a ladder against a high tension lead

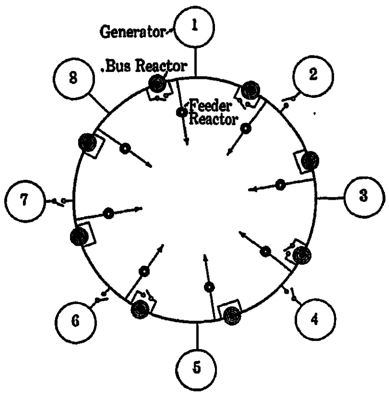

FIG. 2—SCHEME OF CONNECTIONS—GENERATORS NOS. 2, 4, 6 AND 7 SHUT DOWN

in the 66-kv. switchyard. The circuit breaker on the low-tension side of the transformer bank, feeding these bus bars, tripped and cleared the trouble. A few minutes later the low-tension breaker was again closed. Immediately a quantity of oil squirted out of one of the transformers between the tank and cover. The 11-kv. circuit breaker again tripped out and cleared the circuit. An examination of the damaged transformer, which was one unit of a 20,000-kv-a. bank, showed that the lower turns of the 11-kv. coils were badly damaged both by burning and by the destructive forces of heavy currents. The high-tension coils, although un-

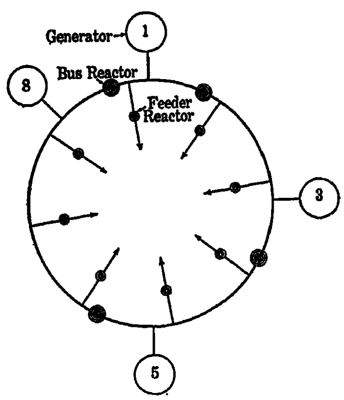

FIG. 3—SIMPLIFIED DIAGRAM OF CONNECTIONS—GENERATORS NOS. 2, 4, 6 AND 7 SHUT DOWN

damaged, were somewhat displaced. The total damage was confined to the one transformer.

2. On May 17, 1922, with four generators running, one of five 3-conductor 500,000-cir. mils 11-kv. cables, feeding a 30,000-kv-a., 132-kv. transformer bank, failed under emergency overload, taking with it several of the adjacent cables. The 11-kv. circuit breaker cleared the trouble from the bus. The following morning a cable on a duplicate transformer bank of the same capacity and voltage failed in a similar manner. In this case also the 11-kv. oil circuit breaker cleared the trouble from the bus bars. These cables were connected directly to the 11-kv. bus bars without series reactors. In neither case did the damage extend beyond the cables and their enclosing conduits.

3. On September 1, 1922, lightning broke down a bushing on one of the 66-kv. oil circuit breakers, causing failure to ground. The overload relay on the 11-kv. side operated properly, but the tripping relay on the 11-kv. oil circuit breaker was out of adjustment and failed to operate. Four generators were connected to the bus at the time, and the flow of current was sufficient to burn out the windings of two transformers of a 20,000-kv-a. bank feeding the 66-kv. bus. The pressure inside of the tanks was so great that the manhole covers were blown off in quick succession, and each transformer sent up a column of flaming oil higher than the stacks of the power-station building. It was several minutes before the switchboard operators discovered the location of the trouble and cleared the transformer bank from the bus, and some time before the oil fire in and around the transformers could be extinguished. Here again, the damage was limited to the two transformers and the area over which the flaming oil had spread.

4. On November 13, 1923, there occurred the most serious electrical trouble which had developed since the station was placed in operation. With all six generators and a seventh duplicate machine operating as a synchronous condenser,—a total of 223,333-kv-a., connected to the bus,—an arc was started by the breakdown of an insulator. The subsequent arcs and flames established a short circuit between the three phases of the main 11-kv. bus. More than a minute elapsed before the switchboard operators located the trouble and killed the power-station bus. A subsequent examination showed that the damage was confined entirely to the short section of bus across which the arc had played. A lighting fixture on the ceiling of the room directly above the arcing bus was not damaged; neither was the reserve bus structure which was separated from the main structure by an aisle space of eight feet. The circuits were, accordingly, transferred to the reserve bus and service was resumed within 48 min.

The West End Power Station of the Union Gas & Electric Company of Cincinnati was placed in operation in 1918, with two 30,000-kw. (31,250-kv-a.) turbo-generator units. In 1920, a third unit, and in 1921, a fourth unit of the same capacity were placed in service making a total present capacity of 120,000 kw. (125,000 kv.a).

All faults on West End Power Station have occurred on the feeders beyond the feeder reactors. Thus, the maximum fault kv-a. has been limited, in all cases, by the feeder reactors which are rated at 0.76 ohm on a basis of 13.2 kv. (three per cent on 300-amperes). Three of the most severe faults are listed below.

1. On July 18, 1921, at 11:42 a. m., a three-phase short circuit developed in a 400,000-cir. mil cable approximately 1½ miles from West End Power Station. At the time, there were two generators running with a total load of 45,000 kw., and two bus reactors in service. The feeder-oil circuit breaker opened to clear the fault without signs of any great disturbance on the rest of the system.

2. On December 15, 1923, a short circuit developed in a 400,000-cir. mil cable approximately ½ mile from West End Power Station. There were three generators running at the time and three bus reactors were in service. The fault current was 6000 amperes in each phase, and was broken by the opening of the feeder-oil circuit breaker. However, there was a sufficient force developed between two of one set of feeder reactors to pull them together with a resultant breaking of the concrete side slabs. These reactors were spaced horizontally one foot apart and were not fastened to the floor. The voltage on the directly affected section of bus was maintained at 70 per

cent of normal, and the rest of the system did not suffer any serious disturbance.

3. The most severe fault that the system has suffered occurred on October 31, 1924, at 9:57 a. m. This was a three-phase short circuit on two adjacent 400,000-cir. mil cables at a point where they changed from underground cables to overhead open lines. At the time there were four generators running and four bus reactors were in service. The two cables were connected to different sections of the bus, so that two of the generators were connected directly to the faulty cables without interposing bus reactors. The fault current was 4300 amperes per phase in each cable (8600 amperes from the system). The bus voltage dropped to 77.5 per cent of normal. One hurling pump motor which was connected to the same section of bus as one of the faulty cables, was tripped out by an undervoltage relay. No other auxiliary motors were affected. The relays operated correctly to open the oil circuit breakers on the two faulty cables.

In 1925, Miami Fort Power Station, with an initial installation of two 38,000-kw. (44,705-kv-a.) turbo-generators will go into service about twenty miles west of West End Power Station. This station will have the same system of bus and feeder reactors that has worked out so successfully at West End Power Station.

In the winter of 1919-1920 the Northeast Power Station of the Kansas City (Missouri) Power & Light Company was placed in operation with two 20,000-kw. (25,000-kv-a.) turbo-generator units. The following table shows the growth by years of this station:

1919—One 20,000-kw. 25,000-kv-a.
1920—Two 20,000-kw. 25,000-kv-a.
1922—One 30,000-kw. 37,500-kv-a.
1925—One 30,000-kw. 37,500-kv-a.

Total present capacity 120,000 kw. (150,000-kv-a.)

The Northeast Power Station is located northeast of the main business district of Kansas City on the low bottom lands which border the Missouri River. As there was initially no practical way of carrying underground cables in ducts across these bottoms, the 13.2-kv. outgoing feeders were carried a distance of one-half to one mile on pole lines with conductors supported on 25-kv. porcelain insulators. Lightning is particularly severe in this district and although the circuits, where they changed from overhead to underground construction, were all protected by oxide-film lightning arresters and some of them also had lightning arresters at the power station end, there were, during the five years from 1920 to 1924 inclusive, a total of six cases where lightning entered the power station over these circuits and damaged equipment in the building. There was also one case of a cable breakdown near the feeder exit bushing and another case where an operator pulled a wrong disconnecting switch near the exit bushing, both of which resulted in practically the same kind and amount of damage as that caused by the lightning.

In the majority of these cases the damage consisted of the breakdown of one or more current transformers followed by an arc which burned one or more feeder reactors and destroyed some of the disconnecting switches, primary and secondary wiring, insulating supports and compartment doors. Each of these cases of trouble caused the temporary loss of a feeder circuit and was accompanied by a momentary drop in voltage. In not one of the eight cases, however, did any of the auxiliary motors drop out of step.

This power station has also had one case of trouble in which the bus bars were directly involved. On August 4, 1922, during a period of construction work, an operator carelessly closed a disconnecting switch on a grounded oil circuit breaker which grounded the *C*-phase of the main bus bars. Three 20,000-kw. units were in service at the time, and the neutral of No. 3 unit was grounded through a 3-ohm resistor.

When the accident occurred, generator No. 3 was tripped out by its balanced relays. The operator then tripped off generators Nos. 1 and 2 thereby shutting down the entire system. A subsequent examination disclosed the following damage: The disconnecting switch, with which the operator established the ground, was burned up. The neutral resistor developed a ground and shunted out 5/7 of the resistance, permitting a current flow calculated at 8800 amperes as against a flow of 2500 amperes had all the resistance been in circuit. This excess current burned out and open-circuited that part of the resistor remaining in circuit. Two jumper connections between coils on the *C* phase of unit No. 3 burned open. Within 12 minutes the station was again in operation, and within 30 minutes the load was back to normal.

At no time in any one of the three Power Stations, even under the worst of short-circuit conditions, has there been any trouble experienced from the shifting of cables and bus bars, or the breaking of bus bar and insulator supports by the mechanical forces which are usually characteristic of a heavy flow of uncontrolled short-circuit current.

Based on the experience given above, the authors feel that short circuits in the largest power stations can be so controlled by a properly designed system of bus reactors that their destructive effects will be confined to the immediate vicinity of the arc. There will be some disturbance in voltage beyond the bus reactors, but in only the most severe cases will this be of sufficient magnitude to cause auxiliary motors to drop out of step. Furthermore, they feel that with properly chosen reactors, it will be possible to tie together power stations and power systems of any magnitude so that a short circuit will be of merely local significance, and will not jeopardize the service of the other parts of the system.

For assistance in compiling the information on short circuits, the authors are indebted to E. H. McFarland of the American Gas & Electric Company, Windsor, West Virginia, C. W. DeForest of the Union Gas & Electric Company, Cincinnati, Ohio, and Edwin Jowett of the Kansas City Power & Light Company, Kansas City, Missouri.

Discussion

J. Lyman: To obtain the minimum concentration of power is an everpresent problem in the design of large power stations, substations, and distribution systems. A circuit breaker must be built, capable of opening its circuit, under any short-circuit conditions, but more serious than the problem of designing adequate circuit breakers are the electrical and mechanical shocks that may be transmitted to the entire electrical system from a modern bulk-power station, or to a power distribution and transmission system, tying-in several such great stations. At least 0.3 sec. elapses before a circuit breaker can operate. During this time the full force of the shock is imparted to the entire system.

As the units of power to be controlled are continually increasing, the design of circuit breakers capable of controlling them is becoming more and more important. The combination of current-limiting reactors with the circuit breakers in such a way that a minimum concentration of power is secured without materially affecting voltage regulation should, therefore, be the aim in the design of power stations and distribution systems. Thus electrical and mechanical impacts due to electrical disturbances of whatever nature, will be kept down to a minimum consistent with successful operation and the greatest reliability of service secured.

Reliable and efficient power stations, transmissions and distributions are rapidly bringing to a reality universal 60-cycle power throughout the country. Clearly in any electric power system the latest, most economical power station should be operated as a strictly base-load plant. In this way the lowest possible cost per kw-hr. is obtained and advantage taken of the remarkable advances in power-station design.

By judicious location of synchronous condensers and reactors, voltage regulation can be maintained and power drawn from any power station over the entire system.

In general, the energy losses in the synchronous condensers are compensated for by the improved efficiency of transmission lines, transformers and generators, supplying power at the higher power factor, while the capital costs of the synchronous condensers are more than offset by the increase in capacity of the system at the higher power factor. Thus, it is possible to operate with reliability the latest power plant on the system as a base-load plant with the resultant system economies. By so doing, the electric power can be supplied over a wide radius to the large industrial plant or to an electrified steam railroad at a lower price than that at which these companies are able to make power because they have a comparatively fixed power demand at a comparatively low load factor; thus when their power stations become obsolete, they cannot write them off their books and discard them. They cannot take advantage of the improved efficiencies of the latest power-station design and of the high load factor that is obtained on an extended improved power system.

H. W. Eales: Mr. Rossman has called attention to the remarkable fact that it is possible for short circuits to occur within power stations and for the operating staff to be unaware of the fact. Mr. Rossman mentions a short circuit of this nature at Windsor Station.

About twelve years ago, one of the 11-kv. busses burned in two in the Keokuk Station. For some time the operators there were unaware that they were delivering single-phase power over the 143-mi. transmission line to St. Louis.

In December 1924 a short circuit occurred in one of the bus chambers at Cahokia Station and although the operator knew that a short circuit existed on the system he did not ascertain for several minutes that it was within his own station although it later developed that it was located on the same floor on which the operating benchboard is situated.

As a result of that and other experiences we have recently concluded to install in Cahokia Station an indicating and ground-current protective system.

We believe that, with the isolated-phase arrangement of oil circuit breakers and other accessory equipment as now completely installed at Cahokia Station, a three-phase short circuit is virtually an impossibility. In designing the indicating and protective system about to be installed, it is necessary to consider only protection from phase to ground.

A review of all cases of trouble which have involved the station bus revealed that in order to clear the short circuit it was finally necessary, by manual operation, to isolate the bus section in trouble and disconnect its generator and other sources of power connected to it. This consumed valuable time during which system service suffered. As long as it is necessary to do this ultimately, it has been decided to arrange for its accomplishment automatically and instantly.

The method to be employed will consist of introducing current transformers in the apparatus ground bus ahead of the connection to earth. The secondary leads from these current transformers will be brought to the benchboard operating room to relays whose operation will cause the lighting of telltale lamps indicating the bus chamber in which the short circuit occurs, and simultaneously cause the opening of the bus-section circuit breakers, at both ends of the bus section involved, open the generator breaker or this bus section, and also tie feeders, if any, from other stations or systems.

E. C. Stone: The determination of the arrangement of bus reactors in a power plant must take into account both the protection of equipment and the safeguarding of service. Of the five cases of bus-reactor operations reported in this paper, three apparently resulted in complete shut-down of the power plant and consequently serious interruption to service. In my opinion the bus reactor problem is not solved until service as well as equipment is completely protected.

H. R. Summerhayes: I have had occasion to review and analyze most of the major bus short circuits that have occurred in large power stations, and it appears in nearly all of them that if the bus section could be segregated instantly from the rest of the station, matters would be better than they are. That is to say, some service might have been lost, but not nearly so much service as has been lost in most of these short circuits. Therefore, I am heartily in favor of some system of protection, which will sectionalize the bus. It has been accomplished by the differential protection used in the Brooklyn Edison Company's system and in the hydroelectric plant at Queenston, Ontario. In the latter, I believe the differential protection has actually worked successfully several times. It is also accomplished by the ground protection system mentioned by Mr. Eales.

The ground protection system is simple and it is based on the probability that nearly all bus troubles on the isolated-phase system, or on the group-phase system, involve a ground, and there is some ground current flowing.

It is very simple, then, to connect all of the non-current-carrying metal in the vicinity of a bus section and the switches pertaining thereto through a current transformer to ground. Instead of connecting them all to the common station ground, we run all the ground connections from switch bases, operating mechanisms, etc., of one bus section through a current transformer to the station ground, and that current transformer is made to trip the section switches, feeder switches and the generator switches on that bus section, and do so instantly. In this manner the service can be resumed with the least amount of interruption.

While reactors are very effective in limiting short-circuit currents, there is one trouble that has been encountered with the use of bus reactors, namely, when a large amount of current is being passed over a bus reactor from one section to another, the bus voltage differs on the two sections, or rather there is a phase

difference which unbalances distribution of load in feeders from different bus sections to the same substation. To prevent this unbalance it is desired to make a reactor which will be of low reactance at normal load, and high reactance at short circuit; this has been the aim of inventors for a good many years.

I hope that that problem will be solved; that some form of linkage will be found which will enable a large amount of power to be exchanged between bus sections or generating stations under normal conditions and will interpose a high reactance instantly before one cycle is passed when short circuit occurs.

F. H. Kierstead: This record of eight years' experience with a variety of reactors and only one instance of a reactor failure (and in this instance, the fault appears to have been with the installation and not with the reactor) is, I think, a positive testimonial of the reliability of modern current-limiting reactors. However, I, personally, am not satisfied with even the fine record that reactors have made, but feel that we must press on toward a still higher degree of the perfection of this device upon which we depend to protect everything else in great power systems. This greater perfection must come not alone from increased efforts on the part of the manufacturers but also through a better understanding of the characteristics of reactors by the operators and from more consideration being given by them to the installation and upkeep of the reactors.

Turning to the record in this paper, it is to be noted that in the one case of a reactor failure the reactors pulled together because they had not been bolted down to the floor. Now I am not bringing up this point in order to excuse a reactor failure, (the reactors were not of our manufacture, but the results would doubtless have been the same had they been our reactors, if the means which we provided for bolting the reactors to the floor had not been used); nor do I bring it up in order to point out a faulty installation, but I am bringing it up for consideration because it illustrates my point that a better understanding of the characteristics of reactors is required and more consideration must be given to their installation in order to obtain a higher degree of perfection in the service that they render. It should be clearly appreciated that there is a large magnetic force between adjacent reactors when carrying short-circuit current and that for this reason reactors should always be bolted to the floor and, in many cases, must be further braced to withstand this force.

There is another source of danger to reactors which I think is worthy of consideration at this time. It is one which we all should realize but one which many of us overlook. I refer now to the failure of a reactor which may be caused by foreign conducting material accidentally dropping into a reactor and lodging in the winding. We have proven, by careful tests, that if a piece of metal, such as a screw, bolt, nut, or washer becomes lodged in the winding and escapes notice during inspection, no indication of its presence in the reactor will usually be given during the normal operation of the circuit because of low voltage between turns, but at the instant a short circuit occurs, when the voltage between the different sections of the winding jumps to many times its previous value, incipient arcs shoot out where the metal bridges across a section of the winding and are followed instantly by a complete flash-over of the reactor. Our tests have further proven that thin insulation on the conductor will not prevent such failures, even though the insulation has ample dielectric strength to withstand the voltage placed across it by a short circuit for the reason that the magnetic force exerted on iron and steel objects will cause them to break through thin insulation.

This danger may be eliminated by a very careful inspection of the reactor before it is placed in service in order to be sure that no such foreign material is lodged in the winding. The inconvenience of making such an inspection should not deter one from making it for it is in those places most difficult to inspect that foreign material is most likely to lodge.

Attention is further called to the fact that the magnetic field of a reactor carrying a short circuit will reach out to a distance at least equal to the diameter of the reactor and draw loose magnetic material into its winding. Therefore, great care must be taken to keep the passageway where reactors are installed clear of such material. Doors or screens across the openings of the compartments in which reactors are installed are recommended as a means of preventing any such material which may be dropped in the passage-way from getting into the reactors.

For those installations where it is very difficult to be sure that foreign material will not enter into the reactors and for those operators who require a safeguard from it in addition to that afforded by inspection, The General Electric Company has developed a thick asbestos insulation which is closely and firmly woven on the reactor conductor and is treated with flame-proof compound which makes the covering very strong and able to resist cutting and tearing very tenaciously. This insulation is used solely to prevent foreign material causing a short circuit between turns. The special grade of Portland cement concrete supports so successfully used for years is still the major insulation. Reactors with this insulation have been thoroughly tested by making many short-circuit tests upon them with a 26,700-kv-a., short-circuit testing generator and these tests have proven that this insulation affords adequate protection to the conductor from foreign material and that the insulation is so free from any inflammable material as to be properly classed as fireproof.

H. W. Osgood: This timely paper is a valuable confirmation of the effectiveness of reactors placed in a ring bus in large generating stations. Reactors placed in a bus between generating units are more effective for limiting short-circuit current than reactors of greater reactive voltage drop placed in series with the generators and in effect paralleled on a bus. Reactors of moderate size are also necessary in the generator leads as these give to the generator circuit and the busses protection equivalent to that provided by feeder reactors.

In looking up earlier information on use of current-limiting reactors, we find that in June, 1909, Mr. Junkersfeld presented a paper at Atlantic City, before the National Electric Light Association on "The Use of Reactance Coils in Generating Stations." In this paper, mention was made of the first application of reactors in the Cos Cob Station of the New York, New Haven and Hartford Railroad, an installation in the Central Station at Baltimore and in the Fish Street Station at Chicago. Reactors of the choke-coil type had, however, been used on many overhead and a few underground circuits prior to these installations in Cos Cob, Baltimore, and Chicago.

Dr. Steinmetz, in his discussion of that paper in 1909, said among other things, "When you come, however, to still larger stations—and some of the largest stations in the country are rapidly approaching that condition—then we meet the condition where even with this generator reactance, limiting the momentary short-circuit current to about ten times full-load current, the rush of current at the bus bars is altogether too much to permit a switch to be designed economically to take care of it, and then we shall be obliged to carry the limitations still further in the manner suggested by Mr. Junkersfeld, in sectionalizing the bus bars by reactance. This suggestion is therefore not an alternative to the generator reactance but is in addition thereto, for those cases of huge powers—200,000 kw. or more—where the generator reactances are no longer sufficient to limit the momentary short-circuit current at the bus bars to a reasonable value; that is, to half a million or a million kilovolt-amperes."

During these 16 years since this discussion by Dr. Steinmetz, the rupturing capacity of oil circuit breakers has been increased, in some cases, to 1,500,000 kv-a., but the ultimate capacity of generating stations has been increased in some cases to a projected total of 600,000 kw. Current-limiting reactors have therefore become indispensable between bus sections, as well as

in the generator leads and feeders to limit the short-circuit current, within the rupturing capacity of circuit breakers.

The isolated-phase arrangement with vertical separation of phases is peculiarly adapted to the installation of current-limiting reactors. Space is afforded in the switchhouse where the generator leads come up or the feeders drop down to the cable tunnel, the bus structures and oil-circuit-breaker compartments being grouped in the center with an operating aisle between structures. With the reactors isolated in this manner there is less likelihood of a phase-to-phase short circuit and if one occurs the reactors intervene to limit the current.

Experience indicates that in addition to a proper scheme of connections for reactors, the following points among others should be given careful consideration:

Terminals should be placed at opposite ends of a reactor to prevent danger from flashover across terminals and with the vertical-phase separation one terminal can be placed at the top and one at the bottom of the coil.

Non-combustible material should be used in their construction.

Reactors should be satisfactorily insulated from ground and enclosed in a compartment arranged for ventilation.

Reasonable clearances should be provided to all magnetic material.

Insulation of conductors, if used, should be of heat-resisting material.

As the reactor is installed as a protective feature, it should be carefully constructed and installed in every detail so that the chances of the reactor, or its connections, being the source of trouble or the means for spreading trouble will be reduced to an absolute minimum.

Mention is made in this paper that when one or more generators are disconnected from the bus, adjacent sets of reactors are automatically shunted by short-circuiting breakers, thereby preventing more than one set of bus reactors being connected between two adjacent running generators. A description of the means for automatic shunting of the reactors would be of interest.

S. I. Oesterreicher: In this paper there is one set of records of particular interest to me, namely, the short-circuit disturbances in the West End Power Station of the Union Gas & Electric Company of Cincinnati.

It is stated in the paper that in one case the magnetic attraction between two adjacent co-axially arranged reactors was of sufficient magnitude to damage the two reactor housings. With a separation of 12 in. between the two concrete housings, the magnetic centers of the two coils are 33 in. apart. At this distance and with 6000 amperes flowing across each reactor the magnetic attractive forces between the reactors was about 14,500 lb. The weight of the reactor was only 13 per cent of the attractive forces. Thus the damage done to the concrete housings due to their tender contact is excusable, if it is known that no interbracings between the two reactors were used.

The other set of records about which I desire to comment refer to the eight disturbances of the North East Power Station of the Kansas City Power & Light Company. Of these eight disturbances, six were caused by lightning troubles. The paper states that: "In the majority of those cases the damage consisted of the breakdown of one or more current transformers followed by an arc which burned one or more feeder reactors, etc." I believe it to be unfair to record in this paper reactor failures caused by lightning disturbances.

In my humble opinion, a current-limiting reactor will give no protection against lightning regardless of its type of construction. It would be of interest to know whether or not these reactors had shunted resistors. This would throw light to some extent upon a very live topic among many engineers.

A. M. Rossman: We are indebted to Mr. Eales for the information he has given us on the recent short circuit in the Cahokia Switch House, and the protective measures he has decided to install to limit the extent of the damage in the event of another short circuit. I believe the ground relaying system which he describes to be a step in the right direction.

Mr. Stone emphasizes the fact that in the two cases which are cited, where the bus bars were directly involved in a short circuit, the power station was completely shut down. Our paper states that in each of these instances the bus bars were cleared, as a safety measure, by the switchboard operators themselves, before they could definitely determine the exact location of the short circuit. Had they opened the bus-section oil circuit breakers instead of the generator breakers, or had there been a relaying system similar to the one described by Mr. Eales, I doubt if there would have been any interruption to service outside of the bus section which was actually involved in the arc.

Mr. Kierstead, Mr. Oesterreicher, and others lay stress on the need for reliability of the reactors themselves. I might say that of all the cases of trouble given, not one originated in the reactor itself, nor did any of the reactors develop weaknesses under short-circuit conditions. Several of the Kansas City feeder reactors were damaged by arcs which started in current transformers when lightning came in over the overhead 13.2-kv. feeder circuits and broke them down. This source of trouble has since been eliminated by placing all of the outgoing 13.2-kv. feeders under ground and by relocating the current transformers.

Mr. Summerhayes has discussed the effect of busbar reactors on the voltage of the different busbar sections. We have found that with the reactors we have used, the ratings of which were carefully determined by considering both voltage regulation under normal conditions and current flow under abnormal conditions, this has given us very little concern. With a radial system of feeders, which is the system followed in the three power stations under discussion, this effect is negligible.

Mr. Osgood has asked how the busbar reactors are automatically shunted in and out of service. This we have done by providing either an auxiliary contact on the control switch of the main generator oil circuit breaker, or an auxiliary switch on the generator oil circuit breaker itself. When the operator closes the generator circuit breaker, the circuit breaker shunting the corresponding busbar reactor opens; when he opens the generator circuit breaker, the breaker shunting the busbar reactor closes.

In concluding, I might state that our experience with power-station reactors has fully justified our expectations and has strengthened our confidence in them as a means of successfully keeping within controllable limits, the flow of current during short circuits.

Mississippi River Crossing of Crystal City Transmission Line

BY H. W. EALES[1]
Member, A. I. E. E.

and

E. ETTLINGER[1]
Non-Member

Synopsis.—*The description and illustrations which follow refer to overhead wire crossing of the Mississippi River near Crystal City, Mo., of a double circuit, 132,000-volt, three-phase, 60-cycle transmission line now in the process of construction. The terminal points of this line at the present time are the Cahokia steam power station of the Union Electric Light & Power Company and the glass manufacturing plant of the Pittsburgh Plate Glass Company at Crystal City, Mo. The general location of this line is shown in the accompanying map, Fig. 1. Its length is 30.8 miles, (49.6 km.), of which 28.4 miles (45.7 km.) are in Illinois and the remainder in Missouri and in the river crossing. The purpose of this article is primarily to describe the problems involved in the river crossing.*

At the point of crossing, the Mississippi River is approximately 4000 ft. (1220 m.) wide, bank to bank. On the Missouri side there is a high limestone bluff the top of which is at elevation 745 with reference to Memphis, Tenn. datum. The average ground level on the Illinois bank is at elevation 395 or 350 ft. (106.8 m.) lower than the Missouri bluff, opposite.

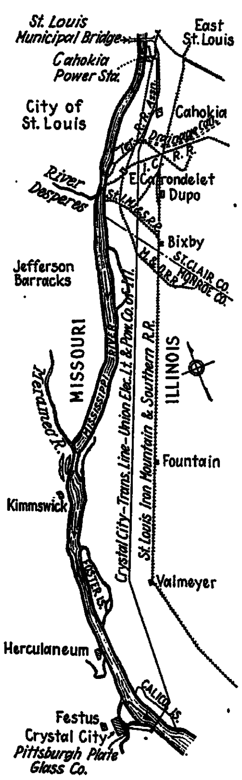

FIG. 1—MAP SHOWING LOCATION OF TRANSMISSION LINE AND MISSISSIPPI RIVER CROSSING

The hydrographic records of the Mississippi River indicate that extreme high water in 1844 was at elevation 410.5 and high water in 1903, at elevation 406. A levee protecting the Illinois low lands parallels the river for a distance of approximately 6500 ft. (1983 m.) from the Missouri bluff. The Illinois shore at, this point between the river's edge and the levee, is known as Calico Island.

It is observed from the foregoing figures that any foundation between the levee and the Missouri bluff would be in an area subject to overflow and in addition would be subject to the characteristic scouring action of the Mississippi River during each such overflow period.

In order to obtain data for the design of foundations for towers two test borings were made to rock on the Illinois bank, the first at a distance of approximately 400 ft. (122 m.) from the river's edge and the second about 50 ft. (15.3 m.) from the edge. Both of these borings showed that the ground was typical river bed deposit consisting of fine silt on the top strata, the lower strata consisting of coarse sand and gravel, the gravel increasing in size to stones several inches in diameter as rock was approached. Since these data checked closely with numerous other borings of the Illinois bed of the river between this location and East St. Louis, Ill., it was not considered necessary to make more than the two borings taken. Government records (House document No. 762, 63rd Congress, 2nd Session) contain reports of test borings taken over a distance of four miles east and west beginning at Steins Street, St. Louis, on the Missouri bluff to the Illinois bluffs. The borings on Calico Island showed deposits very similar to the government borings. Other boring data available were those made at the time of construction of the four bridges spanning the Mississippi at St. Louis and those for the Cahokia power station below East St. Louis, Ill.

The Federal requirements with respect to river clearance at this point called for a mechanical clearance of 64 ft. (19.5 m.) from the lowest point of the sag to high water elevation on the basis of 1903 high water. It was considered advisable to add 10 feet (3.05 m.) for electrical clearance making total clearance 74 feet (22.6 m.)

The preceding description outlines the physical problem; the solution of the problem was made as follows:

It is apparent from the data given that to support a

1. Both of Union Electric Light & Power Co. of Illinois, St. Louis, Mo.

Presented at the Spring Convention of the A. I. E. E., St. Louis, Mo., April 13-17, 1925. Complete copies to members upon request.

crossing span on towers outside the area of overflow would involve a span distance of 7000 feet (2135 m.) It was determined, therefore, to construct the crossing in two spans supported by three towers, the western tower to be placed on top of the Missouri bluff, the intermediate tower approximately 300 ft. (91.5 m.) from the existing water's edge on the Illinois bank, and the third tower a short distance east of the levee. It was further decided to arrange the Missouri tower and the Illinois levee tower as anchor structures, both designed to support the unbalanced stress of all six conductors under worst conditions of ice and wind loading, and to arrange the intermediate tower so as to support the conductors on insulators in suspension position.

Sketch, Fig. 2, shows all these data in graphical form. From this sketch it will be observed that the horizontal distance between the Missouri tower and the intermediate tower is 4279 ft., (1305 m.) and the horizontal distance between the intermediate tower and the Illinois terminal tower, 2681 ft., (818 m.) The profile

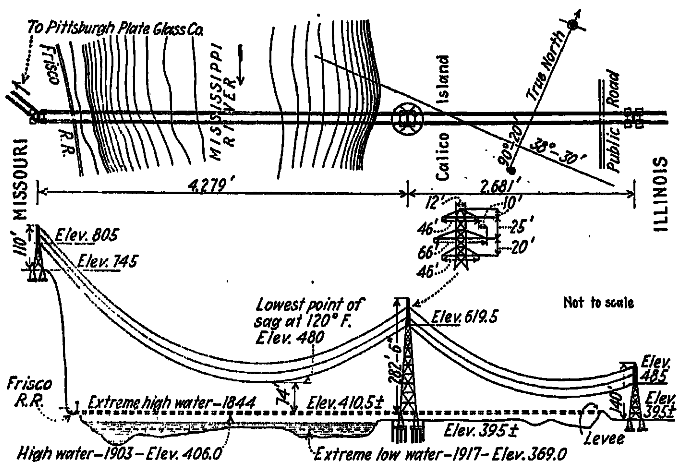

Fig. 2—Plan and Profile of Mississippi River Crossing

shows clearly the different elevations involved. The clearance to river level is shown on the basis of conductor sag at 120 deg. fahr. (48.8 deg. cent.) and under extreme assumption that such sag will occur with the river at an elevation duplicating that of 1903.

The lowest crossarm of the Missouri tower will be 60 ft. (18.3 m.) above its base. The lowest crossarm of the intermediate tower will be 227½ ft. (69.5 m.) above its base, and the lowest arm of the Illinois anchor tower will be 90 ft. (27.5 m.) above its base.

The three conductors of each circuit are to be carried across the river in vertical configuration. From the tower details shown in Fig. 2 it will be noted that there will be a vertical separation of 20 ft. (6.1 m.) between the conductors of each circuit at the two anchor towers, but a vertical separation of 25 ft. (7.6 m.) between the top conductor and the middle conductor at the intermediate tower, and a vertical separation of 20 ft. (6.1 m.) from the middle conductor to the lowest conductor at the intermediate tower. It will be further noted that the center conductors are to be offset outwardly from the towers 10 ft. (3.m.) with respect to the top and bottom conductors, both of the latter being at the same distance from all towers. The length of the crossarms are based upon—

1. The foregoing vertical and horizontal separations of the conductors
2. The length of the assembly of insulating supports, hardware, etc., as will be discussed later, and
3. A minimum clearance to steel structure of 4½ ft. (1.37 m.) with conductor swung at an angle of 45 deg. from the vertical toward the tower

It will be observed that this has resulted in top and bottom crossarm length of 46 ft. (14.03 m.) and middle crossarm length of 66 ft. (20.2 m.)

It will be found upon a detailed analysis of a problem of this character that the final solution of;

a. The strength of crossing conductors
b. The insulating supports at the towers
c. The towers themselves
d. The tower foundations

are interdependent one upon the other and that a joint solution of all four phases of the problem must be made more or less simultaneously. The resulting composite solution should be the one which results in allowing ample factors of safety and the lowest over-all total cost of the crossing.

The specific economical study of this particular problem has resulted in the selection of a steel-reinforced aluminum conductor to be employed. The design tension for the conductors and for the other three factors of the major problem was taken as 33,000 lb. (15,000 kg.) which will occur under conditions of ½-in. (1.27 cm.) ice loading at 0 deg. fahr. (−17.7 deg. cent.) and 12 lb. per square foot wind pressure (58.7 kg. per sq. m.).

The specific requirements which each of the four major elements should meet were then chosen as follows:

1. Towers

a. Anchor Towers. The anchor towers are to be capable of withstanding the unbalanced pull of six conductors with 33,000-lb. (15,000 kg.) tension in each. The design of the tower steel members specifies unit stress requirements to be in accordance with the National Electrical Safety Code for the above loading with the tower steel computed on a basis of 50 per cent overload on the above specific loading. The tower foundation specification requires these to be designed for 75 per cent overload with respect to the above specific tower loading. In addition to the ice and wind loading on the conductors, the tower is required to meet an ice weight and wind loading produced by the weight of ½ inch ice covering on its members and with a wind pressure equivalent to twice the area of one side on the basis of 25 lb. per square foot pressure (122.2 kg. per m^2).

b. Intermediate Tower. The specification for the intermediate tower gives the maximum loading as three

broken conductors with a tension of 33,000 lb. per conductor. The tower steel is to be designed on the basis of 50 per cent overload on this specific loading and with unit stresses on the design basis in compliance with the stresses of the National Electrical Safety Code. In addition to the ice and wind loading on the conductors the tower steel design includes the additional load produced by the weight of ½-in. ice covering on its members and with a wind pressure equivalent to twice the area of one side on the basis of 25 lb. per square foot pressure (122.2 kg. per sq. m.)

2. FOUNDATIONS

General. Since the three towers are of different heights and impose different loadings on their foundations, and since these in turn have different soil conditions, separate foundation computations were required for each tower. For the purpose of foundation data for the anchor towers, the shoreward conductors were assumed broken. It was considered that the unbalanced pull of the conductors on these towers would always be in a direction toward the river and that in consequence the piers on the river side would always be under compression at time of maximum load and those on the land side under uplift conditions. Advantage was taken of this in reducing the size of the two compression piers as compared to the uplift piers.

For the intermediate tower it was concluded that all four piers should be of similar design.

For the two anchor towers, which are at locations not subject to overflow, the full weight of the backfill earth and of the concrete piers is taken into account in resisting the uplift of the base.

In the case of the intermediate tower the weight of the earth backfill was not considered in calculating the uplift quantities and the concrete was figured for its uplift value when submerged in water.

The total reaction and uplift figures for all foundation calculations are indicated in the accompanying Table I.

These conditions have resulted in foundations of the following specific dimensions:

1. MISSOURI TOWER

a. Shoreward Piers. Each of these two piers consists of a reinforced concrete base pad 20 ft. (6.1 m.) square and 2 ft. (0.6 m.) thick from which rises a pier 12 ft. (3.66 m.) square at the base, tapering to 4 ft. (1.22 m.) square at the top, which is 9 ft. (2.74 m.) above the top of the base pad. The entire block is liberally reinforced with formed steel rods. The foundation bolts 2¼ in. (5.72 cm.) in diameter and six in number for each pier, extend 10 ft. (3 m.) into the concrete. Pairs of bolts are tied together with angle plates and reinforcing rods, in turn, are looped over the top of these angles.

b. Riverward Piers. These piers are the same as the shoreward piers with the exception that the base pad is 14 ft. (4.17 m.) square instead of 20 ft. (6.1 m.) square.

TABLE I

Reactions ...	*Wire Pull	Wind	Dead Load	Total
110 Ft. (33.5 m.) Tower—Illinois Bank				
Piers toward river.......	313,100 lb. (142200 kg.)	15,600 lb. (7090 kg.)	25,500 lb. (11600 kg.)	354,200 lb. (161200 kg.)
Uplifts				
Piers toward bank.......	285,700 lb. (129700 kg.)	15,600 lb. (7090 kg.)	25,500 lb. (11600 kg.)	275,800 lb. (125200 kg.)
Tower weight.				132,000 lb. (60000 kg.)
140Ft. (42.8 m.) Tower-Missouri Bank				
Reactions				
Piers toward river.........	326,200 lb. (148400 kg.)	20,100 lb. (9140 kg.)	31,500 lb. (14320 kg.)	377,800 lb. (171500 kg.)
Uplifts				
Piers toward Bank	298,800 lb. (136200 kg.)	20,100 lb. (9140 kg.)	31,500 lb. (14320 kg.)	287,400 lb. (130700 kg.)
Tower weight.				160,000 lbs. (72727 kg.)
285 Ft. (87. m.) Tower-Suspension Type				
Reactions ...	258,450 lb. (117500 kg.)	47,300 lb. (21480 kg.)	66,500 lb. (30200 kg.)	372,250 lb. (169400 kg.)
Uplifts.......	225,050 lb. (102080 kg.)	47,300 lb. (21480 kg.)	66,500 lb. (30200 kg.)	205,850 lb. (93700 lb.)
Tower weight.				288,000 lb. (131000 kg.)

*Weight of wire has been added to reactions and subtracted from uplifts. 16700 lb. (7600 kg.) for 285 ft. (86.8 m.) tower; 13,700 lb. (6230 kg.) 110 (33.5 m.) and 140 ft. (42.8 m.) towers.

All of these foundations are located in hard clay soil on top of a limestone rock bluff. The centers of the piers form a square 32 ft. (9.77 m.) on sides.

2. ILLINOIS ANCHOR TOWER

a. Shoreward Piers. These piers are the same as the shoreward piers of the Missouri anchor tower.

b. Riverward Piers. The riverward piers are the same as the shoreward piers except that the base mat is 17 ft. (5.18 m.) square instead of 20 ft. (6.1 m.) square.

All of these foundations are in silt and sand river bottom land.

The foundation bolts are the same in size and number and arranged in similar manner to those for the Missouri tower. The centers of the piers form a square 42 ft. (12.8 m.) on a side.

3. INTERMEDIATE TOWER

From the boring data mentioned in the preceding part of this article, it was evident that the foundations for the intermediate tower would be required to rest upon piles. From a study of the boring data and the tower uplift and reaction figures given in the preceding tabulation, the arrangement shown in Figs. 3 and 4 was selected. From Fig. 3 it will be noted that each of the four piers is to be supported upon a cluster of sixteen 35 ft. (10.8 m.) reinforced concrete piles driven so that their points will be at elevation approximately 339, *i. e.*, to a depth 47 ft. (14.35 m.) below the present ground level. Each of these piles is to be 15 inches (38.1 cm.) square and the steel reinforcing is so arranged as to connect the pile head with the base of the foundation pier. The base of the foundation pier is approximately square in shape, 17 ft. (5.18 m.) on a side and 6

ft. (1.83 m.) thick. From the top of this base the pier proper tapers from a dimension 11 ft. (3.4 m.) square at its base to 5 ft. (1.52 m.) square at the top. The top is at elevation 407, or 1 ft. (0.3 m.) higher than 1903 high water elevation. Six foundation bolts, 1⅞ inch (4.76 cm.) in diameter, are buried in this concrete pier to a depth of 10 ft. (3.05 m.) The bottoms of pairs of bolts

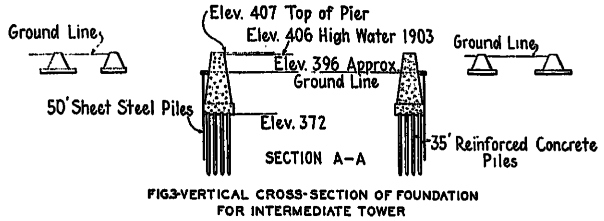

Fig. 3—Vertical Cross-Section of Foundation for Intermediate Tower

are tied together by substantial angle plates and hairpin shaped reinforcing rods in turn extend from the bottom of the pier over the tops of these angle plates. Thus, it will be seen that through the arrangement of the reinforcing employed, tension stresses of the pier are transmitted from the top of the pier to the bottom of the concrete piles. From Fig. 4 it will be observed that the centers of the four piers form a square 80 ft. (24.4 m.) on sides.

To protect these foundations against scour action of the river, it was decided to employ an envelope of steel sheet piling surrounding all four foundations. From Fig. 4 it will be observed that this piling is to be driven in the form of a circle 130 ft. (39.8 m.) in diam-

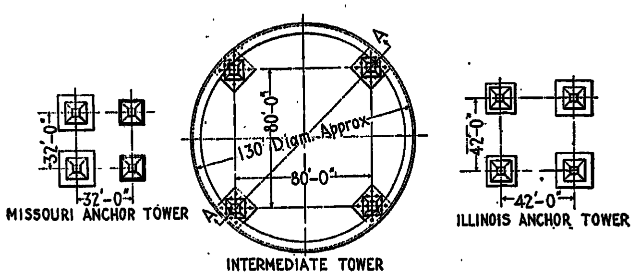

Fig. 4—Plan View All Foundations and Scour Apron for Intermediate Tower

eter, the outer edges of which are in contact with the outer edges of the foundation bases. The sheet steel piling consists of 50-ft. (15.25 m.) lengths made up with 2 per cent copper. From Fig. 3 it will be noted that a circular, reinforced-concrete girder, 1½ft. by 6 ft. (0.46 m. by 1.83 m.) cross section is to extend around the entire top perimeter of the steel piling and to be bonded to the outer edges of each of the four foundations. Thus, this girder will act as a stiffener to the piling and at the same time will reinforce the four base cords of the steel tower. The concrete will also protect the steel piling against rust at the ground line.

Fig. 5 illustrates the process of driving this steel sheet piling envelope. The steel sheet piling was driven by means of a steam hammer suspended from the end of derrick boom and supplemented by 300-lb. per sq. in. pressure water jet. (21.5 kg. per cm².)

Fig. 6 shows the process of driving steel sheet piling for the excavation for the cofferdam for an individual foundation pier, and the method of driving concrete piling in one of these excavations. Note that the steel sheet piling envelope shown in the foreground has been driven to ground level.

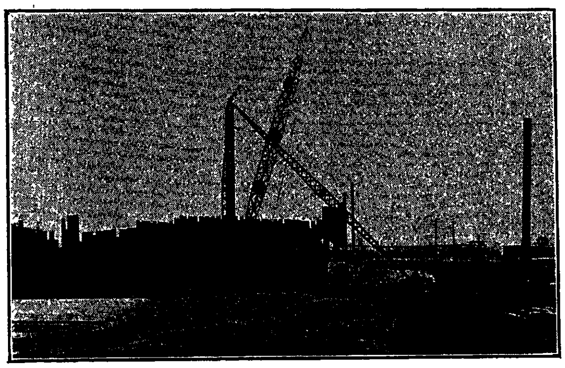

Fig. 5—Construction Progress Driving Steel Sheet Piling Apron Intermediate Tower

Fig. 7 shows the interior view of steel sheet piling cofferdam for one of the foundation piers for the intermediate tower. One of the concrete piles is shown in position ready to be driven.

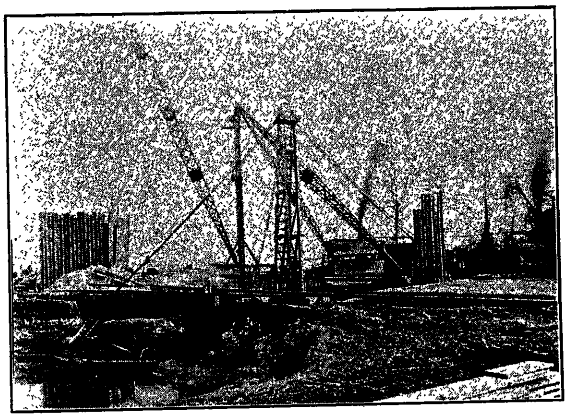

Fig. 6—Construction Progress Driving Sheet Steel Piling for Foundation Pier Excavation and Driving Concrete Piles in one of These Excavations

The concrete piles were driven by the combined efforts of standard pile driver hammer supplemented by 300-lb. per sq. in. (21.5 kg. per cm.²) pressure water jet. In driving the piles the ground was first partially excavated, the sides of the excavation held in place by steel sheet piles and the concrete piles then driven as above to proper cut-off.

A few special features of the river crossing towers may be of interest. Access to the top of each tower will be by means of a ladder the steps of which will be steel bars 4 by ⅜ by 11 in. (10.2 by .95 by 27.9 cm.) bolted to two angles carried up the center of one face of the tower.

From the top of the first panel of the tower, or 15 ft. (4.57 m.) above the base, these steps will be enclosed in a safety basket extending to the top of the tower and with rest platforms at convenient intervals. The bottom of this safety ladder will be provided with gate and padlock. The width of each crossarm will be 12 ft. (3.66 m.). To provide working space for men, each of these crossarms will be constructed as a platform employing subway type grating for flooring and with hand-railings 3 ft. (0.9 m.) high on each side. The space within the basket at the top of each tower will be used for storage boxes to store spare insulators and hardware, construction tools and tackle for the tower. All of these towers will be hot galvanized and will be bolted.

4. Conductors

The conductors for the river crossing consist of 318,000-cir. mil steel reinforced aluminum cables for 250 amperes maximum current requirements and each cable was purchased as one 7500-ft. (2290-meter) continuous length, one spare conductor being supplied.

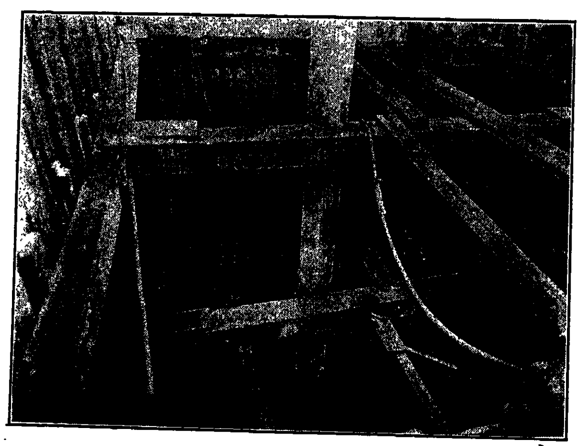

Fig. 7—Interior View of Steel Sheet Piling Cofferdam for Foundation Pier for Intermediate Tower

The steel core consists of 43 strands of various size galvanized steel wires so woven that all wires are woven in the same direction without the crossing of one strand over another. Long experience elsewhere with a number of long crossing spans has indicated the desirability of this arrangement for the purpose of reducing the possibility of breakage of strands due to gradual wearing of one strand into another at points of crossing. Surrounding the steel core are 24 strands of aluminum wires approximately 0.1151 inches (2.92 mm.) in diameter. The aluminum strands are woven on the steel core in a direction the reverse of that of the steel strands. The steel core is to be made up of strands each of which is to be a continuous length without weld, braze, or splice of any character. The above results in a cable the outside diameter of which is approximately 1.036 in. (2.55 cm.). The over-all diameter of the steel core will be 0.807 in. (2.05 cm.) with a breaking strength of 64,000 lb. (29,100 kg.). The ultimate strength of the completed cable is 67,600 lb. (30,700 kg.) and its elastic limit 53,500 lb. (24,300 kg.). The weight of completed bare cable will be 1.684 lb. (0.765 kg.) per foot.

The disposition of towers, cross-arms, etc., as above described will result in the following elevations at various locations of lowest conductor:

a. Crossarm attachment on the Missouri end at elevation 805

b. Lowest point of sag at elevation 480 at temperature 120 deg. fahr. (48.9 deg. cent.)

c. Conductors at the intermediate tower at elevation 620

d. Crossarm attachment at the Illinois terminal tower at elevation 485

Under these conditions the vertical sag at 120 deg. fahr. (48.9 deg. cent.) without wind will be 325 ft. (99 m.) below the Missouri tower support.

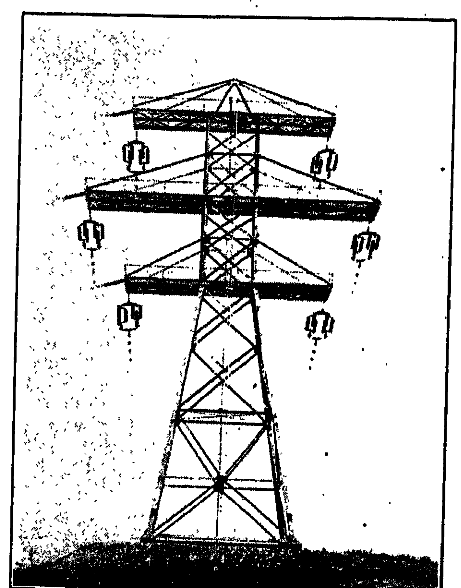

Fig. 7—(a) Missouri Strain Tower, Showing Method of Attaching Conductors

The sag and tension figures for other conditions of ice and wind loading, temperature, etc., are given in Table II below. As an appendix to this article are given the

TABLE II
STRINGING SAGS AND TENSIONS
